Notices
Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary.

Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility.

To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors, assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

Library of Congress Cataloging-in-Publication Data
Fundamental neuroscience / edited by Larry Squire . . . [et al.]. – 4th ed.
p. cm.
Includes bibliographical references and index.
ISBN 978-0-12-385870-2 (alk. paper)
1. Neurosciences. I. Squire, Larry R.
QP355.2.F862 2012
612.8–dc23 2012020285

British Library Cataloguing-in-Publication Data
A catalogue record for this book is available from the British Library.

Cover Image: The confocal image shows dopaminergic (green) and GABAergic (red) neurons in the developing Xenopus accessory olfactory bulb that mediate kinship recognition among siblings. The number of dopaminergic and GABAergic neurons changes in response to sustained exposure to olfactory stimuli. *Courtesy of Davide Dulcis and Nicholas Spitzer.*

Short Contents

I
FUNDAMENTAL NEUROSCIENCE

1. Fundamentals of Neuroscience 3
2. Basic Plan of the Nervous System 15

II
CELLULAR AND MOLECULAR NEUROSCIENCE

3. Cellular Components of Nervous Tissue 41
4. Subcellular Organization of the Nervous System: Organelles and Their Functions 61
5. Membrane Potential and Action Potential 93
6. Neurotransmitters 117
7. Release of Neurotransmitters 139
8. Neurotransmitter Receptors 163
9. Intracellular Signaling 189
10. Postsynaptic Potentials and Synaptic Integration 211
11. Information Processing in Dendrites and Spines 231
12. Brain Energy Metabolism 261

III
NERVOUS SYSTEM DEVELOPMENT

13. Neural Induction and Pattern Formation 287
14. Cellular Determination 309
15. Neurogenesis and Migration 339
16. Growth Cones and Axon Pathfinding 363
17. Synapse Formation 385
18. Programmed Cell Death and Neurotrophic Factors 405
19. Synapse Elimination 437
20. Dendritic Development 457
21. Early Experience and Sensitive Periods 479

IV
SENSORY SYSTEMS

22. Fundamentals of Sensory Systems 499
23. Chemical Senses: Taste and Olfaction 513
24. The Somatosensory System 531
25. Audition 553
26. Vision 577

V
MOTOR SYSTEMS

27. Fundamentals of Motor Systems 599
28. The Spinal and Peripheral Motor System 613
29. Control of Movement 631
30. The Basal Ganglia 653
31. Cerebellum 677
32. Eye Movements 697

VI
REGULATORY SYSTEMS

33. The Hypothalamus: An Overview of Regulatory Systems 717
34. Central Control of Autonomic Functions: Organization of the Autonomic Nervous System 729
35. Neural Control of Respiratory and Cardiovascular Functions 749
36. Food Intake and Metabolism 767
37. Water and Salt Intake and Body Fluid Homeostasis 783
38. Neuroendocrine Systems 799
39. Circadian Timekeeping 819
40. The Neurobiology of Sleep and Dreaming 847
41. Reward, Motivation, and Addiction 871

VII
BEHAVIORAL AND COGNITIVE NEUROSCIENCE

42. Human Brain Evolution 901
43. Cognitive Development and Aging 919
44. Visual Perception of Objects 947
45. Spatial Cognition 969
46. Attention 989
47. Learning and Memory: Basic Mechanisms 1009
48. Learning and Memory: Brain Systems 1029
49. Language 1053
50. The Prefrontal Cortex and Executive Brain Functions 1069
51. The Neuroscience of Consciousness 1091

List of Boxes xv
Preface to the Fourth Edition xix
About the Editors xxi
Contributors xxiii

I
FUNDAMENTAL NEUROSCIENCE

1. Fundamentals of Neuroscience
FLOYD E. BLOOM

A Brief History of Neuroscience 3
The Terminology of Nervous Systems Is Hierarchical, Distributed, Descriptive, and Historically Based 3
Neurons and Glia Are Cellular Building Blocks of the Nervous System 4
Cellular Organization of the Brain 6
Organization of this Text 7
This Book Is Intended for a Broad Range of Scholars of the Neurosciences 8
Clinical Issues in the Neurosciences 8
The Genomic Inventory Is a Giant Step Forward 9
Neuroscience Today: A Communal Endeavor 10
The Creation of Knowledge 10
Responsible Conduct 11
Summary 12
References 12
Suggested Readings 12

2. Basic Plan of the Nervous System
LARRY W. SWANSON

Introduction 15
Evolution Highlights: General Organizing Principles 15
Development Reveals Basic Vertebrate Parts 23
The Basic Plan of Nervous System Connectivity 27
Overview of the Adult Mammalian Nervous System 31
References 37
Suggested Readings 38

II
CELLULAR AND MOLECULAR NEUROSCIENCE

3. Cellular Components of Nervous Tissue
PATRICK R. HOF, GRAHAME KIDD, JAVIER DEFELIPE, JEAN DE VELLIS, MIGUEL A. GAMA SOSA, GREGORY A. ELDER, AND BRUCE D. TRAPP

Neurons 41
Specific Examples of Different Neuronal Types 45
Neuroglia 49
Cerebral Vasculature 55
References 58
Suggested Readings 58

4. Subcellular Organization of the Nervous System: Organelles and Their Functions
SCOTT T. BRADY, DAVID R. COLMAN, AND PETER J. BROPHY

Axons and Dendrites: Unique Structural Components of Neurons 61
Protein Synthesis in Nervous Tissue 65
Cytoskeletons of Neurons and Glial Cells 75
Molecular Motors in the Nervous System 82
Building and Maintaining Cells of the Nervous System 85
References 91

5. Membrane Potential and Action Potential
DAVID A. MCCORMICK

Membrane Potential 94
Passive Electrical Properties of the Neuron 99
Action Potential 102
References 116
Suggested Readings 116

6. Neurotransmitters
ARIEL Y. DEUTCH

Several Modes of Neuronal Communication Exist 117
Chemical Transmission 118
Classical Neurotransmitters 120

Nonclassical Neurotransmitters 129
Peptide Transmitters 130
Unconventional Transmitters 132
The Expanding Synapse and Gliotransmission 136
References 138

7. Release of Neurotransmitters

THOMAS L. SCHWARZ

Transmitter Release Is Quantal 139
Excitation–Secretion Coupling 142
Molecular Mechanisms of the Nerve Terminal 145
Quantal Analysis: Probing Synaptic Physiology 155
Short-Term Synaptic Plasticity 158
References 161
Suggested Readings 161

8. Neurotransmitter Receptors

M. NEAL WAXHAM

Ionotropic Receptors 163
G-Protein Coupled Receptors 177
References 187

9. Intracellular Signaling

HOWARD SCHULMAN

Signaling Through G-Protein-Linked Receptors 189
Modulation of Neuronal Function by Protein Kinases and Phosphatases 197
Intracellular Signaling Affects Nuclear Gene Expression 205
References 208
Suggested Readings 209

10. Postsynaptic Potentials and Synaptic Integration

JOHN H. BYRNE

Ionotropic Receptors: Mediators of Fast Excitatory and Inhibitory Synaptic Potentials 211
Metabotropic Receptors: Mediators of Slow Synaptic Potentials 224
Integration of Synaptic Potentials 226
Synaptic Plasticity 227
References 229
Suggested Readings 230

11. Information Processing in Dendrites and Spines

NELSON SPRUSTON, MICHAEL HÄUSSER, AND GREG STUART

Introduction 231
Synaptic Integration in Passive Dendrites 234
Synaptic Integration in Active Dendrites 239
Structure and Function of Dendritic Spines 250
Computations Performed by Dendrites 254
Summary 258
References 258
Suggested Readings 259

12. Brain Energy Metabolism

IGOR ALLAMAN AND PIERRE J. MAGISTRETTI

Energy Metabolism of the Brain as a Whole Organ 261
Tight Coupling of Neuronal Activity, Blood Flow, and Energy Metabolism 264
Energy-Producing and Energy-Consuming Processes in the Brain 269
Glutamate Metabolism: A Coordinated Shuttle Between Astrocytes and Neurons 274
Brain Energy Metabolism at the Cellular Level 276
The Astrocyte-Neuron Metabolic Unit 283
References 284

III

NERVOUS SYSTEM DEVELOPMENT

13. Neural Induction and Pattern Formation

ANDREW LUMSDEN AND CLEMENS KIECKER

Neural Induction 287
Early Neural Patterning 292
Regionalization of the Central Nervous System 296
Conclusions 306
References 306

14. Cellular Determination

WILLIAM A. HARRIS, VOLKER HARTENSTEIN, AND MARTYN GOULDING

Introduction 309
Neurogenesis 310
The Proneural and Neurogenic Genes 312
Transcriptional Hierarchies and Networks 314
Asymmetric Cell Division and Cell Fate 314
Neurons and Glia 316
Sensory Neurons of the Peripheral Nervous System 320
The Retina 323
The Spinal Cord 328
Motor Neurons 330
The Cerebral Cortex 332
Conclusions 335
References 335

15. Neurogenesis and Migration

MARIANNE BRONNER AND MARY E. HATTEN

Introduction 339
Development of the Peripheral Nervous System 339
Segmental Migration of Neural Crest Cells 345
Cell Migration in the CNS 347
References 357
Suggested Readings 361

16. Growth Cones and Axon Pathfinding

ALEX L. KOLODKIN AND MARC TESSIER-LAVIGNE

Growth Cones Are Actively Guided 363
Guidance Cues for Developing Axons 366
Guidance Cues and the Control of Cytoskeletal Dynamics 374
Guidance at the Midline: Changing Responses to Multiple Cues 378
Topographic Mapping 380
References 382

17. Synapse Formation

STEVEN J. BURDEN AND PETER SCHEIFFELE

Development of the Neuromuscular Synapse 385
Synapse Formation in the Central Nervous System 394
References 402

18. Programmed Cell Death and Neurotrophic Factors

RONALD W. OPPENHEIM, CAROLANNE E. MILLIGAN, AND CHRISTOPHER S. VON BARTHELD

Cell Death and the Neurotrophic Hypothesis 406
The Origins of Programmed Cell Death and Its Widespread Occurrence in the Developing Nervous System 407
Functions of Neuronal Programmed Cell Death 409
Modes of Cell Death in Developing Neurons 410
The Mode of Neuronal Cell Death Reflects the Activation of Distinct Biochemical and Molecular Mechanisms 412
Nerve Growth Factor: The Prototype Target-Derived Neuronal Survival Factor 416
The Neurotrophin Family 418
Neurotrophin Receptors 419
Secretion and Axonal Transport of Neurotrophins and Pro-Neurotrophins 421
Signal Transduction Through TRK Receptors 423
Multiple Cytokines and Growth Factors Implement Neurotrophic Activities 425
Programmed Cell Death Is Regulated by Interactions with Targets, Afferents, and Nonneuronal Cells 429
The Role of Trophic Factors and Programmed Cell Death in Neuropathology 431
References 434
Suggested Readings 435

19. Synapse Elimination

JUAN C. TAPIA AND JEFF W. LICHTMAN

Overview 437
The Purpose of Synapse Elimination 441
A Structural Analysis of Synapse Elimination at the Neuromuscular Junction 443
A Role for Interaxonal Competition and Activity 446
Is Synapse Elimination Strictly a Developmental Phenomenon? 453
References 454

20. Dendritic Development

HOLLIS CLINE, ANIRVAN GHOSH, YUH-NUNG JAN, AND JOSH SANES

Dynamics of Dendritic Arbor Development 457
Transcriptional Control of Dendrite Development 458
Extracellular Regulation of Dendritic Development 460
Dendritic Development and Circuit Formation in Mammalian Retina 466
Laminar Specificity in the Inner Plexiform Layer 466
Activity-Dependent Dendritic Development 469
The Synaptotrophic Model of Dendrite Development 469
Branch Retraction and Synapse Elimination 471
Calcium-Dependent Mechanisms that Mediate Dendritic Growth 471
Protein Synthesis Dependent Regulation of Dendrite Development 472
Convergence and Divergence 472
Conclusion 473
References 474

21. Early Experience and Sensitive Periods

ERIC I. KNUDSEN

Birdsong: Learned by Experience 481
Sound Localization: Calibrated by Early Experience in the Owl 483
Binocular Processing in the Mammalian Visual Cortex Depends on Early Experience 487
A Sensitive Period for Shaping the Temperament of Rats 489
Principles of Sensitive Period Learning 491
References 494
Suggested Readings 495

IV
SENSORY SYSTEMS

22. Fundamentals of Sensory Systems

STEWART H. HENDRY AND STEVEN S. HSIAO

Sensation and Perception 499
Receptors 501
Peripheral Organization and Processing 503
Central Pathways and Processing 505
Sensory Cortex 507
Summary 510
References 510
Suggested Readings 511

23. Chemical Senses: Taste and Olfaction

KRISTIN SCOTT

Taste 513
Olfaction 520

Different Odors Activate Different Combinations of Glomeruli 524
Pheromone Detection 527
References 529
Suggested Readings 530

24. The Somatosensory System

STEWART HENDRY AND STEVEN HSIAO

Peripheral Mechanisms of Somatic Sensation 531
Nociception 538
CNS Components of Somatic Sensation 540
Thalamic Mechanisms of Somatic Sensation 544
The Path from Nociception to Pain 545
Cortical Representation of Touch 549
References 551
Suggested Readings 551

25. Audition

M. CHRISTIAN BROWN AND JOSEPH SANTOS-SACCHI

External and Middle Ear 553
The Cochlea 554
The Auditory Nerve 562
Central Nervous System 566
References 575
Suggested Readings 576

26. Vision

R. CLAY REID AND W. MARTIN USREY

Overview 577
Sensory Systems Detect Contrast or Change 578
The Eye and the Retina 579
The Retinogeniculocortical Pathway 586
References 595
Suggested Readings 595

V
MOTOR SYSTEMS

27. Fundamentals of Motor Systems

STEN GRILLNER

Basic Components of the Motor System 600
Motor Programs Coordinate Basic Motor Patterns 602
Roles of Different Parts of the Nervous System in the Control of Movement 605
Conclusion 611
Suggested Readings 611

28. The Spinal and Peripheral Motor System

GEORGE Z. MENTIS

Locomotion Is a Cycle 613
Connecting the Spinal Cord to the Periphery 615
Spinal Interneuron Networks 622
Descending Control of Spinal Circuits 627
Sensory Modulation 628
References 629
Suggested Readings 630

29. Control of Movement

MARC H. SCHIEBER AND JAMES F. BAKER

The Medial Postural System 631
The Lateral Voluntary System 638
Summary 650
References 650

30. The Basal Ganglia

JONATHAN W. MINK

Anatomy of the Basal Ganglia 653
Signaling in Basal Ganglia 661
The Effect of Basal Ganglia Damage on Behavior 664
Principles of Basal Ganglia Operation for Motor Control 668
Basal Ganglia Participation in Nonmotor Functions 669
References 675
Suggested Readings 676

31. Cerebellum

MARTHA BAGNALL, SASCHA DU LAC, AND MICHAEL MAUK

Cerebellar Anatomy and Circuit 677
Cellular and Synaptic Performance of the Cerebellar Circuit 684
Cerebellar Function 687
References 695

32. Eye Movements

RICHARD J. KRAUZLIS

Eye Movements Are Used to Stabilize Gaze or to Redirect Gaze 697
The Mechanics of Moving the Eyes 700
The Fundamental Circuits for Stabilizing Gaze 703
The Commands for Redirecting Gaze are Formed in the Brainstem 705
Gaze Movements are Controlled by the Midbrain and Forebrain 707

The Control of Gaze Movements Involves Higher-Order Processes 711
Conclusions 713
References 713
Suggested Readings 714

VI
REGULATORY SYSTEMS

33. The Hypothalamus: An Overview of Regulatory Systems

J. PATRICK CARD AND LARRY W. SWANSON

Historical Perspective 717
Hypothalamic Cytoarchitecture 718
Functional Organization of the Hypothalamus 719
Effector Systems of the Hypothalamus are Hormonal and Synaptic 722
References 726
Suggested Readings 727

34. Central Control of Autonomic Functions: Organization of the Autonomic Nervous System

TERRY L. POWLEY

Sympathetic Division: Organized to Mobilize the Body for Activity 730
Parasympathetic Division: Organized for Energy Conservation 734
The Enteric Division of the ANS: The Nerve Net Found in the Walls of Visceral Organs 736
ANS Pharmacology: Transmitter and Receptor Coding 738
Autonomic Coordination of Homeostasis 740
Hierarchically Organized ANS Circuits in the CNS 743
Perspective: Future of the Autonomic Nervous System 746
References 747
Suggested Readings 747

35. Neural Control of Respiratory and Cardiovascular Functions

J.L. FELDMAN, D.R. MCCRIMMON, AND S.F. MORRISON

Breathing 750
Where Are the Neurons Generating the Respiratory Pattern? 751
Discharge Patterns of Respiratory Neurons 752
Models for Respiratory Pattern Generation 752
Mechanoreceptors in the Lungs Adjust Breathing Pattern and Initiate Protective Reflexes 756
Cardiovascular 757
Sensory Regulation of Respiratory and Cardiovascular Systems 761
Modulation and Plasticity of Respiratory Motor Output 762
References 765
Suggested Readings 766

36. Food Intake and Metabolism

STEPHEN C. WOODS AND EDWARD M. STRICKER

Caloric Homeostasis 767
Role of Caloric Homeostasis in Control of Food Intake 769
Central Control of Food Intake 776
Neuropeptides and the Control of Food Intake 777
References 781
Suggested Readings 781

37. Water and Salt Intake and Body Fluid Homeostasis

EDWARD M. STRICKER AND JOSEPH G. VERBALIS

Body Fluid Physiology 783
Osmotic Homeostasis 784
Volume Homeostasis 790
References 796
Suggested Readings 797

38. Neuroendocrine Systems

ANDREA C. GORE

The Hypothalamus is the Central Neuroendocrine Organ 799
Hypothalamic Control of Anterior Pituitary Hormones and Their Regulated Functions 800
Hypothalamic Control of Posterior Pituitary Hormones and Their Regulated Functions 813
Hormones, the Brain, and Behavior 815
References 817

39. Circadian Timekeeping

DAVID R. WEAVER AND PATRICK EMERY

Introduction 819
Overview of the Mammalian Circadian Timing System 819
A Hierarchy of Cell-Autonomous Circadian Oscillators 821
The Molecular Basis for Circadian Oscillation Is a Transcriptional Feedback Loop 824
Circadian Photoreception in Mammals 832
Circadian Output Mechanisms 836
Diversity of Output Pathways Leading to Physiological Rhythms 837
General Summary 843
References 844
Suggested Readings 845

40. The Neurobiology of Sleep and Dreaming

EDWARD F. PACE-SCHOTT AND J. ALLAN HOBSON

The Two States of Sleep: Rapid Eye Movement (REM) and Non–Rapid Eye Movement (NREM) Sleep 847
Neural Control of the Sleep–Wake and REM/NREM Cycles 850
Systems Neuroscience of Sleep and Dreaming 859

Development and Phylogeny of Sleep 861
Sleep Disorders 862
The Purpose of Sleep 865
References 867
Suggested Readings 869

41. Reward, Motivation, and Addiction
GEORGE F. KOOB, BARRY J. EVERITT, AND TREVOR W. ROBBINS

Reward and Motivation 871
Addiction 879
References 896

VII
BEHAVIORAL AND COGNITIVE NEUROSCIENCE

42. Human Brain Evolution
JON H. KAAS AND TODD M. PREUSS

Human Brain Evolution 901
The Brains of Early Mammals 901
Evolution of Primate Brains 906
Conclusions 916
References 917
Suggested Readings 918

43. Cognitive Development and Aging
PETER R. RAPP AND JOCELYNE BACHEVALIER

Brain Development 919
Cognitive Development and Aging: A Life Span Perspective 923
Cognitive Aging 927
Pathological Processes in Cognitive Development and Aging 934
Pathological Manifestations of Cognitive Aging: Dementia 940
References 943
Suggested Readings 944

44. Visual Perception of Objects
ANDREW H. BELL, LUIZ PESSOA, ROGER B.H. TOOTELL, AND LESLIE G. UNGERLEIDER

The Problem of Object Recognition 947
Substrates for Object Perception and Recognition: Early Evidence from Brain Damage 948
Visual Pathways for Object Processing in Nonhuman Primates 950
Neuronal Properties within the Object Recognition Pathway 953
Functional Neuroimaging of Object Recognition 959
Perception and Recognition of Specific Classes of Objects 960
Overall Summary 966
References 966
Suggested Readings 968

45. Spatial Cognition
CARL R. OLSON AND CAROL L. COLBY

Neural Systems for Spatial Cognition 969
Parietal Cortex 970
Frontal Cortex 978
Medial Temporal Lobe 984
Spatial Cognition and Spatial Action 986
References 986
Suggested Readings 987

46. Attention
JOHN H. REYNOLDS, JACQUELINE P. GOTTLIEB, AND SABINE KASTNER

Introduction 989
Definitions and Varieties of Attention 989
Neglect Syndrome: A Deficit of Spatial Attention 990
Attention Affects Neural Activity in the Human Visual Cortex in the Presence and Absence of Visual Stimulation 992
Single Unit Recording Studies in Nonhuman Primates Provide Convergent Evidence for a Fronto-Parietal Attentional Control System 994
Attention Increases Neuronal Responses and Boosts the Clarity of Signals Generated by Neurons in Parts of the Visual System Devoted to Processing Information about Objects 998
Attention Modulates Neural Responses in the Lateral Geniculate Nucleus 1000
The Visual Search Paradigm has been Used to Study the Role of Attention in Selecting Relevant Stimuli from within a Cluttered Visual Environment 1001
Where Is the Computational Bottleneck as Revealed by Search Tasks? 1001
Neuronal Receptive Fields Are a Possible Neural Correlate of Limited Capacity 1002
Filtering of Unwanted Information in Humans 1004
Competition Can Be Biased by Nonspatial Feedback 1005
Conclusions 1006
References 1006
Suggested Readings 1007

47. Learning and Memory: Basic Mechanisms
JOHN H. BYRNE

Paradigms Have Been Developed to Study Associative and Nonassociative Learning 1009
Invertebrate Studies: Key Insights from *Aplysia* into Basic Mechanisms of Learning 1010
Vertebrate Studies: Long-Term Potentiation 1016
Long-Term Depression 1023
How Does a Change in Synaptic Strength Store a Complex Memory? 1023
References 1026
Suggested Readings 1027

48. Learning and Memory: Brain Systems
JOSEPH R. MANNS AND ELIZABETH A. BUFFALO

Introduction 1029
Behavior Supported by Multiple Memory Systems 1048
Conclusion 1049
References 1049
Suggested Readings 1051

49. Language
DAVID N. CAPLAN AND JAMES L. GOULD

Animal Communication 1053
Human Language 1057
Neural Organization for Language 1060
Conclusions 1066
References 1067
Suggested Readings 1067

50. The Prefrontal Cortex and Executive Brain Functions
EARL K. MILLER AND JONATHAN D. WALLIS

Introduction 1069
Anatomy and Organization of the Prefrontal Cortex 1069
Effects of Damage to the Prefrontal Cortex in Humans 1071
Neuroimaging Studies and PFC 1074
Effects of Damage to the Prefrontal Cortex in Monkeys 1075
Neurophysiology of the Prefrontal Cortex 1078
Theories of Prefrontal Cortex Function 1083
References 1088
Suggested Readings 1089

51. The Neuroscience of Consciousness
CHRISTOF KOCH

What Phenomena Does Consciousness Encompass? 1091
The Neurobiology of Free Will 1092
Consciousness in Other Species 1093
Arousal and States of Consciousness 1093
The Neuronal Correlates of Consciousness 1096
The Neuronal Basis of Perceptual Illusions 1097
Perceptual Puzzles of Contemporary Interest 1098
Forward versus Feedback Projections 1099
An Information-Theoretical Theory of Consciousness 1100
Conclusion 1101
References 1102

Index 1105

Preface to the Fourth Edition

In this fourth edition of *Fundamental Neuroscience*, we have tried to improve on the third edition with a volume that effectively introduces students to the full range of contemporary neuroscience. Neuroscience is a large field founded on the premise that all of behavior and all of mental life have their origin in the structure and function of the nervous system. Today, the need for a single-volume introduction to neuroscience is greater than ever. Toward the end of the twentieth century, the study of the brain moved from a peripheral position within both the biological and psychological sciences to become an interdisciplinary field that is now central within each discipline. The maturation of neuroscience has meant that individuals from diverse backgrounds—including molecular biologists, computer scientists, and psychologists—are interested in learning about the structure and function of the brain and about how the brain works. In addition, new techniques and tools have become available to study the brain in increasing detail. New genetic methods have been introduced to delete or overexpress single genes with spatial and temporal specificity. Neuroimaging techniques such as functional magnetic resonance imaging (fMRI) have been developed that allow study of the living human brain while it is engaged in cognition.

This fourth edition attempts to capture the promise and excitement of this fast-moving discipline. All the chapters have been rewritten and updated. The volume begins with an opening chapter that provides an overview of the discipline. A second chapter presents fundamental information about the architecture and anatomy of nervous systems. The remainder of the volume (Sections II–VII) presents the major topics of neuroscience. The second section (Cellular and Molecular Neuroscience) considers the cellular and subcellular organization of neurons, the physiology of nerve cells, and how signaling occurs between neurons. The third section (Nervous System Development) includes discussion of neural induction, cell fate, migration, pathfinding, synapse formation, programmed cell death, synapse elimination, development of dendrites, and early experience, including critical periods. The fourth and fifth sections (Sensory Systems and Motor Systems) describe the neural organization of each sensory modality and the organization of the brain pathways and systems important for locomotion, voluntary action, and eye movements. The sixth section (Regulatory Systems) describes the variety of hypothalamic and extra-hypothalamic systems that support motivation, reward, and internal regulation, including respiration, food and water intake, neuroendocrine function, circadian rhythms, and sleep and dreaming. The final section (Behavioral and Cognitive Neuroscience) describes the neural foundations of the so-called higher mental functions, including perception, attention, memory, language, spatial cognition, and executive function. Additional chapters cover human brain evolution, cognitive development and aging, and consciousness. The chapters contain more than 100 Boxes that describe clinical conditions, techniques, and special topics related to chapter content. The volume is also accompanied by companion websites for students and instructors, which present all the Figures and Boxes. In addition, the instructor's website includes sample test questions for each chapter that draw attention to the key facts and concepts in the chapters.

The authors of the chapters and boxes are working scientists, experts in the topics they cover. The Editors edited the chapters to achieve consistency of style and content. At Academic Press/Elsevier Science, the project was coordinated by Mica Haley (Acquisitions Editor), and we are grateful to her for her leadership and advice throughout the project. In addition, April Graham (Editorial Project Manager) very capably and efficiently supervised the development of the book, and Lisa Lamenzo (Project Manager) expertly coordinated its production.

The Editors of *Fundamental Neuroscience* hope that users of this book, and especially the students who will become the next generation of neuroscientists, find the subject matter of neuroscience as interesting and exciting as we do.

About the Editors

Larry R. Squire is Distinguished Professor of Psychiatry, Neurosciences, and Psychology at the University of California School of Medicine, San Diego, and Research Career Scientist at the Veterans Affairs Medical Center, San Diego. He investigates the organization and neurological foundations of memory. He is a former President of the Society for Neuroscience and is a member of the National Academy of Sciences and the Institute of Medicine.

Darwin K. Berg is Distinguished Professor and Chair of Neurobiology in the Division of Biological Sciences at the University of California, San Diego. He has served as Chair of the Biology Department and Councilor of the Society for Neuroscience. He currently is Treasurer for the Society and a Board member of the Kavli Institute for Brain and Mind. His research is focused on the roles of nicotinic cholinergic signaling in the vertebrate nervous system.

Floyd E. Bloom is Professor Emeritus in the Molecular and Integrative Neuroscience Department (MIND) at The Scripps Research Institute. His recent awards include the Sarnat Award from the Institute of Medicine and the Salmon Medal of the New York Academy of Medicine. He is a former President of the Society for Neuroscience and is a member of the National Academy of Sciences and the Institute of Medicine.

Sascha du Lac is an Investigator of the Howard Hughes Medical Institute and an Associate Professor of Systems Neurobiology at the Salk Institute for Biological Studies. Her research focuses on the cellular machinery and circuit mechanisms that mediate cerebellar learning in the sense of balance.

Anirvan Ghosh is Stephen Kuffler Professor in the Division of Biological Sciences at the University of California, San Diego. His research interests include the development of synaptic connections in the central nervous system and the role of activity-dependent gene expression in cortical development. He is recipient of the Presidential Early Career Award for Scientists and Engineers, the Society for Neuroscience Young Investigator Award, and the UCSD Revelle College Outstanding Faculty Award.

Nicholas C. Spitzer is Distinguished Professor in the Division of Biological Sciences at the University of California, San Diego. His research is focused on the role of electrical activity in neuronal differentiation. He has been chairman of the Biology Department and the Neurobiology Section, a trustee of the Grass Foundation, and served as Councilor of the Society for Neuroscience. He is a member of the American Academy of Arts and Sciences, Co-Director of the Kavli Institute for Brain and Mind and Editor-in-Chief of BrainFacts.org.

CHAPTER

1

Fundamentals of Neuroscience

A BRIEF HISTORY OF NEUROSCIENCE

The field of knowledge described in this book is neuroscience: the collected multidisciplinary sciences that analyze the nervous system to understand the biological basis for behavior. Modern studies of the nervous system have been ongoing since the middle of the nineteenth century. Neuroanatomists studied the brain's shape, its cellular structure, and its circuitry; neurochemists studied the brain's chemical composition, its lipids and proteins; neurophysiologists studied the brain's bioelectric properties; and psychologists and neuropsychologists investigated the organization and neural substrates of behavior and cognition.

In contrast to these separate investigative pursuits, the term *neuroscience* was introduced in the mid-1960s to signal the beginning of an era in which each of these disciplines would work together cooperatively, sharing a common language, common concepts, and a common goal: to understand the structures and functions of both the normal and abnormal brain. Neuroscience today spans a wide range of research endeavors from the molecular biology of nerve cells (i.e., the genes encoding the proteins needed for nervous system function) to the biological basis of normal and disordered behavior, emotion, and cognition (i.e., the mental properties by which individuals interact with one another and their environments). For a more complete, but concise, history of the neurosciences, see Kandel and Squire (2000).

Neuroscience is currently one of the most rapidly growing areas of science. Indeed, the brain is sometimes referred to as "the last frontier of biology." In 1971, 1100 scientists convened at the first annual meeting of the Society for Neuroscience. In 2010, 31,500 scientists participated at the society's 40th annual meeting, at which more than 15,000 research presentations were made.

THE TERMINOLOGY OF NERVOUS SYSTEMS IS HIERARCHICAL, DISTRIBUTED, DESCRIPTIVE, AND HISTORICALLY BASED

Beginning students of neuroscience may understandably find themselves confused. Nervous systems of many organisms have their cell assemblies and macroscopically visible components named by multiple overlapping and often synonymous terms. With a necessarily gracious view to the past, this confusing terminology could be viewed as the intellectual cost of focused discourse with predecessors in the enterprise. The nervous systems of invertebrate organisms often are designated for their spatially directed collections of neurons responsible for local control of operations, such as the thoracic or abdominal ganglia, which receive sensations and direct motoric responses for specific body segments, all under the general control of a cephalic ganglion whose role includes sensing the external environment.

In vertebrates, the components of the nervous system were named for both their appearance and their location. As noted by Swanson & Bota (2010), and expanded upon in Chapter 2 of this volume, the names of the major parts of the brain were based on creative interpretations of early dissectors of the brain, attributing names to brain segments based on their appearance in the freshly dissected state: hippocampus (shaped like the sea horse) or amygdala (shaped like the almond), cerebrum (the main brain), and cerebellum (a small brain).

NEURONS AND GLIA ARE CELLULAR BUILDING BLOCKS OF THE NERVOUS SYSTEM

This book lays out our current understanding in each of the important domains that together define the full scope of modern neuroscience. The structure and function of the brain and spinal cord are most appropriately understood from the perspective of their highly specialized cells: the neurons, the interconnected, highly differentiated, bioelectrically driven, cellular units of the nervous system, and their more numerous support cells, the glia. Given the importance of these cellular building blocks in all that follows, a brief overview of their properties may be helpful.

Neurons Are Heterogeneously Shaped, Highly Active Secretory Cells

Neurons are classified in many different ways: according to function (sensory, motor, or interneuron), location (cortical, spinal, etc.), the identity of the transmitter they synthesize and release (glutamatergic, cholinergic, etc.), and their shape (pyramidal, granule, mitral, etc.). Microscopic analysis focuses on their general shape and, in particular, the number of extensions from the cell body. Most neurons have one axon, often branched, to transmit signals to interconnected target neurons. Other processes, termed dendrites, extend from the nerve cell body (also termed the perikaryon—the cytoplasm surrounding the nucleus of the neuron) to receive synaptic contacts from other neurons; dendrites may branch in extremely complex patterns and may possess multiple short protrusions called dendritic spines. Neurons exhibit the cytological characteristics of highly active secretory cells with large nuclei; large amounts of smooth and rough endoplasmic reticulum; and frequent clusters of specialized smooth endoplasmic reticulum (Golgi apparatus), in which secretory products of the cell are packaged into membrane-bound organelles for transport out of the cell body proper to the axon or dendrites. Neurons and their cellular extensions are rich in microtubules—elongated tubules approximately 24 nm in diameter. Microtubules support the elongated axons and dendrites and assist in the reciprocal transport of essential macromolecules and organelles between the cell body and the distant axon or dendrites.

Neurons Communicate Chemically through Specialized Contact Zones

The sites of interneuronal communication in the central nervous system (CNS) are termed *synapses* in the CNS and *junctions* in somatic, motor, and autonomic nervous systems. Paramembranous deposits of specific proteins essential for transmitter release, response, and catabolism characterize synapses and junctions morphologically. These specialized sites are presumed to be the active zone for transmitter release and response. Paramembranous proteins constitute a specialized junctional adherence zone, termed the ***synaptolemma***. Like peripheral junctions, central synapses also are denoted by accumulations of tiny (500 to 1500 Å) organelles, termed synaptic vesicles. The proteins of these vesicles have been shown to have specific roles in transmitter storage; vesicle docking onto presynaptic membranes, voltage- and Ca^{2+}-dependent secretion, and the recycling and restorage of previously released transmitter molecules.

Synaptic Relationships Fall into Several Structural Categories

Synaptic arrangements in the CNS fall into a wide variety of morphological and functional forms that are specific for the neurons involved. The most common arrangement, typical of hierarchical pathways, is either the ***axodendritic*** or the ***axosomatic*** synapse, in which the axons of the cell of origin make their functional contact with the dendrites or cell body of the target neuron, respectively. A second category of synaptic arrangement is more rare: forms of functional contact between adjacent cell bodies (***somasomatic***) and overlapping dendrites (***dendrodendritic***). Within the spinal cord and some other fields of ***neuropil*** (relatively acellular areas of synaptic connections), serial ***axoaxonic*** synapses are relatively frequent. Here, the axon of an interneuron ends on the terminal of a long-distance neuron as that terminal contacts a dendrite, or on the segment of the axon that is immediately distal to the soma, termed the initial segment, where action potentials arise. Many presynaptic axons contain local collections of typical synaptic vesicles with no opposed specialized synaptolemma. These are termed ***boutons en passant***. The release of a transmitter may not always occur at such sites.

Synaptic Relationships also Belong to Diverse Functional Categories

As with their structural representations, the qualities of synaptic transmission can also be functionally categorized in terms of the nature of the neurotransmitter that provides the signaling; the nature of the receptor molecule on the postsynaptic neuron, gland, or muscle; and the mechanisms by which the postsynaptic cell transduces the neurotransmitter signal into transmembrane changes. So-called "fast" or "classical" neurotransmission is the functional variety seen at the vast majority of synaptic and junctional sites, with a rapid

onset and a rapid ending, generally employing excitatory amino acids (glutamate or aspartate) or inhibitory amino acids (γ-aminobutyrate, GABA, or glycine) as the transmitter. The effects of those signals are largely attributable to changes in postsynaptic membrane permeability to specific cations or anions and the resulting depolarization or hyperpolarization, respectively. Other neurotransmitters, such as the monoamines (dopamine, norepinephrine, serotonin) and many neuropeptides, produce changes in excitability that are much more enduring. Here the receptors activate metabolic processes within the postsynaptic cells—frequently to add or remove phosphate groups from key intracellular proteins; multiple complex forms of enduring postsynaptic metabolic actions are under investigation. The brain's richness of signaling possibilities comes from the interplay on common postsynaptic neurons of these multiple chemical signals.

The Operative Processes of Nervous Systems are also Hierarchical

As research progressed, it became clear that neuronal functions could best be fitted into nervous system function by considering their operations at four fundamental hierarchical levels: molecular, cellular, systems, and behavioral. These levels rest on the fundamental principle that neurons communicate chemically, by the activity-dependent secretion of neurotransmitters, at specialized points of contact named synapses.

At the ***molecular*** level of operations, the emphasis is on the interaction of molecules—typically proteins that regulate transcription of genes, their translation into proteins, and their posttranslational processing. Proteins that mediate the intracellular processes of transmitter synthesis, storage, and release, or the intracellular consequences of intercellular synaptic signaling, are essential neuronal molecular functions. Such transductive molecular mechanisms include the neurotransmitters' receptors, as well as the auxiliary molecules that allow these receptors to influence the short-term biology of responsive neurons (through regulation of ion channels) and their longer-term regulation (through alterations in gene expression). Completion of the human, chimpanzee, rat, and mouse genomes can be viewed as an extensive inventory of these molecular elements, more than half of which are thought to be either highly enriched in the brain or even exclusively expressed there. Genes unique to human brains have been reported and appear to be most frequently expressed during the brain's development. Recent progress has made clear that the ***introns*** (the sections of the genome that contain DNA code that does not lead to production of specific proteins; these noncoding sequences are the largest part of the genome) are important functional control elements that regulate which genes are expressed and which transcribed messenger RNAs are translated into proteins.

At the ***cellular*** level of neuroscience, the emphasis is on interactions between neurons through their synaptic transactions and between neurons and glia. Much current cellular-level research focuses on the biochemical systems within specific cells that mediate such phenomena as pacemakers for the generation of circadian rhythms or that can account for activity-dependent adaptation. Research at the cellular level strives to determine which specific neurons and which of their most proximate synaptic connections may mediate a behavior or the behavioral effects of a given experimental perturbation.

At the ***systems*** level, emphasis is on the spatially distributed sensors and effectors that integrate the body's response to environmental challenges. There are sensory systems, which include specialized senses for hearing, seeing, feeling, tasting, and balancing the body. Similarly, there are motor systems for trunk, limb, and fine finger motions and internal regulatory systems for visceral regulation (e.g., control of body temperature, cardiovascular function, appetite, and salt and water balance). These systems operate through relatively sequential linkages, and interruption of any link can destroy the function of the system.

Systems-level research also includes research into cellular systems that innervate the widely distributed neuronal elements of the sensory, motor, or visceral systems, such as the pontine neurons with highly branched axons that innervate diencephalic, cortical, and spinal neurons. Among the best studied of these divergent systems are the monoaminergic neurons, which have been linked to the regulation of many behavioral outputs of the brain, ranging from feeding, drinking, thermoregulation, and sexual behavior. Monoaminergic neurons also have been linked to such higher functions as pleasure, reinforcement, attention, motivation, memory, and learning. Dysfunctions of these systems have been hypothesized as the basis for some psychiatric and neurological diseases, supported by evidence that medications aimed at presumed monoamine regulation provide useful therapy.

At the ***behavioral*** level of neuroscience research, emphasis is on the interactions between individuals and their collective environment. Research at the behavioral level centers on the integrative phenomena that link populations of neurons (often operationally or empirically defined) into extended specialized circuits, ensembles, or more pervasively distributed "systems" that integrate the physiological expression of a learned, reflexive, or spontaneously generated behavioral response. Behavioral research also includes the operations of higher mental activity, such as memory, learning, speech, abstract reasoning, and consciousness. Conceptually, "animal models" of human psychiatric diseases are based

on the assumption that scientists can appropriately infer from observations of behavior and physiology (heart rate, respiration, locomotion, etc.) that the states experienced by animals are equivalent to the emotional states experienced by humans expressing these same sorts of physiological changes.

As the neuroscientific bases for some elemental behaviors have become better understood, new aspects of neuroscience applied to problems of daily life have begun to emerge. Methods for the noninvasive detection of activity in certain small regions of the cerebral cortex can now resolve areas that are active simultaneously and presumed to act together in networks of cortical assemblies. These concurrently active networks have been linked to discrete forms of mental activity. Such advances have given rise to the concept that it is possible to understand where in the brain the decision-making process occurs or to identify the kinds of information necessary to decide whether or not to act. The detailed quantitative data that now exist on the details of neuronal structure, function, and behavior have driven the development of computational neurosciences. This new branch of neuroscience research seeks to predict the performance of neurons, neuronal properties, and neural networks based on their discernible quantitative properties.

Some Principles of Brain Organization and Function

The central nervous system is most commonly divided into major structural units, consisting of the major physical subdivisions of the brain. Thus, mammalian neuroscientists divide the central nervous system into the brain and spinal cord and further divide the brain into regions readily seen by the simplest of dissections. Based on research that has demonstrated that these large spatial elements derive from independent structures in the developing brain, these subdivisions are well accepted. Mammalian brain thusly is divided into hindbrain, midbrain, and forebrain, each of which has multiple highly specialized regions within it. In deference to the major differences in body structure, invertebrate nervous systems most often are organized by body segment (cephalic, thoracic, abdominal) and by anterior–posterior placement.

Neurons within the vertebrate CNS operate either within layered structures (such as the olfactory bulb, cerebral cortex, hippocampal formation, and cerebellum) or in clustered groupings (the defined collections of central neurons, which aggregate into "nuclei" in the central nervous system and into "ganglia" in the peripheral nervous system, and in invertebrate nervous systems). The specific connections between neurons within or across the macro-divisions of the brain are essential to the brain's functions. It is through their patterns of neuronal circuitry that individual neurons form functional ensembles to regulate the flow of information within and between the regions of the brain.

CELLULAR ORGANIZATION OF THE BRAIN

Present understanding of the cellular organization of the CNS can be viewed simplistically according to three main patterns of neuronal connectivity.

Three Basic Patterns of Neuronal Circuitry Exist

Long hierarchical neurons typically constitute the primary sensory and motor pathways. Here the transmission of information is highly sequential, and interconnected neurons are related to one another in a hierarchical fashion. Primary receptors (in the retina, inner ear, olfactory epithelium, tongue, or skin) transmit first to primary relay cells, then to secondary relay cells, and finally to the primary sensory fields of the cerebral cortex. For motor output systems, the reverse sequence exists with impulses descending hierarchically from the motor cortex to the spinal motoneuron. It is at the level of the motor and sensory systems that beginning scholars of the nervous system will begin to appreciate the complexities of neuronal circuitry by which widely separated neurons communicate selectively. This hierarchical scheme of organization provides for a precise flow of information, but such organization suffers the disadvantage that destruction of any link incapacitates the entire system.

Local circuit neurons establish their connections mainly within their immediate vicinity. Such local circuit neurons frequently are small and may have relatively few processes. Interneurons expand or constrain the flow of information within their small spatial domain and may do so without generating action potentials, given their short axons.

Single-source divergent neurons operate within the hypothalamus, pons, and medulla. From their clustered nuclear locations, these neurons extend multiple branched and divergent connections to many target cells, almost all of which lie outside the brain region in which the neurons of origin are located. Neurons with divergent circuitry could be considered more as interregional interneurons rather than as sequential elements within any known hierarchical system. For example, different neurons of the noradrenergic nucleus, the locus coeruleus (named for its blue pigmented color in primate brains), project from the pons to either the cerebellum, spinal cord, hypothalamus, or

several cortical zones to modulate synaptic operations within those regions.

Glia Are Supportive Cells to Neurons

Neurons are not the only cells in the CNS. According to most estimates, neurons are outnumbered, perhaps by an order of magnitude, by the various nonneuronal supportive cellular elements. Nonneuronal cells include macroglia, microglia, and cells of the brain's blood vessels, cells of the choroid plexus that secrete the cerebrospinal fluid, and meninges, sheets of connective tissue that cover the surface of the brain and comprise the cerebrospinal fluid-containing envelope that protects the brain within the skull.

Macroglia are the most abundant supportive cells; some are categorized as ***astrocytes*** (nonneuronal cells interposed between the vasculature and the neurons, often surrounding individual compartments of synaptic complexes). Astrocytes play a variety of metabolic support roles, including furnishing energy intermediates and providing for the supplementary removal of excessive extracellular neurotransmitter secretions (see Chapter 13). A second prominent category of macroglia is the myelin-producing cells, the oligodendroglia. Myelin, made up of multiple layers of their compacted membranes, insulates segments of long axons bioelectrically and accelerates action potential conduction velocity. Microglia are relatively uncharacterized supportive cells believed to be of mesodermal origin and related to the macrophage/monocyte lineage. Some microglia reside quiescently within the brain. During periods of intracerebral inflammation (e.g., infection, certain degenerative diseases, or traumatic injury), circulating macrophages and other white blood cells are recruited into the brain by endothelial signals to remove necrotic tissue or to defend against the microbial infection.

The Blood–Brain Barrier Protects Against Inappropriate Signals

The blood–brain barrier is an important permeability barrier to selected molecules between the bloodstream and the CNS. Evidence of a barrier is provided by the greatly diminished rate of access of most lipophobic chemicals between plasma and brain; specific energy-dependent transporter systems permit selected access. Diffusional barriers retard the movement of substances from brain to blood as well as from blood to brain. The brain clears metabolites of transmitters into the cerebrospinal fluid by excretion through the acid transport system of the choroid plexus. The blood–brain barrier is much more permeable in the hypothalamus and in several small, specialized organs (termed circumventricular organs; see Chapters 34 and 39) lining the third and fourth ventricles of the brain: the median eminence, area postrema, pineal gland, subfornical organ, and subcommissural organ. The peripheral nervous system (e.g., sensory and autonomic nerves and ganglia) has no such diffusional barrier.

The Central Nervous System Can Initiate Limited Responses to Damage

Because neurons of the CNS are terminally differentiated cells, they cannot undergo proliferative responses to damage, as can cells of skin, muscle, bone, and blood vessels. Nevertheless, small populations of previously unrecognized stem cells have been shown capable of undergoing regulated proliferation and differentiation into neurons and astrocytes. These stem cells, more prominent in rodent than primate brains, provide a natural means for selected neuronal replacement in some regions of the nervous system. As a result, neurons have evolved other adaptive mechanisms to provide for the adaptive responses to environmental demands and can be brought into play for maintenance of function following injury. These adaptive mechanisms range from activity-dependent regulation of gene expression, to modification of synaptic structure, function, and can include actual localized axonal sprouting, changes in dendritic spine numbers and shapes, and new synapse creation. These adaptive mechanisms endow the brain with considerable capacity for structural and functional modification well into adulthood. This plasticity is not only considered to be activity dependent but also to be reversible with disuse. Plasticity is pronounced within the sensory systems (see Chapter 23) and is quite prominent in the motor systems as well. The molecular mechanisms employed in memory and learning may rely upon very similar processes as those involved in structural and functional plasticity.

ORGANIZATION OF THIS TEXT

With these overview principles in place, which are detailed more extensively in Section II, we can resume our preview of this book. Another major domain of our field is nervous system development (Section III). How does a simple epithelium differentiate into specialized collections of cells and ultimately into distinct brain structures? How do neurons grow processes that find appropriate targets some distance away? How do nascent neuronal activity and embryonic experience shape activity?

Sensory systems and motor systems (Sections IV and V) encompass how the nervous system receives information

from the external world and how movements and actions are produced (e.g., eye movements and limb movements). These questions range from the molecular level (how are odorants, photons, and sounds transduced into informative patterns of neural activity?) to the systems and behavioral level (which brain structures control eye movements and what are the computations required by each structure?).

An evolutionarily old function of the nervous system is to regulate respiration, heart rate, sleep and waking cycles, food and water intake, and hormones to maintain internal homeostasis and to permit daily and longer reproductive cycles. In this area of regulatory systems (Section VI), we explore how organisms remain in balance with their environment, ensuring that they obtain the energy resources needed to survive and reproduce. At the level of cells and molecules, the study of regulatory systems concerns the receptors and signaling pathways by which particular hormones or neurotransmitters prepare the organism to sleep, to cope with acute stress, or to seek food or reproduce. At the level of brain systems, we ask such questions as what occurs in brain circuitry to produce thirst or to create a self-destructive problem such as drug abuse?

In recent years, the disciplines of psychology and biology have increasingly found common ground, and this convergence of psychology and biology defines the modern topics of behavioral and cognitive neuroscience (Section VII). These topics concern the so-called higher mental functions: perception, attention, language, memory, thinking, and the ability to navigate in space. Work on these problems traditionally has drawn on the techniques of neuroanatomy, neurophysiology, neuropharmacology, and behavioral analysis. More recently, behavioral and cognitive neuroscience has benefited from several new approaches: the use of computers to perform detailed formal analyses of how brain systems operate and how cognition is organized; noninvasive neuroimaging techniques, such as positron emission tomography and functional magnetic resonance imaging, to obtain dynamic images of the living human brain in action; and molecular biological methods, such as single gene knockouts in mice, which can relate genes to brain systems and to behavior. An especially attractive area of current investigation is the use of fluorescent proteins, such as enhanced green fluorescent protein, to demarcate individual neuronal trajectories, visualizing the "connectome," the collection of all neuronal circuits. An offshoot of this approach is to create transgenic animals in which neurons expressing specific neurotransmitter receptors can be visually identified in living brain slices for precise investigation of synaptic properties. A third example, termed optogenetics, causes light-sensitive proteins to be expressed in discrete neuronal circuits to be activated or inhibited in intact behaving experimental animals, including nonhuman primates.

THIS BOOK IS INTENDED FOR A BROAD RANGE OF SCHOLARS OF THE NEUROSCIENCES

This textbook is for anyone interested in neuroscience. In preparing it we have focused primarily on graduate students just entering the field, understanding that some of you will have majored in biology, some in psychology, some in mathematics or engineering, and even some, like me, in German literature. It is hoped that through the text, the explanatory boxes, and, in some cases, the supplementary readings, you will find the book to be both understandable and enlightening. In many cases, advanced undergraduate students will find this book useful as well.

Medical students may find that they need additional clinical correlations that are not provided here. However, it is hoped that most medical scholars at least will be able to use our textbook in conjunction with more clinically oriented material. Finally, to those who have completed their formal education, it is hoped that this text can provide you with some useful information and challenging perspectives, whether you are active neuroscientists wishing to learn about areas of the field other than your own or individuals who wish to enter neuroscience from a different area of inquiry. We invite all of you to join us in the adventure of studying the nervous system.

CLINICAL ISSUES IN THE NEUROSCIENCES

Many fields of clinical medicine are directly concerned with the brain. The branches of medicine tied most closely to neuroscience are neurology (the study of the diseases of the brain), neurosurgery (the study of the surgical treatment of neurological disease), and psychiatry (the study of behavioral, emotional, and mental diseases). Other fields of medicine also make important contributions, including radiology (the use of radiation for such purposes as imaging the brain—initially with x-rays and, more recently, with positron emitters and magnetic waves) and pathology (the study of pathological tissue). To make connections to the many facets of medicine that are relevant to neuroscience, this book includes discussion of a limited number of clinical conditions in the context of basic knowledge in neuroscience.

The Spirit of Exploration Continues

Less than a decade into the twenty-first century, the Hubble space telescope continues to transmit information about the uncharted regions of the universe and

clues to the origin of the cosmos. This same spirit of adventure also is being directed to the most complex structure that exists in the universe: the human brain. The complexity of the human brain is enormous, describable only in astronomical terms. For example, the number of neurons in the human brain (about 10^{12} or 1000 billion) is approximately equal to the number of stars in our Milky Way galaxy. Whereas the possibility of understanding such a complex device is certainly daunting, it is nevertheless true that an enormous amount has already been learned. The promise and excitement of research on the nervous system have captured the attention of thousands of students and working scientists. What is at stake is not only the possibility of discovering how the brain works. It is estimated that diseases of the brain, including both neurological and psychiatric illnesses, affect as many as 50 million individuals annually in the United States alone, at an estimated societal cost of hundreds of billions of dollars in clinical care and lost productivity. The prevention, treatment, and cure of these diseases will ultimately be found through neuroscience research. Moreover, many of the issues currently challenging societies globally—instability within the family, illiteracy, poverty, and violence, as well as improved individualized programs of education—could be illuminated by a better understanding of the brain.

THE GENOMIC INVENTORY IS A GIANT STEP FORWARD

Possibly the single largest event in the history of biomedical research was presented in published form in February 2001: the initial inventory of the human genome. By using advanced versions of the powerful methods of molecular biology, several large scientific teams have been able to take apart all of an individual's human DNA in very refined ways, amplify the amounts of the pieces, determine the order of the nucleic acid bases in each of the fragments, and then put those fragments back together again across the 23 pairs of human chromosomes.

Having determined the sequences of the nucleic acids, it was possible to train computers to read the sequence information and spot the specific signals that identify the beginning and ending of sequences likely to encode proteins. Furthermore, the computer systems could then sort those proteins by similarity of sequences (motifs) within their amino acid building blocks. After sorting, the computers could next assign the genes and gene products to families of similar proteins whose functions had already been established. In this way, scientists were rapidly able to predict approximately how many proteins could be encoded by the genome (all of the genes an individual has). Whole genome data are now available for humans, for some nonhuman primates, for rats, and for mice.

Scientifically, this state of information has been termed a "draft" because it is based on a very dense, but not quite complete, sample of the whole genome. What has been determined still contains a very large number of interruptions and gaps. Some of the smaller genes, whose beginning and ending are most certain, could be thought of as parts in a reassembled Greek urn, held in place by bits of blank clay until further excavation is done. However, having even this draft has provided some important realities.

Similar routines allowed these genomic scholars to determine how many of those mammalian genes were like genes we have already recognized in the smaller genomes of other organisms mapped out previously (yeast, worm (*Caenorhabditis elegans*), and fruit fly (*Drosophila melanogaster*)) and how many other gene forms may not have been encountered previously. Based on current estimates, it would appear that despite the very large number of nucleotides in the human and other mammalian genomes, about 30 times the length of the worms and more like 15 times the fruit fly, mammals may have only twice as many genes—perhaps some 30,000 to 40,000 altogether. Compared to other completed genomes, the human genome has greatly increased its representation of genes related to nervous system function, tissue-specific developmental mechanisms, and immune function and blood coagulation. Importantly for diseases of the nervous system that are characterized by the premature death of neurons, there appears to have been a major expansion in the numbers of genes related to initiating the process of intentional cell death, or apoptosis. Although still controversial, genes regulating primate brain size have been reported, but links to intellectual capacity remain unproven.

Two major future vistas can be imagined. To create organisms as complex as humans from relatively so few genes probably means that the richness of the required proteins is based on their modifications, either during transcription of the gene or after translation of the intermediate messenger RNA into the protein. These essential aspects of certain proteins account for a small number of brain diseases that can be linked to mutations in a single gene, such as Huntington's disease (see Chapter 31). Second, though compiling this draft inventory represents a stunning technical achievement, there remains the enormously daunting task of determining, for example, where in the brain's circuits specific genes normally are expressed and how that expression pattern may be altered by the demands of illness or an unfriendly environment. That task, at present, is one for which there are as yet no tools equivalently as powerful as those used to acquire the flood of sequence

data with which we are now faced. This stage has been referred to as the end of "naive reductionism."

In the fall of 2005, a six-nation consortium of molecular biologists announced the next phase of genomic research. The new focus will be toward refining the initial inventories to compare whole genomes of healthy and affected individuals for a variety of complex genetic illnesses (the HapMap project). Complex genetic diseases, such as diabetes mellitus, hypertension, asthma, depression, schizophrenia, and alcoholism, arise through the interactions of multiple short gene mutations that can increase or decrease one's vulnerability to a specific disease depending on individual life experiences. Ultimately, as the speeds of genome sequencing improve still further and the cost is reduced, it may be possible to predict what diseases will be more likely to affect a given person and to predict lifestyle changes that person could undertake to improve his or her opportunities to remain healthy. Given the recently recognized importance of the intronic sequences of the genome in determining which genes are expressed, so-called "Next-Gen" or "deep sequencing" methods of very high speed and resolution are forcing investigators to re-examine the genetic basis of heritable disorders. Increasing attention is being devoted to epigenetic regulation of gene expression by means of chemical modification of gene sequences and their expression.

In order to benefit from the enormously rich potential mother lode of genetic information, next we must determine where these genes are expressed, what functions they can control, and what sorts of controls other gene products can exert over them. In the nervous system, where cell–cell interaction is the main operating system in relating molecular events to functional behavioral events, discovering the still murky properties of activity-dependent gene expression will require enormous investment.

NEUROSCIENCE TODAY: A COMMUNAL ENDEAVOR

As scientists, we draw from the work of those who came before us, using other scientists' work as a foundation for our own. We build on and extend previous observations and, it is hoped, contribute something to those who will come after us. The information presented in this book is the culmination of hundreds of years of research. To help acquaint you with some of this work, we have described many of the key experiments of neuroscience throughout the book. We also have listed some of the classic papers of neuroscience and related fields at the end of each chapter, and we invite you to read some of them for yourselves.

The pursuit of science has not always been a communal endeavor. Initially, research was conducted in relative isolation. The scientific "community" that existed at the time consisted of intellectuals who shared the same general interests, terminology, and paradigms. For the most part, scientists were reluctant to collaborate or share their ideas broadly, because an adequate system for establishing priority for discoveries did not exist. However, with the emergence of scientific journals in 1665, scientists began disseminating their results and ideas more broadly because the publication record could be used as proof of priority. Science then began to progress much more rapidly, as each layer of new information provided a higher foundation on which new studies could be built.

Gradually, an interactive community of scientists evolved, providing many of the benefits that contemporary scientists enjoy: working as part of a community allows for greater specialization and efficiency of effort. This not only allows scientists to study a topic in greater depth but also enables teams of researchers to attack problems from multidisciplinary perspectives. The rapid feedback and support provided by the community help scientists refine their ideas and maintain their motivation. It is this interdependence across space and time that gives science much of its power.

With interdependence, however, comes vulnerability. In science, as in most communities, codes of acceptable conduct have evolved in an attempt to protect the rights of individuals while maximizing the benefits they receive. Some of these guidelines are concerned with the manner in which research is conducted, and other guidelines refer to the conduct of scientists and their interactions within the scientific community. Let us begin by examining how new knowledge is created.

THE CREATION OF KNOWLEDGE

Over the years, a generally accepted procedure for conducting research has evolved. This process involves examining the existing literature, identifying an important question, and formulating a research plan. Often, new experimental pathways are launched when one scientist reads with skepticism the observations and interpretations of another and decides to test their validity. Sometimes, especially at the beginning of a new series of experiments, the research plan is purely "descriptive"—for example, determining the structure of a protein or the distribution of a neurotransmitter in the brain. Descriptive initial research is essential to the subsequent inductive phase of experimentation, the movement from observations to theory, seasoned with wisdom and curiosity. Descriptive experiments are valuable both because of the questions that they attempt

to answer and because of the questions that their results allow us to ask. Information obtained from descriptive experiments provides a base of knowledge on which a scientist may draw to develop hypotheses about cause and effect in the phenomenon under investigation. For example, once we identify the distribution of a particular transmitter within the brain or the course of a pathway of connections through descriptive work, we may then be able to develop a theory about what function that transmitter or pathway serves.

Once a hypothesis has been developed, the researcher then has the task of designing and performing experiments that are likely to disprove that hypothesis if it is incorrect. This is referred to as the deductive phase of experimentation, the movement from theory to observation. Through this paradigm the neuroscientist seeks to narrow down the vast range of alternative explanations for a given phenomenon. Only after attempting to disprove the hypothesis as thoroughly as possible can scientists be adequately assured that their hypothesis is a plausible explanation for the phenomenon under investigation.

A key point in this argument is that data may only lend support to a hypothesis rather than provide absolute proof of its validity. In part, this is because the constraints of time, money, and technology allow a scientist to test a particular hypothesis only under a limited set of conditions. Variability and random chance may also contribute to the experimental results. Consequently, at the end of an experiment, scientists generally report only that there is a statistical probability that the effect measured was due to intervention rather than to chance or variability.

Given that one can never prove a hypothesis, how do "facts" arise? At the conclusion of their experiments, the researchers' first task is to report their findings to the scientific community. The dissemination of research findings often begins with an informal presentation at a laboratory or departmental meeting, eventually followed by presentation at a scientific meeting that permits the rapid exchange of information more broadly. One or more research articles published in peer-reviewed journals ultimately follow the verbal communications. Such publications are not simply a means to allow the authors to advance as professionals (although they are important in that respect as well). Publication is an essential component of the advancement of science. As we have already stated, science depends on sharing information, replicating and thereby validating experiments, and then moving forward to solve the next problem. Indeed, a scientific experiment, no matter how spectacular the results, is not completed until the results are published. More likely, publication of "spectacular" results will provoke a skeptical scientist into doing an even more telling experiment, and knowledge will evolve.

RESPONSIBLE CONDUCT

Although individuals or small groups may perform experiments, new knowledge is ultimately the product of the larger community. Inherent in such a system is the need to be able to trust the work of other scientists—to trust their integrity in conducting and reporting research. Thus, it is not surprising that much emphasis is placed on the responsible conduct of research.

Research ethics encompasses a broad spectrum of behaviors. Where one draws the line between sloppy science and unethical conduct is a source of much debate within the scientific community. Some acts are considered to be so egregious that despite personal differences in defining what constitutes ethical behavior, the community generally recognizes certain research practices as behaviors that are unethical. These unambiguously improper activities consist of fabrication, falsification, and plagiarism. Fabrication refers to making up data, falsification is defined as altering data, and plagiarism consists of using another person's ideas, words, or data without attribution. Each of these acts significantly harms the scientific community.

Fabrication and falsification in a research paper taint the published literature by undermining its integrity. Not only is the information contained in such papers misleading in itself, but other scientists may unwittingly use that information as the foundation for new research. If, when reported, these subsequent studies cite the previous, fraudulent publication, the literature is further corrupted. Thus, through a domino-like effect, one paper may have a broad negative impact on the scientific literature. Moreover, when fraud is discovered, a retraction of the paper provides only a limited solution, as there is no guarantee that individuals who read the original article will see the retraction. Given the impact that just one fraudulent paper may have, it is not surprising that the integrity of published literature is a primary ethical concern for scientists.

Plagiarism is also a major ethical infraction. Scientific publications provide a mechanism for establishing priority for a discovery. As such, they form the currency by which scientists earn academic positions, gain research grants to support their research, attract students, and receive promotions. Plagiarism denies the original author of credit for his or her work. This hurts everyone: the creative scientist is robbed of credit, the scientific community is hurt by the disincentive to share ideas and research results, and the individual who has plagiarized—like the person who has fabricated or falsified data—may well find his or her career ruined.

In addition to the serious improprieties just described, which are in fact extremely rare, a variety of much more frequently committed "misdemeanors" in

the conduct of research can also affect the scientific community. Like fabrication, falsification, and plagiarism, some of these actions are considered to be unethical because they violate a fundamental value, such as honesty. For example, most active scientists believe that honorary authorship—listing as an author someone who did not make an intellectual contribution to the work—is unethical because it misrepresents the origin of the research. In contrast, other unethical behaviors violate standards that the scientific community has adopted. For example, although it is generally understood that material submitted to a peer-reviewed journal as part of a research manuscript has never been published previously and is not under consideration by another journal, instances of retraction for dual publications can be found on occasion.

Scientific Misconduct Has Been Formally Defined by U.S. Governmental Agencies

The serious misdeeds of fabrication, falsification, and plagiarism generally are recognized throughout the scientific community. These were broadly recognized by federal regulations in 1999 as a uniform standard of scientific misconduct by all agencies funding research. What constitutes a misdemeanor is less clear, however, because variations in the definitions of accepted practices are common. There are several sources of this variation. Because responsible conduct is based in part on conventions adopted by a field, it follows that there are differences among disciplines with regard to what is considered to be appropriate behavior. For example, students in neuroscience usually coauthor papers with their advisor, who typically works closely with them on their research. In contrast, students in the humanities often publish papers on their own even if their advisor has made a substantial intellectual contribution to the work reported. Within a discipline, the definition of acceptable practices may also vary from country to country. Because of animal use regulations, neuroscientists in the United Kingdom do relatively little experimental work with animals on the important topic of stress, whereas in the United States this topic is seen as an appropriate area of study so long as guidelines are followed to ensure that discomfort to the animals is minimized.

The definition of responsible conduct may change over time. For example, some protocols that were once performed on human and animal subjects may no longer be considered ethical. Indeed, ethics evolve alongside knowledge. We may not currently be able to know all of the risks involved in a procedure, but as new risks are identified (or previously identified risks refuted), we must be willing to reconsider the facts and adjust our policies as necessary. In sum, what is considered to be ethical behavior may not always be obvious, and therefore we must actively examine what is expected of us as scientists.

Having determined what is acceptable practice, we then must be vigilant. Each day neuroscientists are faced with a number of decisions having ethical implications, most of them at the level of misdemeanors: Should a data point be excluded because the apparatus might have malfunctioned? Have all the appropriate references been cited and are all the authors appropriate? Might the graphic representation of data mislead the viewer? Are research funds being used efficiently? Although individually these decisions may not significantly affect the practice of science, cumulatively they can exert a great effect.

In addition to being concerned about the integrity of the published literature, we must be concerned with our public image. Despite concerns over the level of federal funding for research, neuroscientists are among the privileged few who have much of their work funded by taxpayer dollars. Highly publicized scandals damage the public image of our profession and hurt all of us who are dependent on continued public support for our work. They also reduce the public credibility of science and thereby lessen the impact that we can expect our findings to have. Thus, for our own good and that of our colleagues, the scientific community, and the public at large, we must strive to act with integrity.

SUMMARY

You are about to embark on a tour of fundamental neuroscience. Enjoy the descriptions of the current state of knowledge, read the summaries of some of the classic experiments on which that information is based, and consult the references that the authors have drawn on to prepare their chapters. Think also about the ethical dimensions of the science you are studying; your success as a professional and the future of our field depend on it.

CHAPTER

2

Basic Plan of the Nervous System

INTRODUCTION

The brain often is compared with a computer these days. True, the brain is a computer, but it is a very special kind of computer—a biological computer that has evolved by natural selection over hundreds of millions of years and countless generations. Furthermore, it has no obvious design features in common with human-engineered computers. Instead, the brain is a unique organ that thinks and feels, generates behavioral interactions with the environment, keeps bodily physiology relatively stable, and enables reproduction of the species—its most important role from evolution's grand perspective. And for strictly personal reasons the brain is the most precious thing we have simply because it is the organ of consciousness, as reflected in René Descartes's famous seventeenth-century aphorism, "I think, therefore I am."

Aristotle first emphasized that structure and function are inextricably intertwined, two sides of the same coin, with structure providing obvious physical constraints on function. Just think about the difference between a hammer and a saw. Unfortunately, as knowledge becomes more and more specialized, there is a tendency to analyze the structure, function, and chemistry of the nervous system from different, sometimes even isolated, perspectives. The main theme of this chapter is the basic structure-function organization of the nervous system: what are the parts and how are they interconnected into functional systems? In other words, what are the organizing principles—the basic design features—of its circuitry?

Evolution and development are two approaches often used to understand biological complexity—because they start with the simplest condition—and the human brain is far and away the most complex object we know of, with its roughly 100 billion neurons and 100 trillion axonal connections between them. One remarkable conclusion emerging from these two perspectives is that nerve cells in all animals—from jellyfish to humans—are basically the same in terms of cell biology; what changes most during ontogeny and phylogeny is the *arrangement* of nerve cells into functional circuits: the architecture of the nervous system. The "bricks" or "Legos" are similar, but the "buildings" constructed with them can vary tremendously in size and functionality. An ultimate goal of neuroscience may be to understand the human brain, but remarkable progress can nevertheless be made through analyzing "lower" animals and early embryos. The other equally remarkable conclusion is that all vertebrates, from fish to humans, share a common basic plan of the nervous system, with the same major parts and functional systems.

EVOLUTION HIGHLIGHTS: GENERAL ORGANIZING PRINCIPLES

Protists and the simplest multicellular animals (sponges) display ingestive, defensive, reproductive, and other behaviors without any nervous system whatsoever, raising the question, what is the adaptive value of adding a nervous system to an organism? We will now examine key structure-function correlates of nervous system organization in animals with relatively simple body plans and behaviors.

The Nerve Net is the Simplest Type of Nervous System

In his provocative 1919 book *The Elementary Nervous System*, George Parker outlined a reasonable scenario for how nervous systems evolved. An updated version begins with the first multicellular animals—similar to modern-day sponges—that emerged over half a billion years ago. They are seemingly amorphous animals that spend their adult

© 2013 Elsevier Inc. All rights reserved.

lives immobile, submerged in water. Their relatively simple behavior is mediated largely by a set of primitive smooth muscle cell (myocyte) sphincters regulating water flow through body wall pores. These specialized cells are called *independent effectors* because their contraction is evoked by stimuli like stretch or environmental chemicals acting directly on the plasma membrane of individual cells.

The first animal phylum with a nervous system was the Cnidaria, which includes jellyfish, corals, sea anemones, and the elegantly simple hydra. In contrast to sponges, hydra locomote and show active feeding behavior (Fig. 2.1). These behaviors are coordinated and mediated by a nervous system, a network of specialized units or cells called nerve cells or *neurons* (Box 2.1).

Sensory Neurons

Hydra's body wall is simple, with an outer *ectoderm* layer contacting the external environment, an inner *endoderm* layer facing the body cavity's internal environment and promoting digestion and waste elimination, and a vague middle or *meso* layer in between. Neurons probably differentiated initially from the ectoderm, and perhaps the first to evolve were *sensory neurons*. One cytoplasmic extension of these bipolar cells facing the external environment became specialized to detect stimuli much weaker than those activating independent effectors, whereas the other pole became specialized to transmit information about these stimuli to a *group* of independent effectors (Fig. 2.3). Experimental evidence

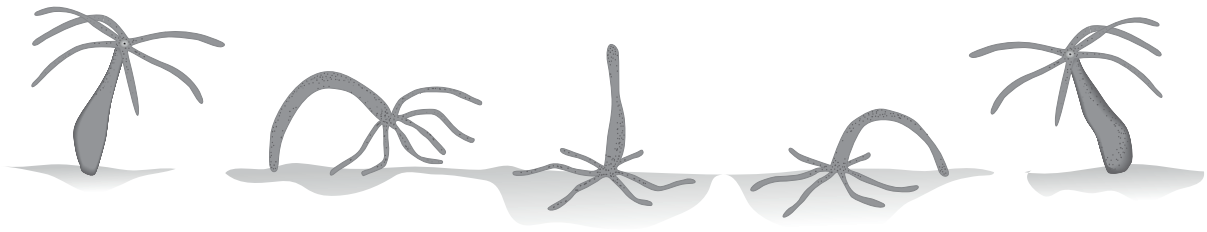

FIGURE 2.1 Locomotor behavior in hydra resembles a series of somersaults, as shown in the sequence beginning on the left. The tiny black dot in the region between the tentacles in the figure at the far right is the animal's mouth. Ingestive (feeding) behavior involves guiding food particles into the mouth with coordinated tentacle movements.

BOX 2.1

THE NEURON DOCTRINE

The cell theory, which states that all organisms are composed of individual cells, was developed around the middle of the nineteenth century by Mattias Schleiden and Theodor Schwann. However, this unitary vision of the cellular nature of life was not immediately applied to the nervous system, as most biologists at the time believed in the cytoplasmic continuity of nervous system cells. Later in the century, the most prominent advocate of this *reticularist* view was Camillo Golgi, who proposed that axons entering the spinal cord actually fuse with other axons (Fig. 2.2A). The reticularist view was challenged most thoroughly by Santiago Ramón y Cajal, a founder of contemporary neuroscience and without doubt the greatest observer of neuronal architecture. In beautifully written and carefully reasoned deductive arguments, Cajal presented us with what is now known as the *neuron doctrine*. This great concept in essence states that the cell theory applies to the nervous system: each neuron is an individual entity, the basic unit of neural circuitry (Fig. 2.2B). The acrimonious debate between reticularists and proponents of the neuron doctrine raged for decades. Over the years, the validity of the neuron doctrine has been supported by a wealth of accumulated data. Nevertheless, the reticularist view is not entirely incorrect, because some neurons do act syncytially via specialized intercellular gap junctions, a feature that is more prominent during embryogenesis.

In 1897, Charles Sherrington postulated that neurons establish functional contact with one another and with other cell types via a theoretical structure he called the synapse (Greek *synaptein*, to fasten together). It was not until 50 years later that the structural existence of synapses was demonstrated by electron microscopy (see Fig. 3.3). The synaptic complex is built around an *adhesive* junction, and in this and other respects the complex is quite similar to the desmosome and the adherens junctions of epithelia. In fact, similarities in ultrastructure between the adherens junction and the synaptic complex of central nervous tissue were noted even in early electron microscopic studies (see Peters, Palay, & Webster, 1991).

indicates that sensory neurons provide four major selective advantages in evolution:

- Increased stimulus sensitivity
- Faster effector cell responses
- Stronger behavioral responses because multiple effector cells are influenced
- Sensory neurons responding to different stimulus modalities can be distributed strategically in different body regions

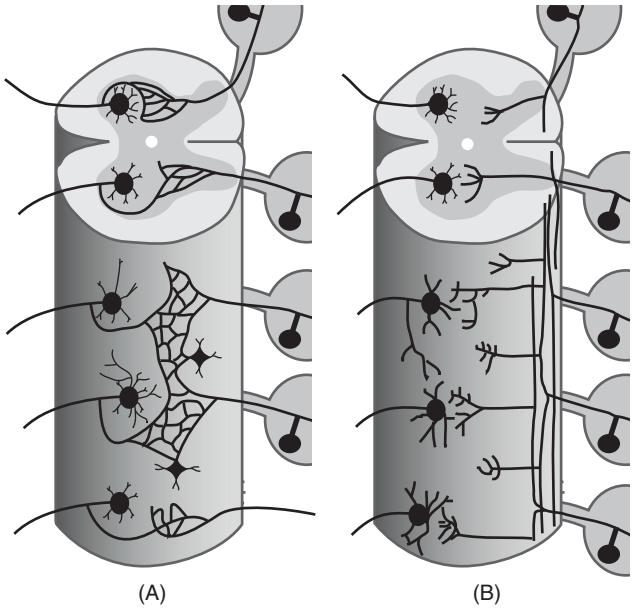

FIGURE 2.2 Two competing views: The nervous system as a reticulum or the neuron doctrine. (A) Proponents of the reticular theory believed that neurons are physically continuous with one another, forming an uninterrupted network. (B) In contrast, the neuron doctrine regards each neuron as an individual entity communicating with target cells by way of contiguity rather than continuity, across an appropriate intercellular gap. *Adapted from Cajal (1909–1911).*

The bipolar shape of sensory neurons is fundamentally important. The prototypical theory about neural circuit organization was presented by Santiago Ramón y Cajal in his classic "bible" of structural neuroscience, *The Histology of the Nervous System in Man and Vertebrates* (1909–1911). According to the cornerstone *functional polarity theory*, information normally flows in one direction through most neurons, and thus through most neural circuits—from *dendrites* and *cell body*, the input or receptive parts of the neuron, to a single *axon*, the output or effector part. In other words, most neurons have two classes of *cytoplasmic extensions*: one or more dendrites detecting inputs and a single axon conducting an output that can influence multiple cells through branching or *collateralization*. At least in early developmental stages, all sensory neurons have this fundamental bipolar shape, and over the course of evolution they have become specialized to detect a remarkable variety of stimuli from light, temperature, and a wide range of chemicals and ions, to vibration and other mechanical deformations.

Motor Neurons

A second stage of differentiation or complexity in hydra's nervous system was the addition of neurons between sensory and effector. They are defined as motor neurons (*motoneurons*) because they directly innervate effector cells (usually muscle or gland cells), which in turn receive their inputs from sensory neurons (Figs. 2.2B, 2.3C). Conceptually, this provides a *two-layered nervous system*, with the first or top layer having sensory neurons, and the second or bottom layer having motor neurons. In this prototypical network sensory neurons project (send axon collaterals) to multiple motoneurons, and then each motoneuron innervates a set of effector cells (with a motoneuron and its effector cell set defined as a *motor unit*). During

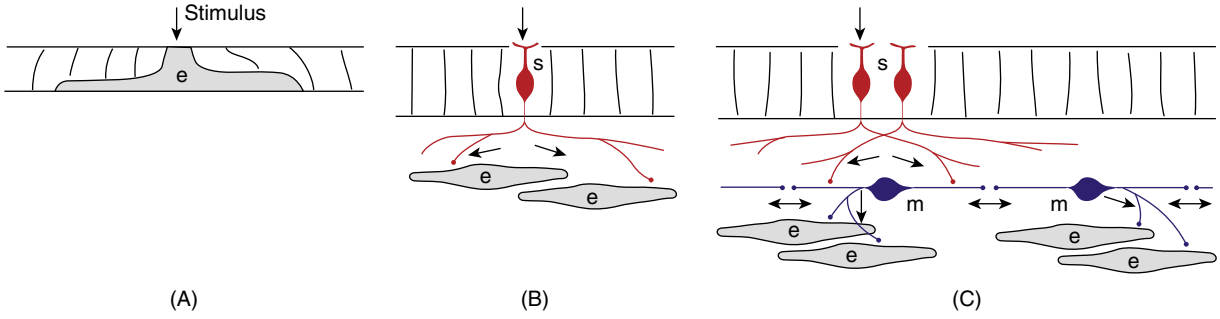

FIGURE 2.3 Activation of effector cells (e) in simple animals. (A) Sponges lack a nervous system; stimuli act directly on effector cells, which are thus called independent effectors. (B) In cniderians, bipolar sensory neurons (s) differentiate in the ectoderm. The sensory neuron outer extension detects stimuli and is thus a dendrite. The inner extension of some sensory neurons transmits information directly to effector cells and is thus an axon. Because this type of sensory neuron innervates effector cells directly, it is actually a sensorimotor neuron. (C) Most cnidarian sensory neurons send their axon to motoneurons (m), which in turn send an axon to effector cells. Cnidarian motoneurons may also have lateral extensions interacting with other motoneurons, and these extensions typically conduct information in either direction via reciprocal chemical synapses (and are thus amacrine extensions). Arrows show the direction of information flow.

an animal's normal behavior, information flow is unidirectional or polarized from one cell type, sensory neuron, to another cell type, motoneuron, to a third cell type, effector. This is the basic definition of a simple reflex, as defined by Charles Sherrington in his cornerstone of systems neuroscience, *The Integrative Action of the Nervous System* (1906).

In this hypothetical scenario (Fig. 2.3) an environmental stimulus detected by a sensory neuron's dendrite is transmitted by its axon to the dendrites of a motoneuron population. Then the axon of each motoneuron innervates an effector cell population. This is the functional polarity rule applied to a simple two-layer, sensory-motor network mediating reflex behavior.

Another general feature of the hydra two-layered nervous system has been observed: sensory neurons do not innervate one another, whereas motoneurons do interact directly. Here, motoneurons have two projection classes: one to effector cells and another to other motoneurons. Structurally and functionally, many of these hydra motoneurons also have two types of output extensions. One is a typical axon innervating an effector cell population. However, the other is an extension that contacts homologous extensions from other motoneurons. Interestingly, many of these "tangential" extensions between motoneurons transmit information in either direction; either motoneuron can transmit information to the other via these extensions. This is an exception to the functional polarity rule and is mediated by reciprocal rather than the more common unidirectional synapses. Cajal (1909–1911) described several examples of neurons that lack a clear axon (in retina, olfactory bulb, and intestine) and called them amacrine cells. As an extension of this, it is useful to divide neuronal extensions into three types: dendritic (input), axonal (output), or amacrine (bidirectional).

Adding a second layer to the nervous system has obvious adaptive advantages related to increased capacity for response complexity and integration. Consider a stimulus to one specific part of the animal or even one sensory neuron. Its influence may radiate to distant parts of the animal because one sensory neuron innervates multiple motoneurons, those motoneurons innervate additional motoneurons, and each motoneuron innervates multiple effector cells—an example of what Cajal called "avalanche conduction." There may be great *divergence* between stimulus and effector cells producing a response, with the actual divergence pattern shaped by the structure–function architecture of the nervous system: how the neurons and their interconnections are arranged in the body. It is easy to imagine how this arrangement in hydra might coordinate the tentacles to bring a food morsel detected by just one of them to the mouth or how it might coordinate locomotion (Fig. 2.1).

A second basic consequence of this structural arrangement is information *convergence* in the nervous system. Just consider a particular motoneuron: it can receive inputs from more than one sensory neuron and from other motoneurons as well.

Nerve Nets

At first glance, hydra's nervous system is distributed fairly uniformly around the radially symmetrical body wall and tentacles (Fig. 2.4). Its essentially double-layered arrangement of distributed sensory and motor neurons is called a *nerve net*. However, in certain regions of the body with specialized function, like around the mouth and base of the tentacles, neurons tend to aggregate—a tendency toward *centralization* that will now be examined more carefully.

Bilateral Symmetry, Centralization, and Cephalization Emerge in Flatworms

In contrast to cnidarians, flatworms are bilaterally symmetrical predators with rostral (head) and caudal (tail) ends, and dorsal and ventral surfaces. These changes in body plan and behavior are accompanied by equally important changes in nervous system organization. Many flatworm neurons are clustered into distinct ganglia interconnected by longitudinal and transverse axon bundles called *nerve cords* (Fig. 2.5). This condensation of neural elements, or centralization, allows faster

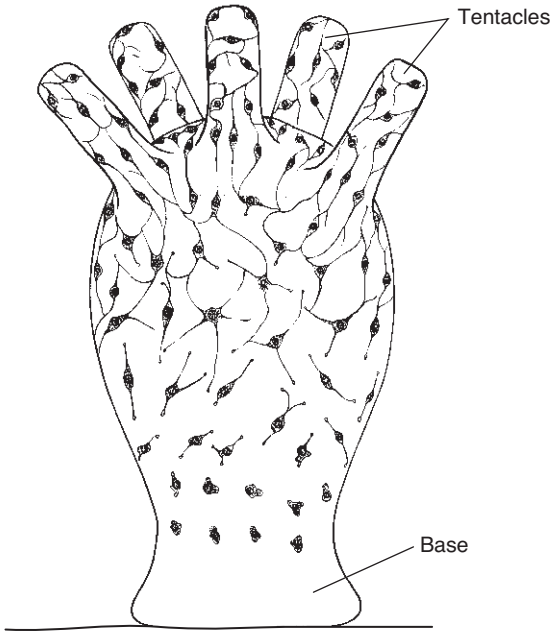

FIGURE 2.4 The nerve net of hydra, a simple cnidarian, is spread diffusely throughout the body wall of the animal. This drawing shows maturation of the nerve net in a hydra bud, starting near the base and finishing near the tentacles. *Refer to McConnell (1932) and Koizumi (2002).*

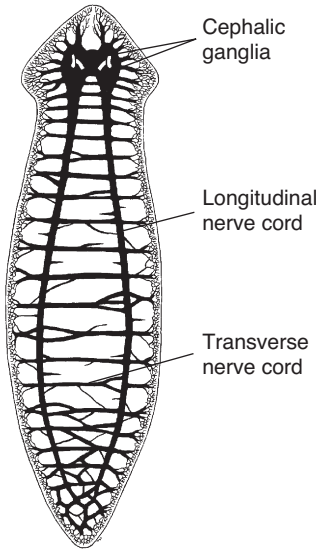

FIGURE 2.5 The nervous system of the planarian, a flatworm, includes longitudinal and transverse nerve cords associated with centralization, and two fused cephalic ganglia (the invertebrate brain) in the rostral end associated with cephalization. Centralization and cephalization probably are related to the flatworm's bilateral symmetry and ability to swim forward rapidly. *Refer to Lentz (1968). Reproduced with permission from Yale University Press.*

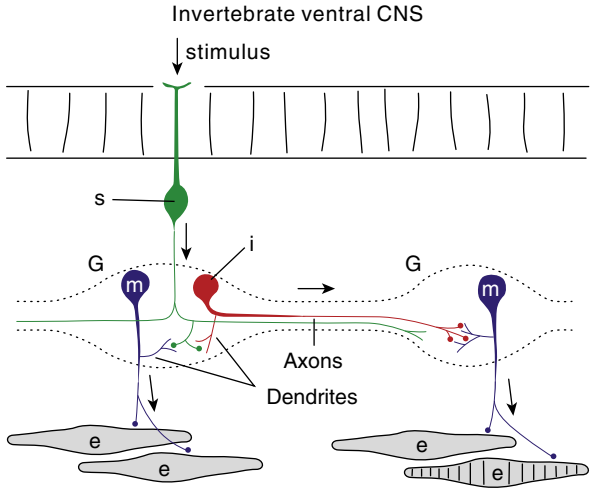

FIGURE 2.6 Invertebrate ganglia (G) usually display two neuron classes: motor neurons (m) and interneurons (i), both typically unipolar, with dendrites arising from a single axon. Here neuronal cell bodies are arranged peripherally and synapses occur in a central region called the neuropil. Sensory neurons (s) usually innervate motoneurons and interneurons but not effectors (e). Arrows show the usual direction of information flow.

and thus more efficient communication between neurons because cellular material is conserved and conduction times are reduced. The largest, most complex ganglia (*cephalic ganglia* or invertebrate brains) are localized rostrally, where they receive information from specialized sensory receptors in the front of the animal as it swims. Bilateral symmetry, centralization, and cephalization are three cardinal organizational trends in nervous system evolution.

Interneurons

Flatworms are the simplest animals, with an abundant, clearly distinct third neuron division, *interneurons*, which are interpolated between sensory and motor neurons (Fig. 2.6). As already noted, Cajal recognized some atypical interneurons that apparently lack distinguishable dendrites and axon (amacrine neurons, or more precisely, amacrine interneurons). However, most interneurons have recognizable dendrites and axon and so presumably transmit information down the axon in only one direction: toward its terminals. They are *typical neurons* conforming to the functional polarity rule.

One consequence of adding a third "layer" of neurons to the nervous system is simply to increase convergence and divergence of information processing, and thus the capacity for response complexity. There are, however, three other critical functions interneurons subserve. They can act as *excitatory* or *inhibitory* "*switches*" in neuronal networks, assemblies of them can act as *pattern detectors* and *generators* between sensory and motor neurons, and they can be *pacemakers* if they generate intrinsic rhythmical activity patterns.

By this definition the vast majority of vertebrate brain neurons are interneurons. So it is useful at the outset to recognize two broad interneuron categories: intraregional or local and interregional or projection. *Intraregional interneurons*, or local circuit neurons, have an axon that remains confined to a distinguishable gray matter region or ganglion, whereas *interregional interneurons* send a longer axon to a different gray matter region or ganglion, although it may also generate local axon collaterals.

The omnidirectional information flow typical of cnidarian nerve nets is unusual in the rest of the animal kingdom, where most neurons are functionally polarized with information flowing through neural circuits sequentially from dendrites and cell body to axon and axon terminals. However, most invertebrate motoneurons and interneurons are unipolar: a single extension, the axon, emanates from the cell body. Dendrites branch *from* the axons in the center of a ganglion—entering the *neuropil*—where most synapses are formed (Fig. 2.6). In vertebrates most neurons are multipolar, with several dendrites, plus an axon extending from the cell body or a dendrite.

Features of simple nervous systems are preserved throughout evolution. For example, the part of the nervous system in the wall of the human gastrointestinal tract (the enteric plexuses) has many features of a highly refined nerve net, and a "layer" of amacrine

BOX 2.2

CAJAL: ICONOCLAST TO ICON

Santiago Ramón y Cajal (1852–1934) is considered by many people to be the founder of modern neuroscience—a peer of Darwin and Pasteur in nineteenth-century biology. He was born in the tiny Spanish village of Petilla de Aragon on May 1, 1852, and as related in his delightful autobiography, he was somewhat mischievous as a child and determined to become an artist, much to the consternation of his father, a respected local physician. However, he eventually entered the University of Zaragoza and received a medical degree in 1873. As a professor of anatomy at Zaragoza, his interests were mostly in bacteriology (the nineteenth-century equivalent of molecular biology today in terms of an exciting biomedical frontier) until 1887, when he visited Madrid at age 35 and first saw through the microscope histological sections of brain tissue treated with the Golgi method, which had been introduced in 1873. Although very few workers had used this technique, Cajal saw immediately that it offered great hope in solving the most vexing problem of nineteenth-century neuroscience: How do adult nerve cells interact with one another? This realization galvanized and directed the rest of his scientific life, which was extremely productive in terms of originality, scope, and accuracy.

Shortly after Jacob Schleiden, Theodor Schwann, and Rudolf Virchow proposed the cell theory in the late 1830s, Joseph von Gerlach Sr. and Otto Deiters suggested that nerve tissue was special in the sense that nerve cells are not independent units but instead form a continuous cytoplasmic syncytium or reticular net (Fig. 2.2A). This concept was later refined by Camillo Golgi, who, based on the use of his silver chromate method, concluded that axons of nerve cells form a continuous reticular net, whereas in contrast dendrites do not anastomose but instead serve a nutritive role, much like the roots of a tree. Using the same technique, Cajal almost immediately arrived at the opposite conclusion, based first on his examination of the cerebellum, and later of virtually all other parts of the nervous system. In short, he proposed that neurons interact by way of contact or contiguity rather than by continuity and are thus structurally independent units, which was finally proven when the electron microscope was used in the 1950s to characterize synapses. This concept became known as the *neuron doctrine*.

Cajal's second major conceptual achievement was the theory of **functional polarity**, which stated that the dendrites and cell bodies of neurons receive information, whereas the single axon with its collaterals transmits information to the other cells. This rule allows prediction of information flow direction through neural circuits based on the morphology or shape of individual neurons forming them, and it was the cornerstone of Charles Sherrington's (1906) revolutionary physiological analysis of mammalian reflex organization. Recent evidence that many dendrites transmit an action potential or graded potential in the retrograde direction would not violate the tenets of the functional polarity theory unless the potential led to altered membrane potentials in the associated presynaptic axon—and if this were the case the "dendrite" would be classed instead as an amacrine process (see text).

Around the close of the nineteenth century, Cajal made a remarkable series of discoveries at the cellular level. In addition to the two concepts outlined earlier, they include (1) the mode of axon termination in the adult CNS (1888), (2) the dendritic spine (1888), (3) the first diagrams of reflex pathways based on the neuron doctrine and functional polarity (1890), (4) the axonal growth cone (1890), (5) the chemotactic theory of synapse specificity (1892), and (6) the hypothesis that learning could be based on the selective strengthening of synapses (1895).

In one of the great ironies in the history of neuroscience, Cajal and Golgi shared the Nobel Prize for Medicine in 1906, though they had used the same technique to elaborate fundamentally different views on nervous system organization! The meeting in Stockholm may not have diminished the great personal friction between them. In 1931 Cajal wrote, "What a cruel irony of fate to pair like Siamese twins united by the shoulders, scientific adversaries of such contrasting characters."

interneurons is found in the human retina and olfactory bulb.

A Segmented Ventral Nerve Cord Typifies Annelids and Arthropods

Annelid worms and arthropods have even more complex body plans and behaviors than flatworms, partly because of *segmentation*. Body segments (*metameres*) are repeated serially along the body's rostrocaudal axis and presumably share a common underlying genetic developmental program, although terminal differentiation (adult structure) may vary in each. This strategy allows for more complex body plans (including the nervous system) to evolve without a linear or exponential increase in genetic material. Annelids and all the more complex invertebrates share another characteristic feature, a *ventral nerve cord* with a pair of ganglia (or a single fused

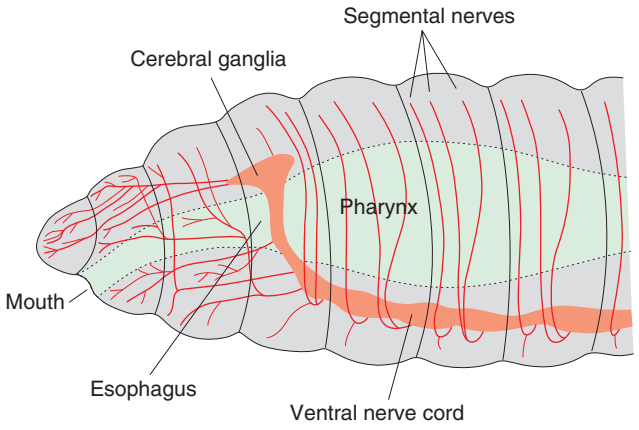

FIGURE 2.7 Nervous system organization in the rostral end of an annelid worm. A ventral nerve cord with more or less distinct ganglia connects with a fused pair of cerebral ganglia (brain) dorsal to the pharynx (part of the digestive tract). Note nerves extending from ventral nerve cord and cerebral ganglia. *Refer to Brusca and Brusca (1990).*

ganglion) in each segment, and longitudinal axon bundles between ganglia in adjacent segments (Fig. 2.7). Transverse *nerves* also extend from each ganglion to sensory structures and muscles in the same segment.

The Basic Plan of the Vertebrate Nervous System is Found in Lancelets

Vertebrates are a subphylum of the Chordates and are the most complex of all animals in terms of structure and behavior. They share a basic body plan where common organ systems are arranged in a relatively strict anatomical relationship with one another (Box 2.3 and Figs. 2.8, 2.9). Like other Chordates, vertebrates display two key features during some part of their life: a cartilaginous rod, the *notochord*, extending dorsally along the body, and above it a hollow *dorsal nerve cord*. In most vertebrates the notochord's body stiffening and protective functions are supplanted by the vertebral column and bony skull, with the notochord reduced to a series of cartilaginous cushions (discs) between or within the vertebrae. The vertebrate central nerve cord is tremendously expanded, thickened, and folded to form the brain and spinal cord (the central nervous system, CNS).

The vertebrate nervous system's basic parts are revealed in the lancelet (amphioxus), a simple, nonvertebrate chordate (subphylum Cephalochordata). The lancelet is a slender, fish-like filter-feeder living half buried in the sand of shallow, tropical marine waters (Fig. 2.9). The body is stiffened by a notochord, and a hollow dorsal nerve cord runs the length of the body, generating segmental nerves innervating muscles and organs. Locomotor behavior (swimming) is produced by alternately contracting right and left segmental muscles (myotomes). Without a notochord, these contractions would shorten the animal rather than generate forward propulsive force.

Although typical vertebrate brain regions are not obvious rostrally in the lancelet nerve cord, genes specifying

BOX 2.3

ANATOMICAL RELATIONSHIPS IN THE VERTEBRATE BODY

To describe the physical relationships between structures in the nervous system and the rest of the vertebrate body, it is best to use terms that accurately and unambiguously describe the position of a given structure in three dimensions without reference to the external world. The major axis of the body is the **rostrocaudal axis**, which extends along the length of the animal from the *rostrum* (beak) to the *cauda* (tail) (Fig. 2.8), as well as the length of the embryonic neural plate and neural tube (see Figs. 2.10 and 2.12). A second axis, the orthogonal **dorsoventral axis**, is vertical and runs from the *dorsum* (back) to the *ventrum* (belly). Finally, the third perpendicular axis, the **mediolateral axis**, is horizontal and runs from the midline (medial) to the lateral margin of the animal (lateral). Unfortunately, the rostrocaudal axis undergoes complex bending during embryogenesis, and the bending pattern is unique to each species. It would be ideal if the three cardinal axes were used in a topologically accurate way—say, with reference to the body as it might appear with a "straightened out" rostrocaudal axis. In practice, however, this is rarely the case, which leads to a certain degree of ambiguity, as is obvious when looking at the fish, frog, cat, and human bodies shown in Figure 2.8.

The problem is especially difficult in human anatomy where use of an idiosyncratic terminology has a long, ingrained tradition. The basic principles are much easier to illustrate than to describe in writing (see Fig. 2.8), but one major source of confusion in the human brain is related to the fact that the rostrocaudal axis makes a 90-degree bend in the midbrain region (unlike in rodents and carnivores, for example, where the axis is relatively straight). The other source of confusion is simply the different names that are used. For example, in human anatomy the spinal cord has anterior and posterior horns, and posterior root ganglia, whereas in other mammals they usually are referred to as ventral and dorsal horns, and dorsal root ganglia. The merits of a uniformly applied nomenclature based on comparative structural principles seem obvious.

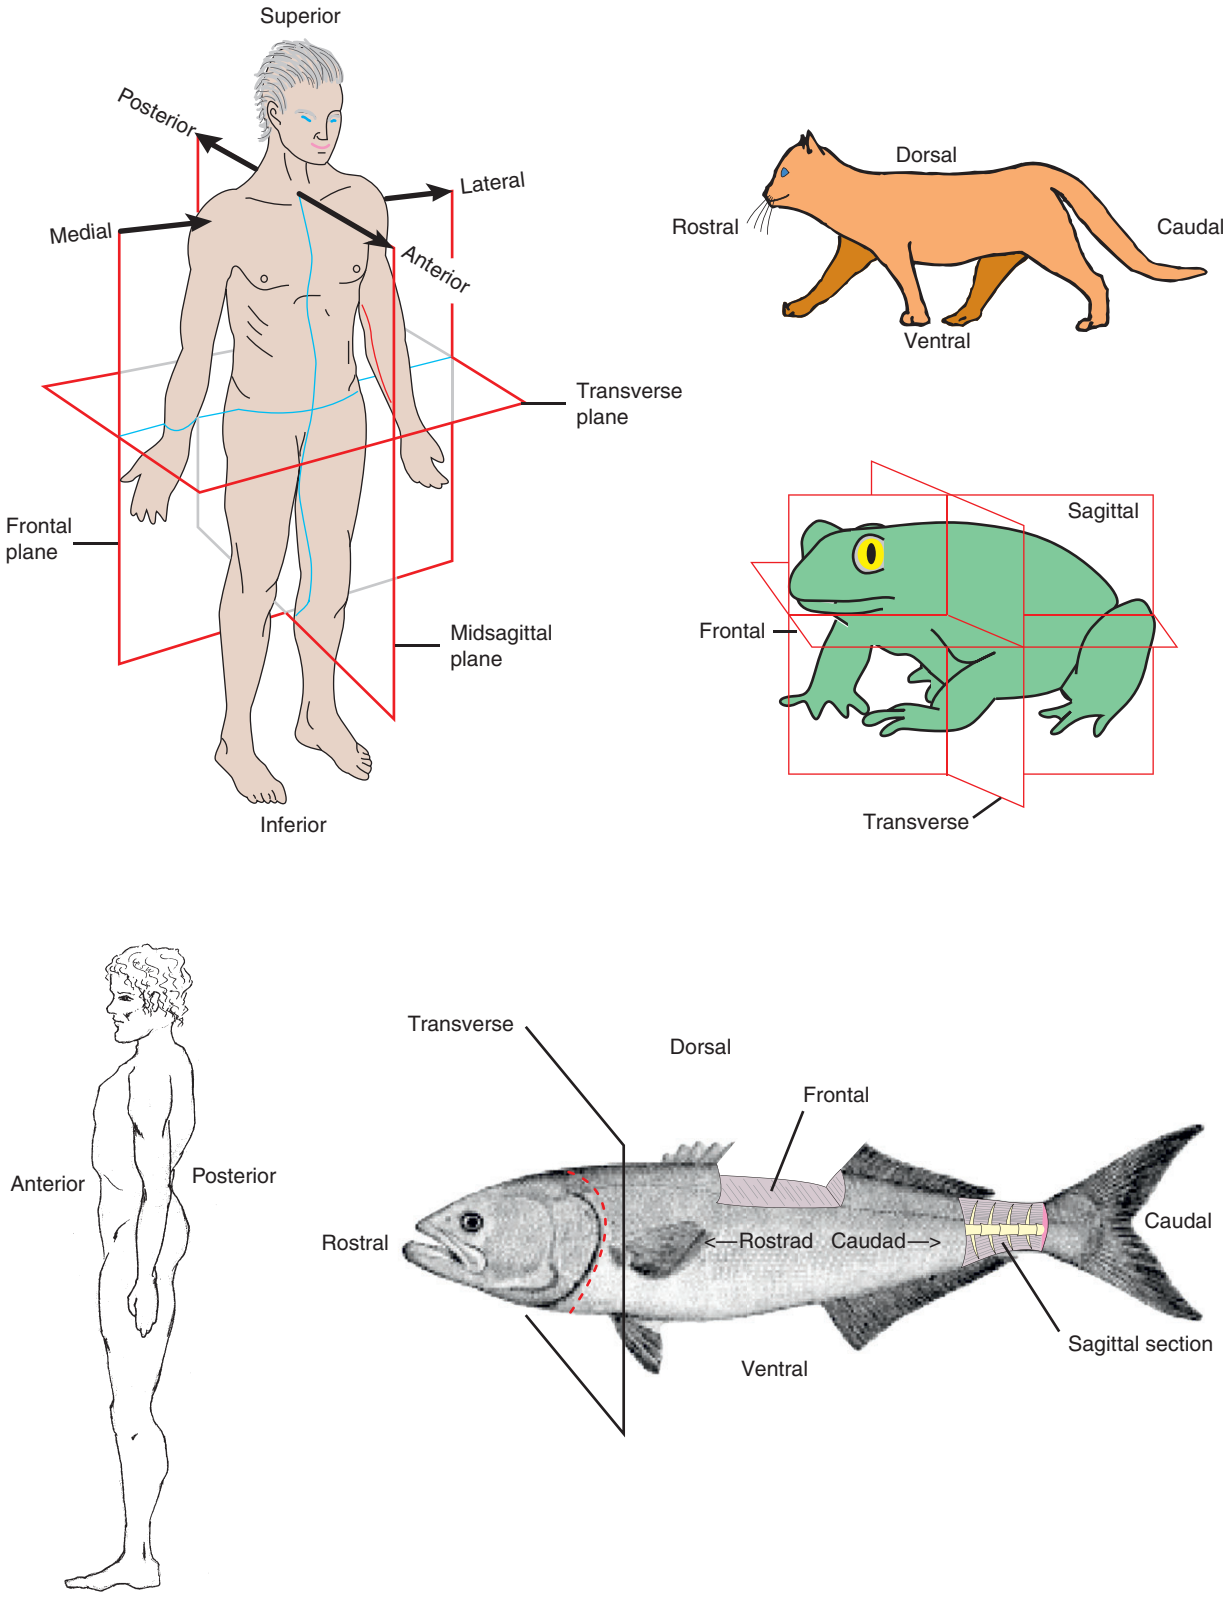

FIGURE 2.8 Orientation of the vertebrate body. Orientation planes for fish, quadrupeds, and bipeds are depicted. Associated with the three cardinal planes (rostrocaudal, dorsoventral, and mediolateral) are three orthogonal planes: frontal, sagittal, and transverse, which are the same in all early vertebrate embryos. For more explanation, see Williams (1995).

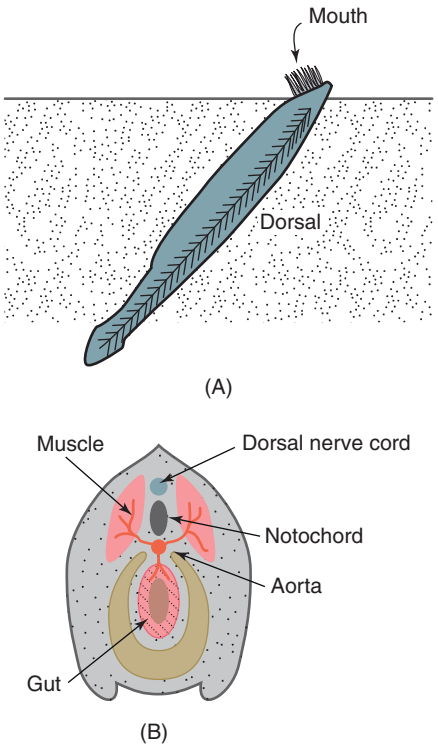

FIGURE 2.9 The lancelet (amphioxus) is a forerunner of the vertebrates. (A) Lateral view of the animal in its native habitat under the ocean floor, with its mouth protruding above the sand. (B) A cross-section of the lancelet body showing relationships between gut, aorta, notochord, and dorsal nerve cord. *Adapted from Cartmill, Hylander, and Shafland (1987).*

early vertebrate head embryogenesis also are expressed rostrally in the lancelet body. Thus, some components of the molecular program specifying modern vertebrate head development apparently were present early in chordate evolution (Holland & Takahashi, 2005).

Summary

The cniderian nerve net displays most of the basic cellular features of nervous system organization, including convergence and divergence of sensory and motor information. In more complex bilaterally symmetrical invertebrates, neurons and axons tend to aggregate in ganglia, nerve cords, and nerves (centralization), and there is a greater concentration of neurons and sensory organs in the body's rostral end (cephalization). Segmented invertebrates have a ventral nerve cord that includes a bilateral pair of ganglia (or single fused ganglion) in each segment. The primitive chordate, lancelet, displays the basic nervous system organization characteristic of vertebrates, including mammals and humans.

DEVELOPMENT REVEALS BASIC VERTEBRATE PARTS

One nineteenth-century biology triumph was the demonstration that early stages of embryogenesis are fundamentally the same in all vertebrates. The CNS and heart are the first organs to differentiate in the embryo, and the basic CNS divisions differentiating early in development are also common to all vertebrates. The names and arrangement of these divisions are the starting point for regional or topographic neuroanatomical nomenclature (Swanson, 2000a).

Nervous System Regionalization Begins in the Neural Plate

During embryogenesis the CNS develops as a hollow cylinder (*neural tube*) from a topologically flat sheet of cells (*neural plate*), by a process of *neurulation* (Chapter 13). Here we simply consider macroscopic structural changes during the transformation.

The neural plate is a spoon-shaped differentiation of the trilaminar embryonic disc's one-cell-thick ectodermal layer (Fig. 2.10). Its wide end lies rostrally and becomes the brain, whereas the narrow end lies caudally and becomes the spinal cord—the two major CNS divisions. A midline *neural groove* divides the neural plate into right and left halves, so the plate displays three cardinal morphogenetic features: *polarity*, *bilateral symmetry*, and *regionalization*. Furthermore, the neural plate differentiates from rostral to caudal, so the brain plate regionalizes first. Signs of this include appearance of the *optic vesicles*, evaginating near the rostral end of the neural plate (in the presumptive hypothalamus); a midline *infundibulum* evaginating between optic vesicles and rostral end of the notochord, and indicating the presumptive pituitary stalk (again in presumptive hypothalamus); and the *otic rhombomere* (presumptive or future rhombomere 4), a swelling near the center of what will become the adult rhombicbrain (Figs. 2.11, left; 2.14).

At the junction between neural plate and remaining ectoderm (later forming the skin's epidermal layer or skin) lies a narrow strip of transitional ectoderm, the *neural crest*, a distinctive vertebrate feature (Fig. 2.10). It generates a variety of adult structures, including most neurons of the peripheral nervous system (PNS).

In summary, the CNS and PNS divisions are represented by the neural plate and neural crest, respectively, during the neural plate stage of vertebrate development. The two major CNS divisions, the brain and spinal cord, are also indicated in the neural plate, which at this developmental stage is topologically simple: a bilaterally symmetrical, flat sheet that is one cell thick.

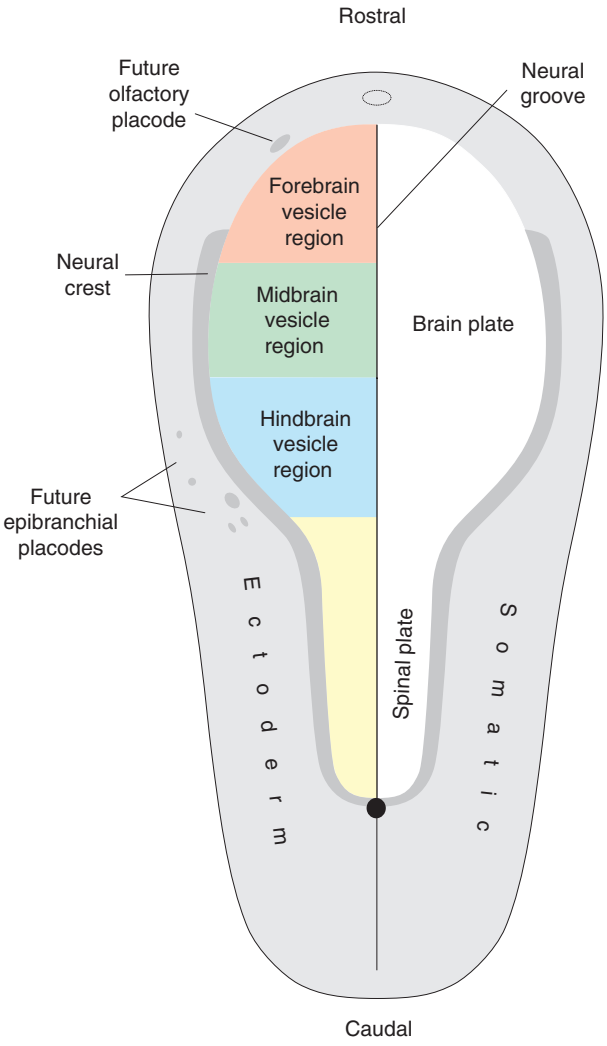

FIGURE 2.10 The neural plate is a spoon-shaped region of ectoderm (neural ectoderm) forming the CNS; surrounding it is somatic ectoderm. The neural plate is polarized (wider rostrally than caudally), bilaterally symmetrical (divided by the midline neural groove), and regionalized (brain plate rostrally, spinal plate caudally). The neural crest is a thin zone between neural and somatic ectoderm, and a series of placodes develops as "islands" within the somatic ectoderm. The neural crest and placodes generate PNS neurons. The approximate location of the future primary brain vesicles (Fig. 2.12A) in the neural plate is shown in color on the left. The same color scheme is used in Figs. 2.11, 2.12, and 2.14. *Refer to Swanson (1992).*

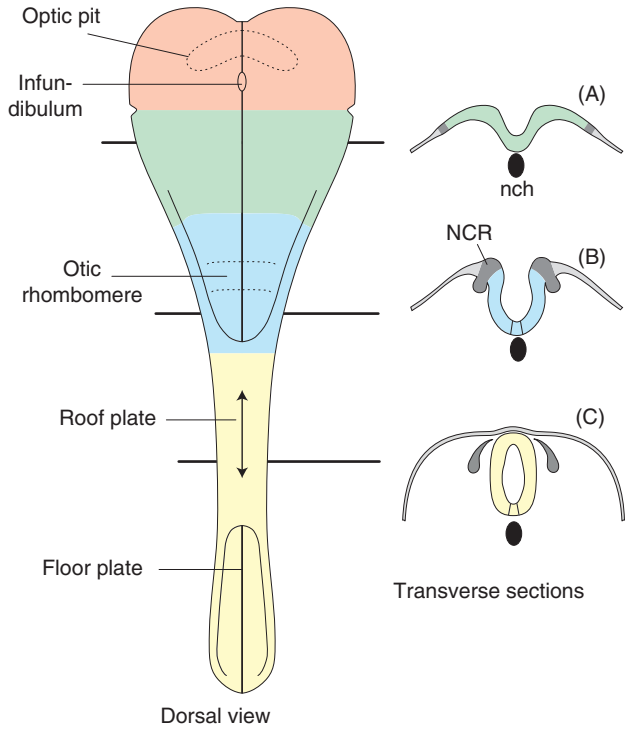

FIGURE 2.11 Optic pits, infundibulum, and otic rhombomere (dorsal view on left) are the earliest clear structural differentiations of the neural plate, other than the neural groove. The neural tube forms by neuroectoderm invagination (transverse sections A and B), followed by fusion of the lateral edges of the neural plate (roughly in the neck region of humans), and proceeds both rostrally and caudally (double arrows in roof plate). Note how the neural crest (NCR) pinches off in the process. Also observe notochord (nch) position ventral to neural groove. *Refer to Swanson (1992).*

Further Regionalization Occurs in the Neural Tube

As neurulation progresses, the neural plate becomes U-shaped as the two halves (*neural folds*) become vertically oriented (Fig. 2.11, right). Then the dorsal tips of the folds fuse, forming an open tube—and finally the tube's ends (*neuropores*) also fuse, producing a completely closed neural tube with a one-cell-thick wall (*neuroepithelium*).

Marcello Malpighi, the great seventeenth-century founder of histology, who also discovered the capillary network between arteries and veins postulated by William Harvey in 1628, recognized that the early chick neural tube displays three rostrocaudally arranged swellings now called primary brain vesicles. They include the *forebrain* (prosencephalic) vesicle, with the optic stalks and infundibulum; the *midbrain* (mesencephalic) vesicle; and the *hindbrain* (rhombencephalic) vesicle, with the otic rhombomere (Fig. 2.12A).

These vesicles are the fundamental structural or regional brain divisions. Transitory rhombomeres are the most characteristic primary hindbrain vesicle feature at this stage, and they develop in association with the pharyngeal pouches (Chapter 13). As embryogenesis continues, the forebrain vesicle divides into *endbrain* (telencephalic) and *interbrain* (diencephalic) vesicles, whereas the hindbrain vesicle becomes the *rhombicbrain*, which differentiates vaguely into two regions: rostrally the (secondary) *hindbrain* (epencephalon) and caudally the *medulla* (metencephalon); see Figure 2.12B. These divisions transform the "three primary vesicle stage" into

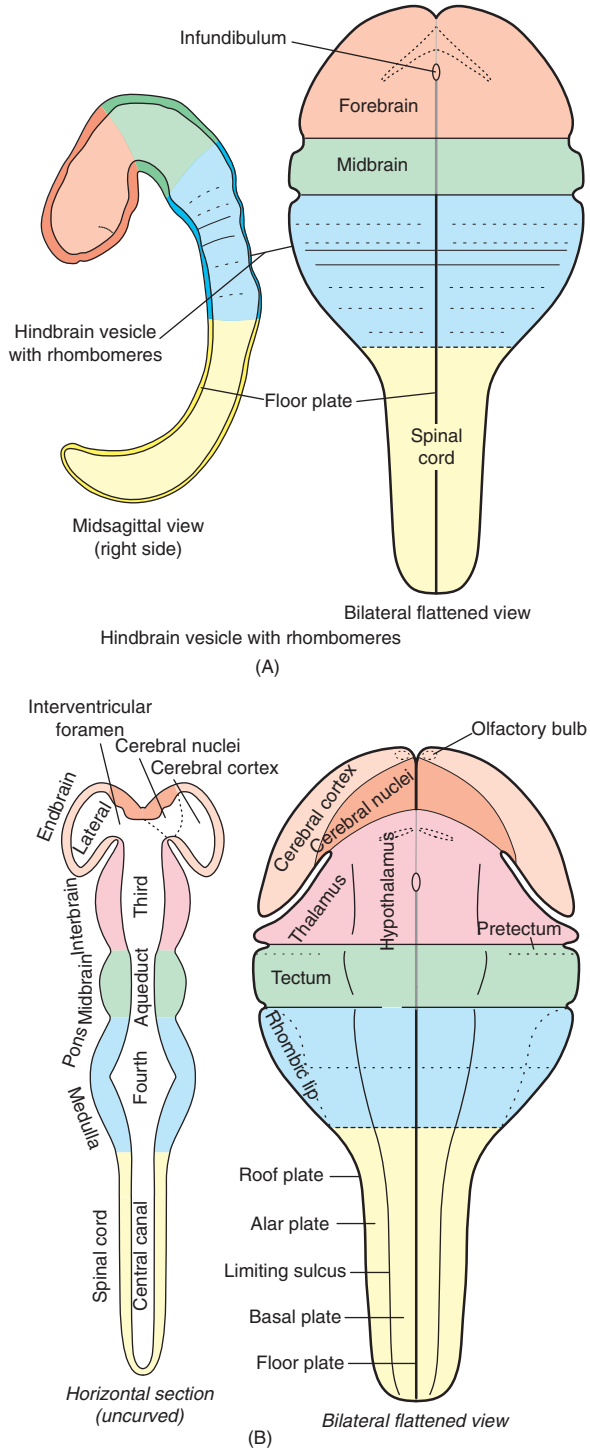

FIGURE 2.12 Formation and regionalization of the neural tube. (A) The early neural tube brain region develops three swellings: forebrain, midbrain, and hindbrain vesicles. The hindbrain vesicle then differentiates a series of transverse swellings called rhombomeres. (B) As differentiation continues, the forebrain vesicle displays right and left endbrain (cerebral hemisphere) vesicles and a medial interbrain vesicle, and the hindbrain vesicle shows vague pontine and medullary regions. This is the five-vesicle stage of neural tube transverse regionalization. Then longitudinal, dorsoventral, regionalization begins. The endbrain vesicle divides into cerebral cortex (including olfactory bulb) and cerebral nuclei (basal ganglia), the interbrain vesicle divides into thalamus and hypothalamus, the midbrain vesicle divides into tectum and tegmentum, the hindbrain vesicle becomes known as the rhombicbrain and divides into rhombic lip, alar plate, and basal plate, and the spinal cord divides into alar and basal plates. Whether the pretectal region (sometimes called synencephalon) is part of interbrain or midbrain is controversial. At this developmental stage major components of the adult ventricular system are seen in the neural tube lumen. *Refer to Swanson (1992) and Alvarez-Bolado and Swanson (1996).*

the "five secondary vesicle stage," with the hindbrain then producing a dorsal *cerebellum* and a ventral *pons*.

The neural tube lumen becomes the adult CNS *ventricular system* (Fig. 2.12B, left), and its adult shape conforms to extensive differential regionalization of the neural tube wall. Each endbrain vesicle contains a *lateral ventricle*, which communicates through an *interventricular foramen* with the *third ventricle* in the interbrain vesicle's center. The third ventricle continues into the midbrain's *cerebral aqueduct*, which becomes the rhombicbrain's *fourth ventricle* and then the spinal cord's *central canal*. In older embryos and adults, the ventricular system contains *cerebrospinal fluid* (CSF), much of which is elaborated by specialized, highly vascular regions of *choroid plexus* in the roof of the lateral, third, and fourth ventricles.

Migrating Neurons form the Mantle Layer's Gray Matter

In the early five secondary vesicle neural tube, cells divide repeatedly, although the neural tube remains one cell thick, a *pseudostratified epithelium* of stem cells for neurons and glia. Shortly thereafter many of these cells begin a terminal differentiation into young neurons migrating from the luminal proliferation zone to form a new, more superficial *mantle layer* (Chapter 16). In some CNS regions, mantle layer neurons segregate into layers parallel to the surface, whereas in other regions, neurons cluster in nuclei, relatively uniform neuron populations (usually multiple types) that are structurally distinct from surrounding nuclear or layered regions.

Mantle layer formation leads to further CNS regionalization (Fig. 2.12B). In rhombicbrain and spinal cord, it emerges because motoneurons are generated earliest and ventrally (corresponding to medial neural plate regions). This correlates with observations that gross, relatively uncoordinated embryonic motor behavior starts before reflex pathways become functional—and implying that such behavior is generated endogenously in the CNS itself (Hamburger, 1973).

Ventral mantle layer formation accompanies the transient appearance of a longitudinal groove (*limiting sulcus*) on the neural tube's inner surface. The leading nineteenth-century Swiss embryologist Wilhelm His noted that the limiting sulcus divides much of the neural tube into dorsal or *alar plate* and ventral or *basal plate*, with predominantly sensory and motor functions, respectively (Fig. 2.13). This observation complemented the earlier fundamental discovery of François Magendie that spinal sensory and motor fibers are completely segregated in spinal roots: sensory axons enter through dorsal roots, whereas motor axons leave through ventral roots. It is now clear that alar and basal plates are not

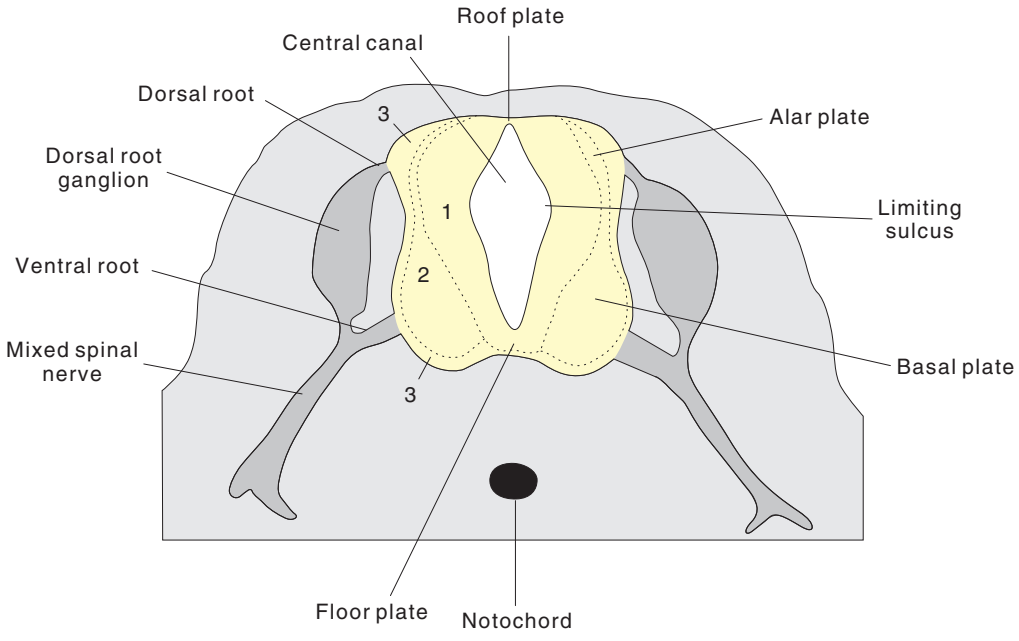

FIGURE 2.13 The early spinal cord and rhombicbrain are divided into dorsal (alar) and ventral (basal) plates by the limiting sulcus. This morphology reflects earlier ventral differentiation of the mantle layer (2), accompanied by earlier ventral thinning of the neuroepithelial or ventricular layer (1) of the neural tube, which remains as the adult ependymal lining of the ventricular system. The mantle layer develops into adult gray matter. This schematic drawing of a transverse spinal cord histological section also shows dorsal (sensory) and ventral (motor) spinal cord roots, dorsal root ganglia containing sensory neurons derived from the neural crest, and mixed (sensory and motor) spinal nerves distal to the ganglia. The peripheral area (3) is called the marginal zone and develops into the spinal cord white matter or funiculi containing ascending and descending axonal fiber tracts.

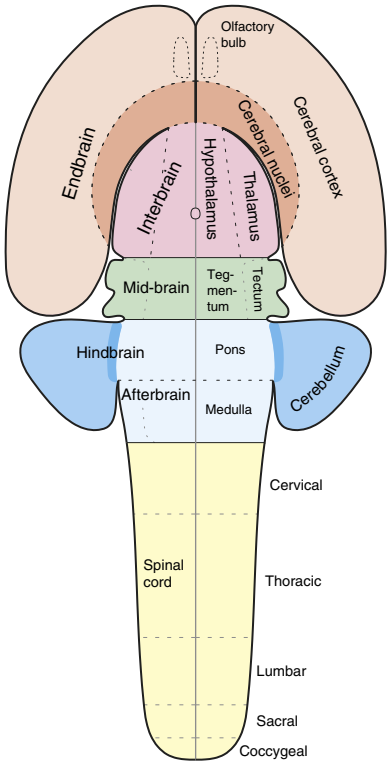

FIGURE 2.14 Major divisions of the adult mammalian CNS are derived from neural plate and neural tube regionalization illustrated in Figs. 2.10–2.12. *Modified from Swanson (1992).*

purely sensory or motor because each contains projection interneurons. Nevertheless, it is helpful to view the rhombicbrain and spinal cord as having three longitudinal zones: sensory, integrative (reticular formation), and motor. Regionalization of midbrain and forebrain does not fit this scheme neatly and is relatively poorly understood conceptually.

Dorsal regions of the rhombicbrain alar plate form a unique structure, the *rhombic lip*. In the rostral half it generates cerebellar granule cells, whereas more caudally it produces neuron populations like the precerebellar and vestibulocochlear nuclei. Many rhombic lip neuron populations are interesting because they migrate tangentially, parallel to the neural tube's surface to reach their final destinations, instead of radially (transversely) like most CNS neurons (Chapter 16). This differentiation continues until the adult CNS configuration is achieved (Figs. 2.14 and 2.15). The most obvious late-developing structures are the cerebral cortex and cerebellar cortex.

Summary

The vertebrate CNS develops from a sheet of cells called the neural plate that invaginates to form the neural tube. The tube's rostral end differentiates a series of vesicles that constitute the major brain regions, and the caudal end forms the simpler spinal cord. Most PNS neurons differentiate from the neural crest, with the rest arising from nearby somatic ectodermal placodes.

THE BASIC PLAN OF NERVOUS SYSTEM CONNECTIVITY

Functional Systems Consist of Interconnected Gray Matter Regions

The nervous system's wiring diagram can be described in terms of the neuron types in each of its distinct gray matter regions and their stereotyped pattern of axonal connections to cell types both locally (within the region) and in other gray matter regions or other tissues (like muscle or gland). A long-term goal of systems neuroscience is to provide a global wiring diagram for the nervous system that systematically accounts for its various functional subsystems—analogous to the circulatory system model provided by Harvey. Little work has been done on this synthetic problem, although interest is accelerating with the development of online neuroinformatics workbenches for connectional information (Bota & Swanson, 2010) and with plans for complete tables of nervous system connections—connectomes (Sporns, Tonono, & Kötter, 2005).

The high-level model of nervous system information processing shown in Figure 2.16 synthesizes basic neurobiological concepts pioneered by Cajal and Sherrington with basic cybernetic principles pioneered by Norbert Wiener (1948) and John von Neumann (1958). In essence, the model postulates that behavior is determined by CNS motor system output and that this output is a function of three inputs: sensory system (reflexive), cognitive system (voluntary), and intrinsic behavioral state system. The relative importance of each input in controlling motor output (behavior) varies qualitatively in different species and quantitatively in different individuals. Note that behavior elicits sensory feedback from the external and internal environments that helps determine future motor activity and thus behavior. Each component is now considered further without trying to place all nervous system parts within the global model.

Motor Systems are Organized Hierarchically

There are three different motor systems: skeletal, autonomic, and neuroendocrine. The first controls striated muscles responsible for voluntary behavior; the second controls smooth and cardiac muscle, and many glands; and the third controls pituitary gland hormone secretion. The skeletal motor system is understood best and thus serves as a prototype for examining basic organizing principles presumably similar for all three.

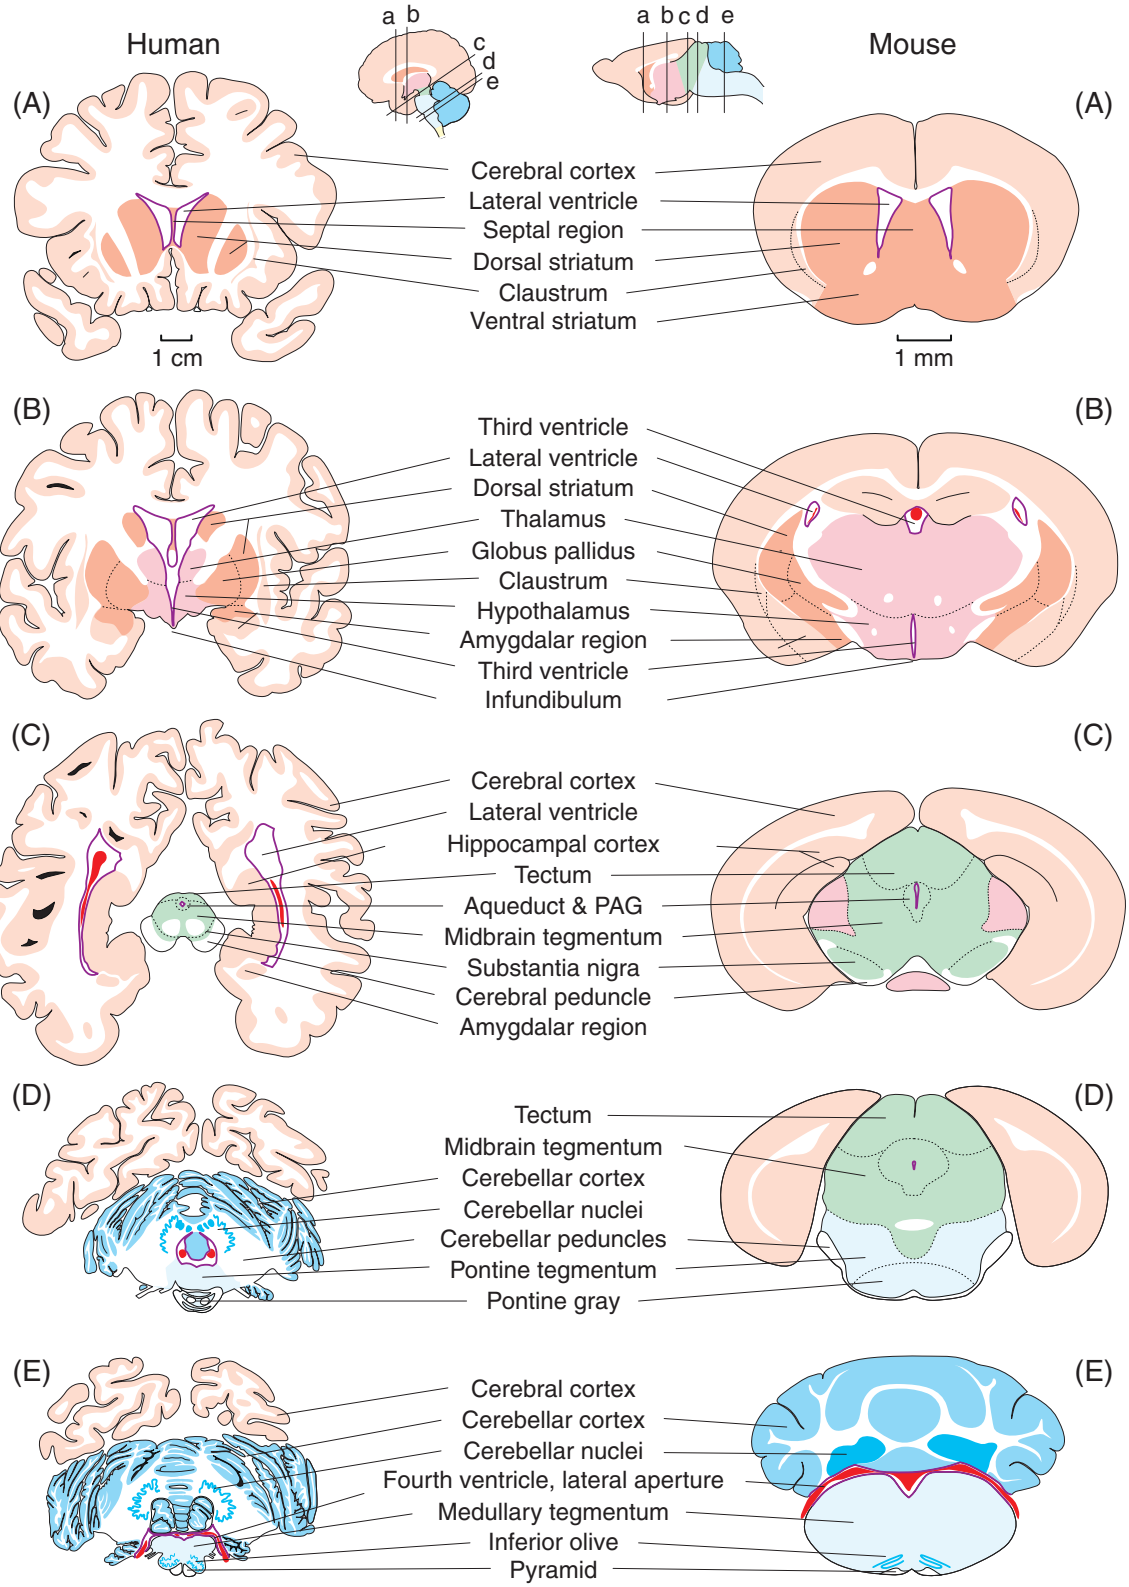

FIGURE 2.15 Mini atlases to compare major adult brain regions in humans and mice. The brains are cut approximately transversely to the CNS longitudinal axis and illustrate five major levels, arranged from rostral to caudal: a, endbrain; b, interbrain; c, midbrain; d, pons; and e, medulla. The color scheme follows that in Figs. 2.10–2.12 and 2.14, with the choroid plexus of the lateral, third, and fourth ventricles shown in red. *Adapted from Nieuwenhuys, Voogd, and Van Huijzen (1988) and Sidman, Angevine, and Webster (1971).*

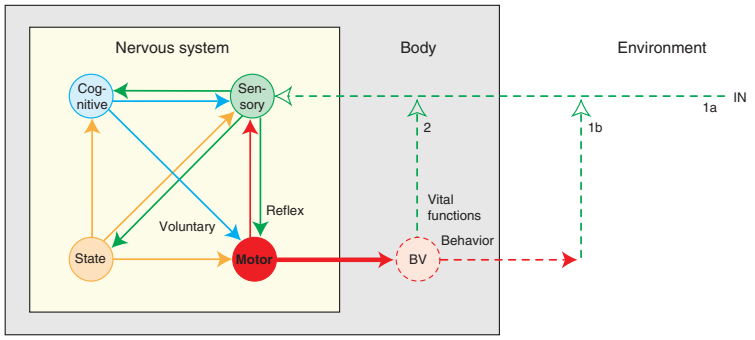

FIGURE 2.16 A model of the nervous system's basic wiring diagram. The model of information flow through the nervous system (yellow box) postulates that behavior and vital body functions are controlled by the motor system (red), which is influenced by three classes of neural input: sensory (green), intrinsic behavioral state (gold), and cognitive (blue). Sensory inputs lead directly to reflex responses, cognitive inputs mediate voluntary responses, and intrinsic inputs act as control signals to regulate behavioral state. Motor system outputs produce behaviors whose consequences are monitored by sensory feedback (1b, 2). Sensory feedback may be used by the cognitive system for perception and by the intrinsic system to generate affect (e.g., positive and negative reinforcement/pleasure and pain). The cognitive, sensory, and intrinsic systems are all strongly interconnected in the indicated pattern. *Refer to Swanson (2012).*

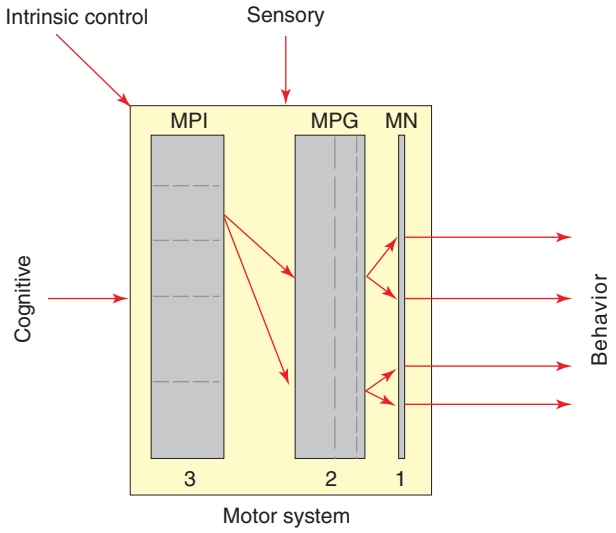

FIGURE 2.17 Hierarchical organization of the skeletal motor system. At the simplest level (1), motoneuron pools (MN) innervate individual muscles generating individual components of behavior. At the next higher level (2), additional interconnected interneuron pools, called motor pattern generators (MPG), innervate specific motoneuron pool sets. At the highest level (3), additional interconnected interneuron pools, called motor pattern initiators (MPI), innervate specific MPG sets. MPIs can activate complex, stereotyped behaviors when activated (or inhibited) by specific patterns of sensory, intrinsic, and/or cognitive inputs. Note that MPGs and MPIs themselves may be organized hierarchically (dashed lines) and that sensory, intrinsic, and cognitive inputs may go directly to any level of the motor system hierarchy. *Refer to Swanson (2012).*

The skeletal motor system is arranged hierarchically (Fig. 2.17), the lowest level consisting of brainstem-spinal cord α-motoneurons whose axons synapse directly on striated muscle fibers. The next higher level consists of motor pattern generators (MPGs), and the highest level has motor pattern initiators (MPIs) that "recognize" or alter their output in response to specific input patterns and project to unique sets of MPGs. Ethologists refer to MPIs as "innate releasing mechanisms." One reason central neural circuitry is so complex is that each of the three input types (sensory, intrinsic, cognitive) may go directly to each general level of the motor system hierarchy.

The MPGs and MPIs themselves are hierarchically arranged. This organization is particularly easy to see conceptually for the MPGs subserving locomotor behavior. In the spinal cord, simple MPGs coordinate the reciprocal innervation of muscle pair antagonists across individual joints, more complex MPGs coordinate activity in the set of simpler MPGs for all the joints in a limb, and still more complex MPGs coordinate activity in MPGs for all four limbs. At the next higher level there is a brain hierarchy of MPIs for locomotion that is activated by specific input patterns and projects to the spinal locomotor pattern generator network.

Multiple Sensory Systems Function in Parallel

A set of sensory systems provides information to the CNS from various receptor types, and all the systems can function simultaneously. Cajal noted that unimodal sensory pathways generally branch with some information going directly to the motor system and some going to the cerebral cortex for sensation and perception. The former typically evokes reflex behavior, and the latter potentially reaches consciousness and plays an important role in cognition.

Several general features characterize the sensory system (Section IV covers subsystems in detail). First, the CNS receives a wide range of information about the external environment and about the body's internal state. Thus, sensory receptors lie near the body's surface (e.g., touch and olfactory receptors), deep within the body (e.g., aortic stretch receptors), and even within

the brain itself (e.g., hypothalamic insulin receptors). Second, each of the three motor systems receives a broad range of sensory inputs. Third, the range of sensory modalities is remarkably similar (though not identical) across vertebrate classes, and information about specific modalities enters the CNS through homologous cranial and spinal nerves in all vertebrates. And fourth, the number of synapses between sensory receptor and cerebral cortex varies in different systems. There is one synapse in the olfactory system and at least four in the visual system.

The Cognitive System Generates Anticipatory Behavior

It is very likely that the cerebral cortex—along with its cerebral nuclei (basal ganglia)—is the most important, if not sole, part of the cognitive system and that the cerebral cortex is responsible for planning, prioritizing, initiating, and evaluating the consequences of voluntary behavior (Section VII). The fundamental nature of voluntary behavior is obviously a difficult problem to address, but one useful approach is simply to compare it with reflexive behavior. Interestingly, most if not all behaviors mediated by skeletal muscle can be initiated either reflexively or voluntarily, as Descartes pointed out long ago. What seems to distinguish reflexive and voluntary behaviors most clearly is that the former involves a stereotyped response to a defined stimulus, whereas the latter is anticipatory, with a duration and content impossible to predict with anywhere near the same degree of certainty.

Intrinsic Systems Control Behavioral State

The CNS generates considerable endogenous activity (action potential patterns); it is definitely not just a passive system waiting to respond to sensory input, as the behaviorist approach a century ago assumed. All CNS parts apparently have a basal activity level that can be either increased or decreased. In many cases, it is still not established whether particular neuron types generate intrinsic activity patterns. It is clear, however, that motoneurons and related MPGs do generate intrinsic activity; as already noted, the embryonic spinal cord produces motor output before sensory circuits develop. Thus, in addition to the three extrinsic input types to the motor system illustrated in Figure 2.16, intrinsic activity within the motor system itself can produce behavior that is neither reflexive nor voluntary.

Certain CNS regions generate intrinsic rhythmic activity patterns. The most important rhythmic behavioral pattern is the sleep–wake cycle that is entrained to the day-night cycle by an endogenous circadian clock, the hypothalamic suprachiasmatic nucleus (Chapters 39 and 40). The sleep–wake cycle is profoundly important because during sleep the body is maintained entirely by ongoing intrinsic and reflexive systems controlling behaviors like respiration and sustained sphincter contractions. In contrast, voluntary mechanisms dominate in wakefulness though reflexive and intrinsic mechanisms are also vitally important then.

Behavioral state control is thus a fundamental intrinsic brain activity. Another aspect of behavioral state—arousal—is especially important during wakefulness. Arousal level generally is correlated with an animal's motivational state or drive level (Chapter 41). The neural system mediating drive is not fully elucidated but is critically dependent on the hypothalamus, and attainment of specific goal objects (foraging behavior) depends on the cognitive system. Arousal and drive may be controlled by subcortical systems but behavior's actual direction and prioritization mainly is determined cortically.

The full identity of neural systems elaborating pleasure and pain is one of neuroscience's deep mysteries. Many regard pleasure and pain as conscious expressions of positive and negative reinforcement, influencing how likely a particular voluntary behavior will be repeated or avoided in the future. Here, reinforcement depends on sensory feedback about a particular behavior's consequences (Fig. 2.16), and one suggestion is that pleasurable and painful sensations, like those associated with drive, are elaborated subcortically within intrinsic control systems. According to this view, thinking or cognition arises in cerebral cortex, whereas feeling or affect arises subcortically. It is also possible that all aspects of consciousness (thinking and feeling) arise only from cortical neural activity (Chapter 51).

How Pharmacological and Genetic Networks Relate to Functional Systems

Specific neurotransmitter systems have been incorporated into models of CNS function since the 1950s. Two examples are cholinergic and noradrenergic systems, defined as the total sets of CNS neurons releasing acetylcholine or noradrenalin, respectively, as a neurotransmitter (Chapter 5). In general, these systems are not obviously correlated with traditional CNS functional systems or major topographic parts; typically they are not restricted to one functional system or one major CNS division, though some exceptions may exist. Thus, neurotransmitter systems are not functional systems in the traditional sense. However, they are conceptually or operationally important in helping define networks or functional systems influenced by particular drug actions. For example, administering centrally acting acetylcholine receptor agonists influences synapses in a variety of traditional *functional systems*, and the set of these functional systems could be defined as a *pharmacological system* with a specific set of behavioral and other

responses. If a drug is targeted for therapeutic reasons to a specific neural system (e.g., a cholinergic agonist targeted to the cerebral cholinergic system in Alzheimer's disease; Chapter 43), it will also act on other functional systems with appropriate cholinergic receptors (e.g., in the thalamus and lower brainstem). Responses in these other systems produce "side effects" that may be good or bad.

Likewise, any gene product's distribution pattern can also be used to define a chemical, molecular, or neural *gene expression system*. For example, a system could be defined in terms of all neurons expressing the calbindin or μ-opioid receptor gene, and expression of the corresponding gene might be prevented or altered in experimental knockout mice or natural mutations in genetic diseases. These alterations may produce an obvious and stereotyped phenotype or syndrome, but in most instances the gene normally is expressed in multiple functional systems and has complex (even if subtle) physiological and behavioral effects.

Finally, it is important to remember that a genetic program constructs the nervous system's basic *macrocircuitry* during embryogenesis. Determining the correspondence between gene expression networks and neural networks may be the ultimate achievement of systems neuroscience. The nervous system's *microcircuitry*—quantitative aspects of synapse number and strength associated with individual neurons—may be sculpted by experience throughout life.

Summary

There is no simple relationship between the CNS's topographic or regional differentiation and its functional organization. So it is mistaken to assume *a priori* that CNS information simply is processed hierarchically with the spinal cord at the lowest level and the cerebral cortex at the top. An alternative view is that the CNS displays a network rather than hierarchical organization scheme—a circuit where the motor system is driven by sensory, cognitive, and intrinsic behavioral state inputs, and future motor activity is determined partly by sensory feedback about the initial behavior's consequences.

Two major features complicate this simple network model. First, the motor system itself is organized hierarchically, whereas the sensory system transmits multiple modalities in parallel, and this sensory information can reach directly each level of the motor system hierarchy. And second, sensory information also reaches the intrinsic and cognitive systems. In fact, all three input systems are interconnected in a genetically determined pattern. The basic plan of neural circuit architecture must be understood on its own terms, not through simple preconceived ideas or superficial analogies with computers, the Internet, irrigation systems, or complicated robots. How traditional CNS functional systems relate to pharmacological systems and genetic networks remains to be determined.

OVERVIEW OF THE ADULT MAMMALIAN NERVOUS SYSTEM

This section reviews structural neuroscience methods used to achieve our current—still very incomplete—understanding of nervous system architectural principles and introduces the major nervous system components. Long experience teaches that nothing approaches actual dissection for gaining an appreciation of overall brain structure.

A Brief History of Structural Neuroscience Methods

The human brain's macroscopic structure was observed by early Greek physician-philosophers and thoroughly understood by the early 1800s. However, its circuitry's astounding complexity was not appreciated until microscopy effectively identified individual pathways (axon bundles) and neuronal regions (distinguishable neuronal cell body aggregates) toward the end of the 1800s—applying to thin CNS tissue sections neurohistological reagents and reactions developed by the textile and photographic industries (Swanson, 2000b).

Perhaps the single most enduring contribution of nineteenth-century neurohistology was Camillo Golgi's 1873 silver impregnation method. The full morphology of individual neurons was visible for the first time (Fig. 2.18; Boxes 2.1 and 2.2)—their dendritic tree, cell body shape, axon and all its collaterals, and points of presumed functional contact with other cells, which Sherrington named "synapses" in 1897. The Golgi method involves impregnating brain tissue alternately in potassium dichromate and silver nitrate solutions over periods of weeks to years, and mysteriously (the reaction's chemistry remains elusive) about 1% of the neurons are filled (apparently randomly) with a dense precipitate. The Golgi stain thus reveals more by staining less. Today, selective labeling of individual neurons also is achieved by injecting markers directly into living neurons with micropipettes, allowing simultaneous electrophysiological and cytoplasm analysis.

Unfortunately, Golgi's method provided little information about longer CNS connections: axonal projections between nonadjacent regions. This was approached with methods selectively staining fibers degenerating from pathological or experimental lesions. Augustus Waller showed (1850) that nerve transection causes the nerve's distal segment to degenerate (Wallerian, anterograde degeneration), inspiring his proposal that the cell body is

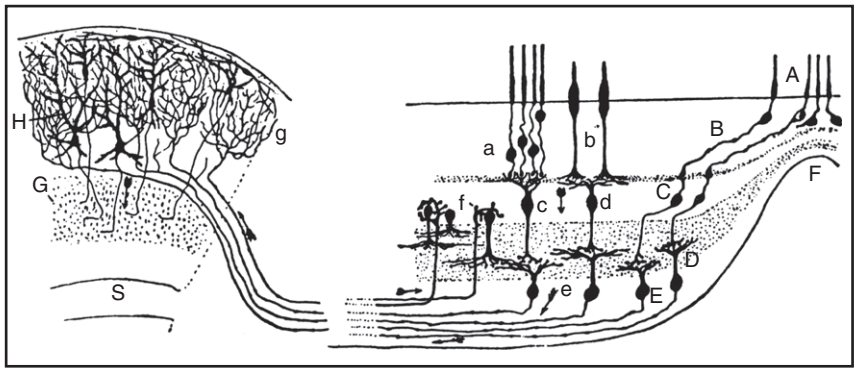

FIGURE 2.18 Cajal's (1909–1911) neural architecture drawing based on the Golgi method. It shows the organization of four major retinal neuron types (right) and connections between two gray matter regions: retina to optic tectum (superior colliculus; left). Applying the neuron doctrine and functional polarity rule (Boxes 2.1 and 2.2) to the entire vertebrate nervous system by Cajal and many other researchers a century ago led to the "classical" way neuron types defining each gray matter region have been described structurally ever since, a view beautifully illustrated here. Three major neuron types tend to populate specific retinal layers: photoreceptors (subtypes a, b, A, B), bipolar cells (subtypes c, d), and ganglion cells (subtypes e, D, E). A specific neuron type's cardinal feature is its axon's distribution—the neuron's function in terms of output. Photoreceptors detect light and their axon innervates bipolar cells. The latter in turn innervate ganglion cells whose axon projects through the optic nerve to the tectum. Photoreceptors are classical sensory neurons (Fig. 2.3), bipolar cells are local interneurons, and ganglion cells are projection interneurons. Also note a second retinal local interneuron class, amacrine cells (f). Cajal pointed out that retinal neuronal cell bodies aggregate in three layers with synaptic neuropil zones in between, and illustrated a clear structural gradient—reflecting a foveal region (F) with greater visual acuity because of multiple structural features, some of which are obvious in the drawing. The power of Cajal's functional polarity theory is evident: he drew arrows to indicate the presumed normal direction of information flow through the network, based on the sequential arrangement of dendrites and axons associated with each neuron type.

the nerve cell's "trophic center," which the axon depends on for survival. Thirty years later Bernard von Gudden showed that Wallerian degeneration may be accompanied by pathological changes in the cell body when its axon is cut, suggesting retrograde transport of "trophic factors" from axon to cell body.

Marchi and Algeri developed the first method to stain selectively central pathways (1885), revealing degenerating myelin sheaths of severed axons as black particles on a light background—effectively isolating degenerating from healthy sheaths in tissue sections. Anatomists could produce discrete CNS lesions in experimental animals and after several weeks trace the course of neural pathways arising in the lesioned site. The method was severely limited, however, because unmyelinated or thinly myelinated axons, and terminal fields, were unlabeled, and there were many "false-positive" results from transecting fibers simply passing through the lesion (the "fiber-of-passage" problem common to many experimental methods).

By the 1950s selective silver impregnation and degeneration methods were combined by Walle J.H. Nauta and colleagues to stain unmyelinated axons and their terminal fields. The CNS was remapped at finer resolution with these methods, which still suffered from the fiber-of-passage problem (false-positive results) and were not nearly as sensitive (false-negative results) as the next generation of methods developed around 1970. Instead of relying on lesion-induced pathology the latter (current) are based on a combination of (1) physiological mechanisms (anterograde and retrograde intraaxonal marker transport) in healthy neurons and (2) histochemical detection of antibodies and complementary nucleic acid strands.

Also in the 1950s, the electron microscope opened a whole world of ultrastructure previously only guessed at. It provided the first glimpses of synapse structure (with a typical cleft only about 20 nm wide, far below the 1 mm resolution of light microscopes, and presynaptic vesicles), myelin sheath organization, and many cellular organelles. It also allowed biologists to examine in detail the biosynthetic apparatus residing within each cell.

These methods provide far more detail about CNS connectivity patterns or circuit organization than ever before in many species. As a result, comparative neuroanatomy has flourished and forms a solid structural foundation on which contemporary physiological and behavioral studies are based (Luo, Callaway, & Svoboda, 2008).

The PNS has Sensorimotor and Autonomic Divisions

Overall, the nervous system is divided into CNS (brain and spinal cord) and PNS (nerves, ganglia, and related plexuses). However, this CNS–PNS distinction is just a gross anatomical convenience that ignores circuit organization because nerves contain axons from neuronal cell bodies in both CNS and peripheral ganglia.

Functionally, the PNS has (1) a sensory ganglion component with accompanying dorsal and ventral roots and functionally mixed nerves, (2) the autonomic nervous system's (ANS) motor ganglia and communicating roots, and (3) plexuses (literally "braids"). The sensory part has dorsal root ganglia sensory neurons with one extension (embryologically and phylogenetically an axon) entering the CNS through dorsal roots and the other extension (embryologically and phylogenetically a dendrite) traversing peripheral nerves to sites throughout the body. However, peripheral nerves also contain axons of skeletal motoneurons with cell bodies in spinal cord and brainstem; for spinal nerves the axon's initial part traverses a ventral root. Thus, most peripheral nerves carry *afferent* ("sensory") information toward the CNS and *efferent* (motor) information toward the body (Fig. 2.13). Sensory neurons carry afferent information from receptors in skin, skeletal muscles, tendons, joints, blood vessels, and deep viscera. The autonomic nervous system has a network of efferent pathways, ganglia, and nerve nets (plexuses) controlling gut peristalsis, glandular secretions, blood vessel diameter, and other visceral functions—and their output is modulated by both somatic and visceral afferents. Thus, a typical peripheral nerve carries a mixture of afferents and efferents innervating body wall and viscera.

Somatic afferents distribute near the body surface in a pattern reflecting the body wall's segmental origins: each spinal nerve innervates a narrow mediolateral band of skin called a *dermatome* (Fig. 25.9), although adjacent nerves innervate overlapping territories (otherwise single nerve interruption would produce complete sensation loss in a band of skin, which is not the case). The segmental dermatome pattern is obvious in the torso where very little differential body wall growth occurs, whereas limb dermatomes are distorted because they form before the limbs grow out fully in the embryo.

Peripheral nerves often ramify and join with nerves from other segments to form *nerve plexuses* that serve as crossroads and distribution centers for the nerves, allowing axons to reorganize into complex nerve bundles innervating body structures. Brachial and lumbosacral plexuses near the origins of the upper and lower limbs, respectively, are the largest examples of these enigmatic structures that also provide great mechanical strength to nerves passing through the shoulders and hips, which may undergo extreme rotation and stretching. The ANS also has a bewildering variety of *ganglionated plexuses* in the abdomen and pelvis, where nerves converge and redistribute axons to their target organs and where individual neurons and/or clumps of autonomic neurons are found.

The ANS has structural and functional *sympathetic* and *parasympathetic* divisions (Chapter 34). The two divisions function in a kind of push-pull relationship with each other. One or the other is never completely on or off. Instead, there are degrees of sympathetic and parasympathetic tone. During sleep, certain involuntary functions like digestion are accelerated. Glands participating in digestion are activated parasympathetically and sympathetic tone is correspondingly decreased. In contrast, Walter B. Cannon noted almost a century ago that during the "fight or flight" reaction characterizing defensive behavior, sympathetic tone is markedly enhanced and parasympathetic tone is reduced sharply. Sympathetic outflow is vastly amplified and coordinated through a set of ganglia and the adrenal medulla, so that sympathetic function occurs relatively synchronously throughout the body. In contrast, the parasympathetic system is relatively finely tuned.

The Cerebrospinal Trunk Generates Cranial and Spinal Nerves

From a more systematic perspective on nervous system organization, the spinal cord and brainstem (together the cerebrospinal trunk) generate a continuous series of spinal and cranial nerves, respectively. The human spinal cord, roughly as thick as an adult's little finger, is ultimately surrounded and protected by the vertebral column, whereas the cranial part of the skull protects the brain. In cross section, the spinal cord's two basic types of nervous tissue are obvious: *gray matter* and *white matter*. Gray matter forms an H-shaped region surrounding the central canal (the ventricular system's spinal segment) and consists mainly of neuronal cell bodies and neuropil. White matter surrounds gray matter in the spinal cord and consists mostly of axons collected into overlapping fiber bundles. Many axons have a myelin sheath, a uniquely vertebrate feature allowing rapid nerve impulse conduction (Chapter 4) and giving white matter its pale appearance.

The spinal cord looks segmented because bilateral pairs of dorsal and ventral roots emerge regularly along its length. These pairs form five sets: cervical (in the neck above the rib cage), thoracic (associated with the rib cage), lumbar (near the abdomen), sacral (near the pelvis), and coccygeal (associated with tail vertebrae). In humans there are typically 31 spinal nerve pairs (8 cervical, 12 thoracic, 5 lumbar, 5 sacral, and 1 coccygeal) that are named according to the intervertebral foramen they pass through. This enumeration varies between species.

Based on human brain macroscopic dissection, Samuel Thomas von Sömmerring in 1778 recognized a sequence of 12 cranial nerve pairs, and his basic classification scheme remains traditional for vertebrates in general, although it is problematic in terms of completeness (e.g., not including the nasal cavity's terminal nerve) and nonconformance with contemporary fate maps of cranial nerve nucleus development (e.g., motoneurons

for nerve VII are generated rostral to those for nerve VI). In any event, cranial nerves are more heterogeneous functionally than spinal nerves, and indeed most cranial nerve pairs have distinct compositions in terms of functional fiber types.

In humans (Fig. 2.19), seven cranial nerves transmit information about the so-called special senses associated with the head: olfaction (I, olfactory nerve—purely sensory, arising in nasal olfactory epithelium), vision (II, optic nerve from retina), hearing and balance (VIII, vestibulocochlear nerve from inner ear), and taste (V, VII, IX, and X; parts of the trigeminal, facial, glossopharyngeal, and vagus nerves, respectively). Nerves III (oculomotor), IV (trochlear), and VI (abducens) primarily control conjugate eye movements, although the third nerve also mediates autonomic control of the pupillary light reflex and lens accommodation. Major parts of the trigeminal (V) nerve carry sensory axons from the face (a rostral extension of the spinal somatosensory system) and motor axons innervating the muscles of mastication (chewing). The intermediofacial (VII) nerve controls the muscles of facial expression (facial nerve) and also innervates the salivary and lacrimal glands (intermediate nerve, VII′)—its role in emotional expression is obvious. The glossopharyngeal (IX) nerve innervates the tongue and pharynx and mediates the swallowing reflex. The vagus ("wandering," X) nerve has an exceptionally complex and widespread innervation pattern, including laryngeal muscles producing speech, and the parasympathetic innervation of most thoracic and abdominal viscera. The accessory (XI) nerve innervates several muscles that stabilize the head and neck and the hypoglossal (XII) nerve innervates the tongue musculature.

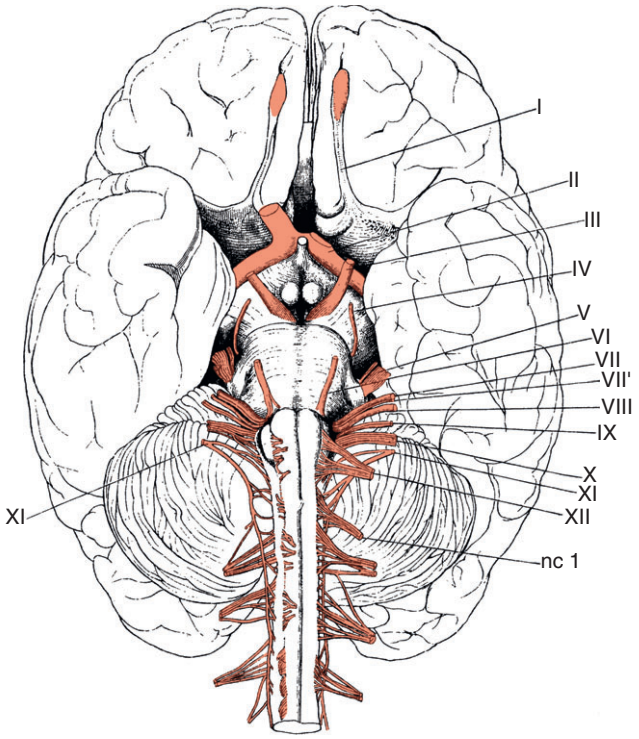

FIGURE 2.19 Origins of the cranial nerves viewed from the base of the adult human brain. The traditional numbering system dating back to the eighteenth century is indicated, but does not consider the terminal and accessory olfactory nerves. I, indicates the olfactory peduncle, with the olfactory bulb at the end shaded pink to indicate the termination site of the olfactory nerve; II, the optic tract leading from the optic chiasm to the thalamus and superior colliculus, with the stump of the right optic nerve indicated but the left optic nerve cut off at the chiasm; III, oculomotor nerve; IV, trochlear nerve, which courses around the side of the cerebral peduncle from the dorsal surface of the brainstem; V, trigeminal nerve; VI, abducens nerve; VII, facial nerve component of intermediofacial nerve; VII′, intermediate nerve component of intermediofacial nerve; VIII, vestibulocochlear nerve; IX, glossopharyngeal nerve; X, vagus nerve; XI, accessory nerve, with cranial and spinal roots; and XII, hypoglossal nerve; nc I, first cervical spinal nerve with the second through fourth also shown arising more caudally from the spinal cord. Cranial nerves exit through holes in the cranium whereas spinal nerves exit between the vertebrae (the first cranial nerve exits between the cranium and first vertebra). *Adapted from Henle (1871).*

Cerebral Hemispheres and Cerebellum are Divided into Cortex and Nuclei

Macroscopically the mammalian cerebrospinal trunk has two great expansions—the cerebral hemispheres and cerebellum—and both have an outer laminated cortex surrounding deep nonlaminated nuclei. The most extraordinary growth of the mammalian brain occurs in the endbrain or cerebral hemispheres (Fig. 2.20), which develop more or less as mirror images of one another and are separated in the dorsal midline by a deep interhemispheric (longitudinal) fissure. In humans, the sulcal pattern is, however, asymmetric and unique in each person, and there are functional asymmetries as well; for example, the speech centers typically are lateralized (Chapter 49). Hemisphere volume is restricted by skull capacity, so as the hemispheres grow during embryogenesis they develop folds (*gyri*) separated by invaginations (*sulci*, and when deeper, *fissures*). This corrugation allows cerebral (and cerebellar) cortex to have a larger surface area. The extent and pattern of folding vary stereotypically with species, although like any trait there are quantitative differences between individuals of a particular species. Two major grooves, the central sulcus and lateral (Sylvian) fissure, are used as anatomical landmarks in the human cerebrum. The central sulcus extends roughly vertically along the hemisphere's lateral surface where it approaches the horizontally oriented lateral fissure. Together they divide arbitrarily the lateral cerebral cortical surface into four lobes (*frontal*, *parietal*, *occipital*, and *temporal*), named for the overlying cranial bones. In addition, the *insular lobe* is folded completely inside the hemisphere, deep to the lateral fissure (actually about two-thirds of the folded cortical surface lies buried and unexposed to the outer hemisphere surface), and

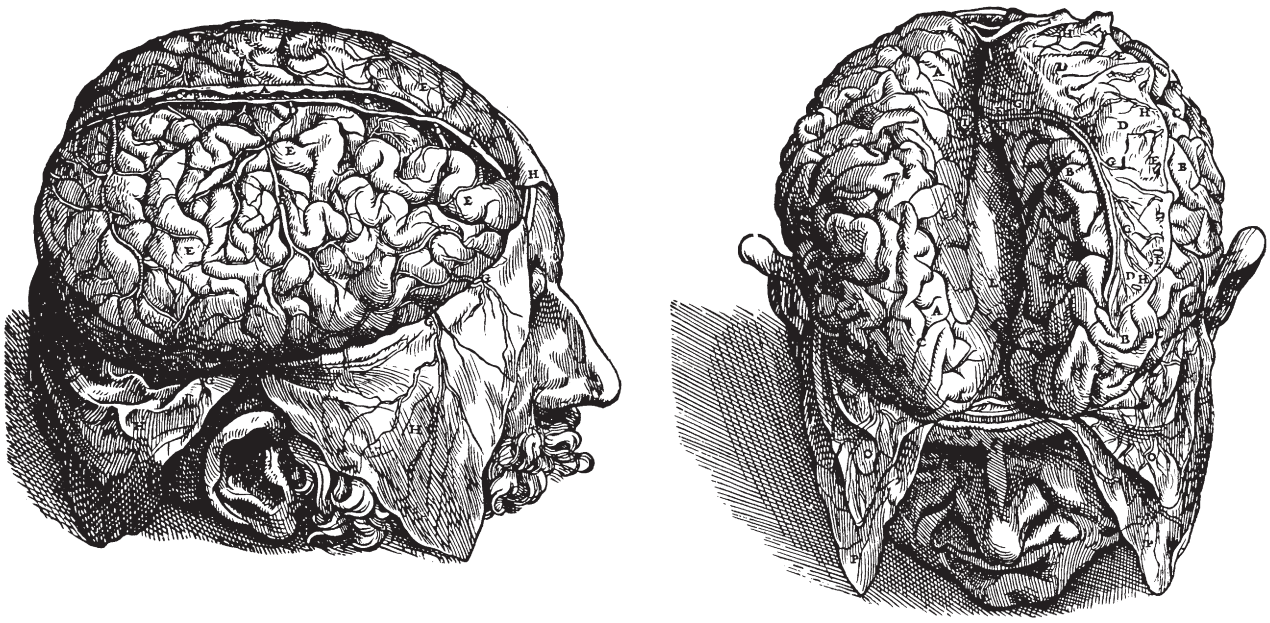

FIGURE 2.20 Surface features of the human cerebral cortex, which is thrown into gyri separated by sulci. In the drawing on the right, the right and left hemispheres have been pulled apart at the interhemispheric or longitudinal fissure to reveal a white matter tract, the corpus callosum (L), interconnecting the two hemispheres. The drawings are from perhaps the most important book in the history of medicine by Andreas Vesalius, *Fabric of the Human Body*, published in 1543. The drawings were probably executed by an artist from Titian's studio. See Singer (1952).

the *limbic lobe* forms the hemisphere's medial border along the interhemispheric fissure.

These lobes are only crude guides to the cerebrum's functional organization. Over the last 150 years, progressively better analysis has parceled the cortical mantle into a mosaic of roughly 50 to 100 areas with more or less distinct structural and functional characteristics. The most famous and enduring cortical *regionalization maps* were generated by Korbinian Brodmann a century ago (Fig. 2.21), although refinements and alternative interpretations abound. Nevertheless, cortical regionalization maps are fundamentally important guides for understanding CNS architecture. Just as one example, virtually the entire thalamus projects topographically on the cortical mantle, which in turn projects topographically on the entire cerebral nuclei (basal ganglia). Information from every sensory modality reaches the cerebral cortex and it in turn sends inputs to virtually the entire motor system.

Most cerebral cortical areas directly modulate activity on the opposite (contralateral) side of the body through descending pathways that cross the midline to reach motor system parts in the contralateral CNS. Furthermore, axon bundles called *commissures* connect cerebral cortical areas of one hemisphere with the same or related areas of the opposite hemisphere—and different areas in the same hemisphere are interconnected through complex *association pathways*. Thus, commissural and association pathways allow comparison and integration of information between cortical areas within and between the cerebral hemispheres. Descending, commissural, and association connections tend to arise from different sets of pyramidal neurons, which helps explain the highly laminated organization of the cerebral cortex: descending connections arise mostly from the deep layers 5 and 6, commissural connections from layer 3, and association connections from layer 2.

Communication between hemispheres is eliminated by commissurotomy, the surgical division of all cerebral commissures (including the hippocampal and anterior commissures). This procedure sometimes is used to treat otherwise intractable epilepsy cases, preventing spread of severe epileptic activity from one hemisphere to the other. Incredibly, commissurotomy patients function very well most of the time, and behavioral studies on such "split brain" patients have yielded remarkable information about cerebral cortical organization (Gazzaniga, 2005). Axon bundles (tracts or pathways) connecting very different structures on the two sides of the CNS usually are called *decussations* to distinguish them from commissures.

The Nervous System is Protected by Membranous Coverings

The CNS is completely surrounded by three concentric connective tissue membranes: *pia*, *arachnoid*, and *dura*. The pia ("faithful") is a very thin layer that adheres

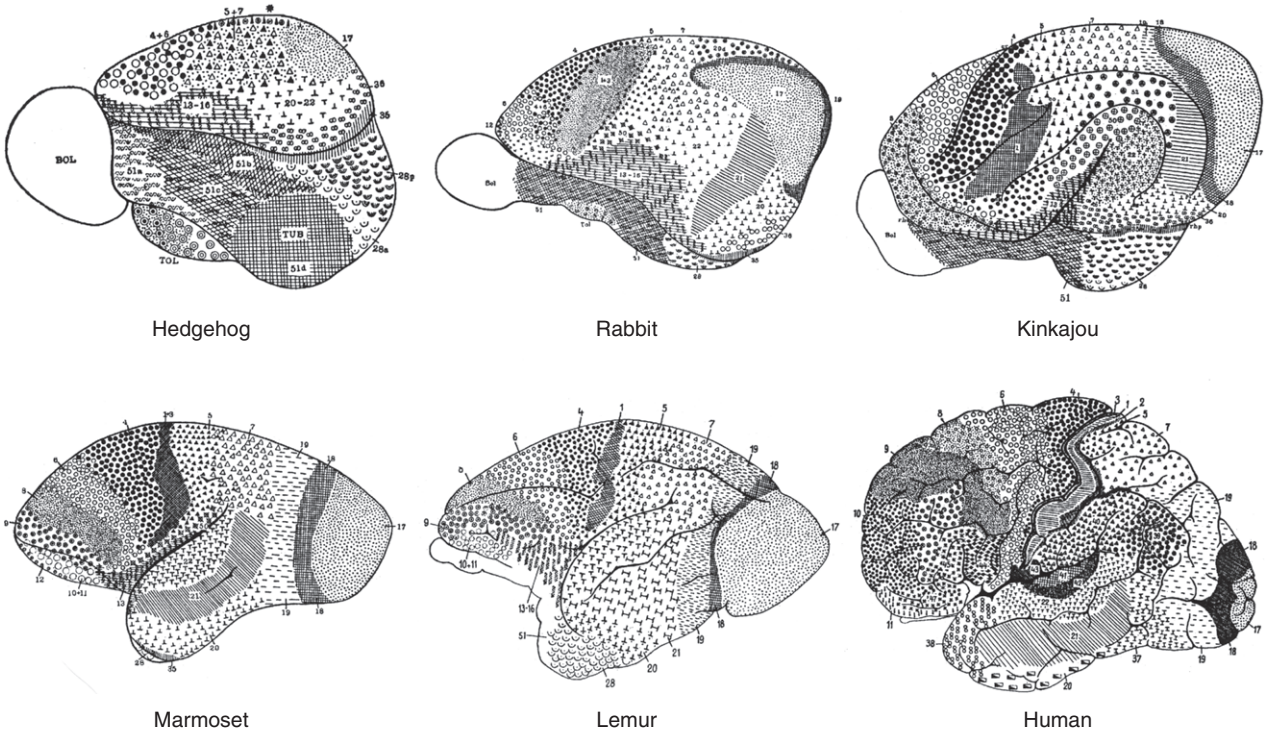

FIGURE 2.21 A similar cerebral cortical regionalization plan for mammals was proposed by Korbinian Brodmann in 1909. His cortical parceling was based on regional differences in how neuronal cell bodies tend to distribute in layers, an approach referred to as cytoarchitectonics. This figure summarizes his findings in six species, with different regions, or "areas," as he called them, indicated with different symbols and numbers. He distinguished 47 areas in the human cerebral cortex and showed that generally similar patterns applied to all nine species he analyzed.

closely to the CNS's surface, even where there are deep invaginations, as in the cerebral and cerebellar cortex. Then comes the arachnoid ("spidery"), which has a tenuous, web-like structure but is histologically similar to pia. Finally, the dura ("tough") is a thick, inelastic covering apposed to the skull and vertebral canal's inner surface (Fig. 2.20*H,O,P*). Membranes covering the CNS are continuous with similar coverings of the PNS, where the terminology differs.

In certain CNS regions neural tissue is absent but meninges persist. Here, ependymal cells lining the ventricular system (the monolayer vestige of the embryonic neuroepithelial layer that ends up lining the adult ventricular system) fuse with the pia and arachnoid layers to form structures known as *choroid plexus*, which contains abundant blood vessels and serves as a component of the blood–brain barrier (the blood–CSF barrier; see Chapter 3). The choroid plexus produces CSF in the roof of the lateral, third, and fourth ventricles, and this fluid fills the brain ventricles, and perhaps at least part of the spinal central canal. Under positive hydrostatic pressure, CSF passes out of the brain's interior through three foramina (holes) in the fourth ventricle's roof, to fill the subarachnoid space between pia and arachnoid.

The Brain is Highly Vascular

The human brain consumes about 20% of the body's oxygen supply at rest, even though it usually weighs only about a kilogram. Thus, the brain must continuously receive a voluminous blood supply, on the order of a liter per minute. Blood reaches the brain through two arterial roots—*vertebral* and *internal carotid arteries*—that anastomose in the circle of Willis, which essentially surrounds the base of the hypothalamus and pituitary gland's stalk. The functional importance of this arterial circle cannot be overemphasized because afterward there is a drastic reduction in anastomoses between major arteries within brain tissue itself. As a result, blockage or rupture of an artery rapidly deprives the supplied brain region of oxygen, causing a *stroke* or brain attack.

After entering the skull through the foramen magnum with the spinal cord, the paired vertebral arteries fuse into a single *basilar artery*, generating the cerebellar arteries and the posterior cerebral arteries, which supply occipital cerebral regions. The internal carotid arteries divide to form the anterior and middle cerebral arteries; the former supplies each hemisphere's medial surface (especially the limbic lobe), and the latter supplies the rest of the hemisphere (including the speech and somatic sensorimotor areas).

By and large, the major arteries course along the cerebral surface and branches dive perpendicularly into the brain and proliferate into arterioles and capillaries.

A system of large *venous sinuses* collect blood from brain capillaries, and CSF from the subarachnoid space, and return them to the heart, mostly via the paired *internal jugular veins*. The major venous sinuses lie within the dura, whose inelasticity essentially holds the sinuses open. Blood flow through sinuses is slow and under low hydrostatic pressure. Thin-walled venous sinuses surrounded by the tough and immovable dura sets the stage for serious injury when the head is subjected to physical trauma. A well-known example is traumatic injury to the great cerebral vein (of Galen) in the midline that can occur when a boxer is struck in the head. The blow's impact causes the brain to recoil in its CSF cushion, exerting a shearing force against the dura, which remains attached to the skull. This force may rupture the great cerebral vein, leading to serious hemorrhage of venous blood into the subdural space between dura and arachnoid.

Summary

This chapter reviews common approaches to the problem of understanding the nervous system's fundamental structure and wiring diagram—the basic plan or architecture. One approach examines a series of increasingly complex animals from an evolutionary perspective to gain insight into basic organizing principles. It reveals trends toward centralization, cephalization, bilateral symmetry, and regionalization of the nervous system. It also suggests that basic molecular and cellular mechanisms of neuronal function, including electrical signal propagation and neurotransmitter release, have changed little since the appearance of the simplest nervous systems in hydra, jellyfish, and other cnidarians.

Another approach follows the vertebrate nervous system's development from embryo to adult. At early developmental stages the CNS of all vertebrates has the same basic structure. A polarized, bilaterally symmetrical, regionalized neural plate of ectodermal origin invaginates to form a neural tube whose rostral half presents three swellings (forebrain, midbrain, and then hindbrain), followed by a caudal presumptive spinal cord. These four basic CNS divisions, arranged from rostral to caudal, go on to subdivide repeatedly until all laminated and nuclear neuron groups (regions) of the adult CNS are formed. A topographic, "geographic," or regional account of the CNS emerges from this developmental approach.

How the CNS's functional systems or circuitry are arranged into a unified whole is a tantalizing, deep, unsolved problem. The model discussed here equates behavior with motor output, which is driven by a combination of sensory, intrinsic behavioral state, and cognitive inputs—as well as by endogenous neuronal activity within each system. Future behavior is determined partly by sensory feedback related to the original behavior's consequences. As this is written, the relationship between CNS macroregionalization (Figs. 2.14 and 2.15) and functional systems (Fig. 2.16) is not obvious. The correspondence between functional neural systems and gene expression networks is even more obscure, although promising results are beginning to emerge in the embryonic spinal cord and brainstem cranial nerve nuclei.

CELLULAR AND MOLECULAR NEUROSCIENCE

CHAPTER

3

Cellular Components of Nervous Tissue

Several types of cellular elements are integrated to constitute normally functioning brain tissue. The neuron is the communicating cell, and many neuronal subtypes are connected to one another via complex circuitries, usually involving multiple synaptic connections. Neuronal physiology is supported and maintained by neuroglial cells, which have highly diverse and incompletely understood functions. These include myelination, secretion of trophic factors, maintenance of the extracellular milieu, and scavenging of molecular and cellular debris from it. Neuroglial cells also participate in the formation and maintenance of the blood–brain barrier, a multicomponent structure that is interposed between the circulatory system and the brain substance and that serves as the molecular gateway to brain tissue.

NEURONS

The neuron is a highly specialized cell type and is the essential cellular element in the CNS. All neurological processes are dependent on complex cell–cell interactions among single neurons as well as groups of related neurons. Neurons can be categorized according to their size, shape, neurochemical characteristics, location, and connectivity, which are important determinants of that particular functional role of the neuron in the brain. More importantly, neurons form circuits, and these circuits constitute the structural basis for brain function. *Macrocircuits* involve a population of neurons projecting from one brain region to another region, and *microcircuits* reflect the local cell–cell interactions within a brain region. Detailed analysis of these macro- and microcircuits is essential for understanding neuronal function and dysfunction in the healthy and the diseased brain.

Broadly speaking, therefore, there are five general categories of neurons: inhibitory neurons that make local contacts (e.g., GABAergic interneurons in the cerebral and cerebellar cortex), inhibitory neurons that make distant contacts (e.g., medium spiny neurons of the basal ganglia or Purkinje cells of the cerebellar cortex), excitatory neurons that make local contacts (e.g., spiny stellate cells of the cerebral cortex), excitatory neurons that make distant contacts (e.g., pyramidal neurons in the cerebral cortex), and neuromodulatory neurons that influence neurotransmission, often at large distances. Within these general classes, the structural variation of neurons is systematic, and careful analyses of the anatomic features of neurons have led to various categorizations and to the development of the concept of cell type. The grouping of neurons into descriptive cell types (such as chandelier, double bouquet, or bipolar cells) allows the analysis of populations of neurons and the linking of specified cellular characteristics with certain functional roles.

General Features of Neuronal Morphology

Neurons are highly polarized cells, meaning that they develop distinct subcellular domains that subserve different functions. Morphologically, in a typical neuron, three major regions can be defined: (1) the cell body (*soma* or *perikaryon*), which contains the nucleus and the major cytoplasmic organelles; (2) a variable number of dendrites, which emanate from the perikaryon and ramify over a certain volume of gray matter and that differ in size and shape, depending on the neuronal type; and (3) a single axon, which extends, in most cases, much farther from the cell body than the dendritic arbor (Fig. 3.1). Dendrites may be spiny (as in pyramidal cells) or nonspiny (as in most interneurons), whereas the axon is generally smooth and emits a variable number of branches (collaterals). In vertebrates, many axons are surrounded by an insulating myelin sheath, which

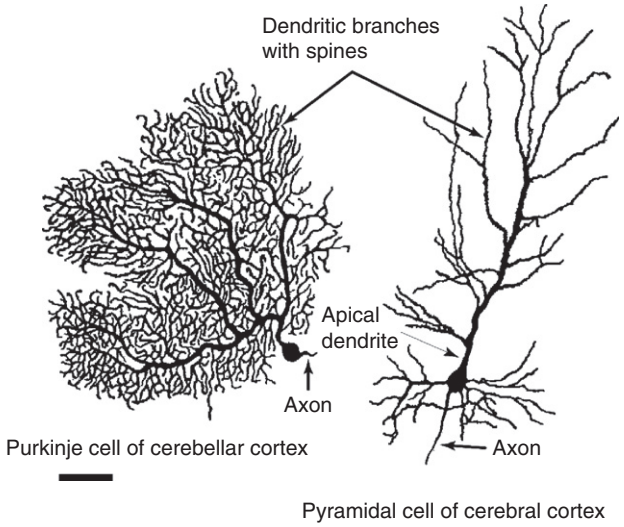

FIGURE 3.1 Typical morphology of projection neurons. (Left) A Purkinje cell of the cerebellar cortex and (right) a pyramidal neuron of the neocortex. These neurons are highly polarized. Each has an extensively branched, spiny apical dendrite, shorter basal dendrites, and a single axon emerging from the basal pole of the cell. The scale bar represents approximately 200 μm.

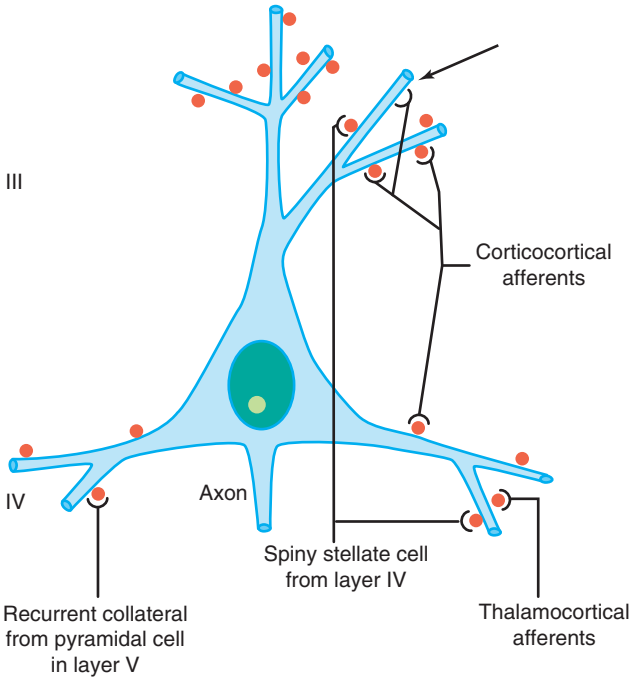

FIGURE 3.2 Schematic representation of four major excitatory inputs to pyramidal neurons. A pyramidal neuron in layer III is shown as an example. Note the preferential distribution of synaptic contacts on spines. Spines are labeled in red. Arrow shows a contact directly on the dendritic shaft.

facilitates rapid impulse conduction. The axon terminal region, where contacts with other cells are made, displays a wide range of morphological specializations, depending on its target area in the central or peripheral nervous system.

The cell body and dendrites are the two major domains of the cell that receive inputs, and dendrites play a critically important role in providing a massive receptive area on the neuronal surface. In addition, there is a characteristic shape for each dendritic arbor, which can be used to classify neurons into morphological types. Both the structure of the dendritic arbor and the distribution of axonal terminal ramifications confer a high level of subcellular specificity in the localization of particular synaptic contacts on a given neuron. The three-dimensional distribution of dendritic arborization is also important with respect to the type of information transferred to the neuron. A neuron with a dendritic tree restricted to a particular cortical layer may receive a very limited pool of afferents, whereas the widely expanded dendritic arborizations of a large pyramidal neuron will receive highly diversified inputs within the different cortical layers in which segments of the dendritic tree are present (Fig. 3.2) (Mountcastle, 1978). The structure of the dendritic tree is maintained by surface interactions between adhesion molecules and, intracellularly, by an array of cytoskeletal components (microtubules, neurofilaments, and associated proteins), which also take part in the movement of organelles within the dendritic cytoplasm.

An important specialization of the dendritic arbor of certain neurons is the presence of large numbers of dendritic spines, which are membranous protrusions. They are abundant in large pyramidal neurons and are much sparser on the dendrites of interneurons (see later).

The perikaryon contains the nucleus and a variety of cytoplasmic organelles. Stacks of rough endoplasmic reticulum are conspicuous in large neurons and, when interposed with arrays of free polyribosomes, are referred to as *Nissl substance*. Another feature of the perikaryal cytoplasm is the presence of a rich cytoskeleton composed primarily of neurofilaments and microtubules, discussed in detail in Chapter 4. These cytoskeletal elements are dispersed in bundles that extend from the soma into the axon and dendrites.

Whereas dendrites and the cell body can be characterized as domains of the neuron that receive afferents, the axon, at the other pole of the neuron, is responsible for transmitting neural information. This information may be primary, in the case of a sensory receptor, or processed information that has already been modified through a series of integrative steps. The morphology of the axon and its course through the nervous system are correlated with the type of information processed by the particular neuron and by its connectivity patterns with other neurons. The axon leaves the cell body from a small swelling called the *axon hillock*. This structure is

particularly apparent in large pyramidal neurons; in other cell types, the axon sometimes emerges from one of the main dendrites. At the axon hillock, microtubules are packed into bundles that enter the axon as parallel fascicles. The axon hillock is the part of the neuron where the action potential is generated. The axon is generally unmyelinated in local circuit neurons (such as inhibitory interneurons), but it is myelinated in neurons that furnish connections between different parts of the nervous system. Axons usually have higher numbers of neurofilaments than dendrites, although this distinction can be difficult to make in small elements that contain fewer neurofilaments. In addition, the axon may show extensive, spatially constrained ramifications, as in certain local circuit neurons; it may give out a large number of recurrent collaterals, as in neurons connecting different cortical regions, or it may be relatively straight in the case of projections to subcortical centers, as in cortical motor neurons that send their very long axons to the ventral horn of the spinal cord. At the interface of axon terminals with target cells are the synapses, which represent specialized zones of contact consisting of a presynaptic (axonal) element, a narrow synaptic cleft, and a postsynaptic element on a dendrite or perikaryon.

Synapses and Spines

Synapses

The exchange of information between neurons mainly takes place through two types of highly specialized structures: chemical synapses (the majority) and electrical synapses. In the latter case, although the plasma membranes of adjacent neurons are separated by a gap of about 2 nm, they contain small channels (gap junctions) that connect the cytoplasm of the adjoining neurons, permitting the diffusion of small molecules and the flow of electric current (Bennett & Zukin, 2004). Each chemical synapse (referred to as "synapse" in the remainder of this chapter) is a complex of several components: (1) a *presynaptic element*, (2) a *cleft*, and (3) a *postsynaptic element*. The presynaptic element is a specialized part of the presynaptic neuron's axon, the postsynaptic element is a specialized part of the postsynaptic somatodendritic membrane, and the space between these two closely apposed elements is the cleft. The portion of the axon that participates in the synapse is the *bouton*, and it is identified by the presence of synaptic vesicles and a presynaptic thickening at the active zone (Fig. 3.3). The postsynaptic element is marked by a postsynaptic thickening opposite the presynaptic thickening. When both sides are equally thick, the synapse is referred to as *symmetric*. When the postsynaptic thickening is greater, the synapse is *asymmetric*. Edward George Gray noticed this difference and divided synapses into two types: *Gray's type 1* synapses are asymmetric and have variably shaped, or pleomorphic, vesicles; *Gray's type 2* synapses are symmetric and have clear, round vesicles. The significance of this distinction is that research has shown that in general, Gray's type 1 synapses tend to be excitatory, whereas Gray's type 2 synapses tend to be inhibitory. This correlation greatly enhanced the usefulness of electron microscopy in neuroscience.

In cross section on electron micrographs, a synapse looks like two parallel lines separated by a very narrow space (Fig. 3.3). Viewed from the inside of the axon or dendrite, it looks like a patch of variable shape. Some synapses are a simple patch, or *macule*. Macular synapses can grow fairly large, reaching diameters over 1 mm. The largest synapses have discontinuities or holes within the macule and are called *perforated synapses* (Fig. 3.3). In cross section, a perforated synapse may resemble a simple macular synapse or several closely spaced smaller macules.

The portion of the presynaptic element that is apposed to the postsynaptic element is the *active zone*. This is the region where the synaptic vesicles are concentrated and where at any time a small number of vesicles are docked, and presumably ready for fusion. The active zone is also enriched with voltage gated calcium channels, which are necessary to permit activity-dependent fusion and neurotransmitter release.

The synaptic cleft is truly a space, but its properties are essential. The width of the cleft (~20 nm) is critical because it defines the volume in which each vesicle releases its contents and, therefore, the peak concentration of neurotransmitter upon release. On the flanks of the synapse, the cleft is spanned by adhesion molecules, which are believed to stabilize the cleft.

The postsynaptic element may be a portion of a soma or a dendrite or, rarely, part of an axon. In the cerebral cortex, most Gray's type 1 synapses are located on dendritic spines, which are specialized protrusions of the dendrite, and most Gray's type 2 synapses are located on somata or dendritic shafts. A similar segregation is seen in cerebellar cortex. In nonspiny neurons, symmetric and asymmetric synapses are often less well separated. Irrespective of location, a postsynaptic thickening marks the postsynaptic element. In Gray's type 1 synapses, the postsynaptic thickening (or postsynaptic density, PSD) is greatly enhanced. Among the molecules that are associated with the PSD are neurotransmitter receptors (e.g., NMDA receptors) and molecules with less obvious function, such as PSD-95.

Spines

Spines are protrusions on the dendritic shafts of some types of neurons and are the sites of synaptic contacts, usually excitatory. Use of the silver impregnation techniques of Golgi or of the methylene blue introduced by Ehrlich in the late nineteenth century led

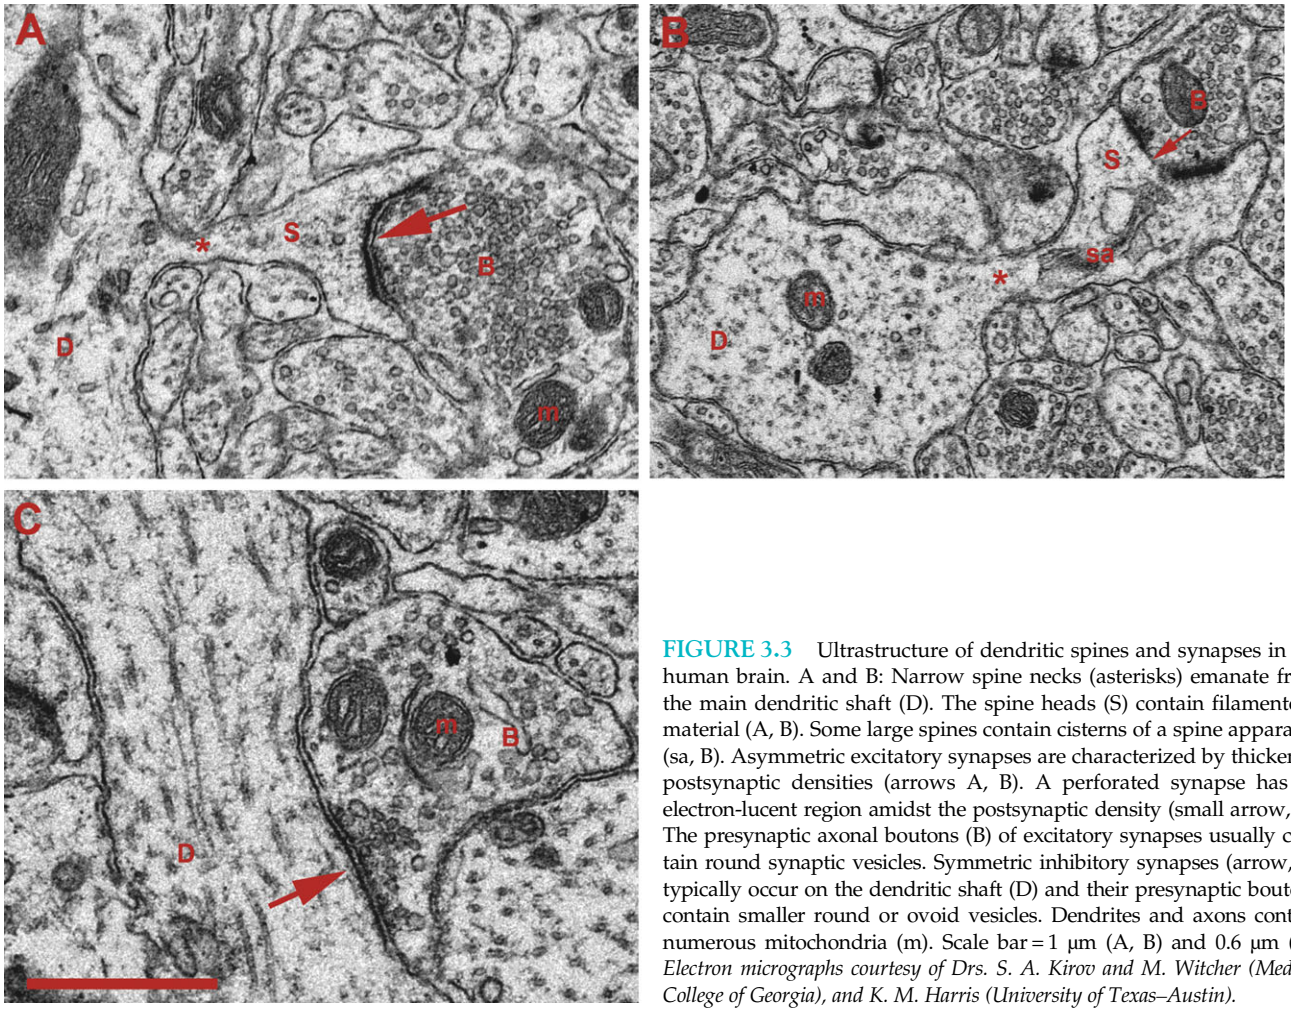

FIGURE 3.3 Ultrastructure of dendritic spines and synapses in the human brain. A and B: Narrow spine necks (asterisks) emanate from the main dendritic shaft (D). The spine heads (S) contain filamentous material (A, B). Some large spines contain cisterns of a spine apparatus (sa, B). Asymmetric excitatory synapses are characterized by thickened postsynaptic densities (arrows A, B). A perforated synapse has an electron-lucent region amidst the postsynaptic density (small arrow, B). The presynaptic axonal boutons (B) of excitatory synapses usually contain round synaptic vesicles. Symmetric inhibitory synapses (arrow, C) typically occur on the dendritic shaft (D) and their presynaptic boutons contain smaller round or ovoid vesicles. Dendrites and axons contain numerous mitochondria (m). Scale bar = 1 μm (A, B) and 0.6 μm (C). *Electron micrographs courtesy of Drs. S. A. Kirov and M. Witcher (Medical College of Georgia), and K. M. Harris (University of Texas–Austin).*

Santiago Ramón y Cajal to the discovery of spiny appendages on dendrites of a variety of neurons. The best known are those on pyramidal neurons and Purkinje cells, although spines occur on neuron types at all levels of the central nervous system. As early as 1890, Santiago Ramón y Cajal suggested that spines could collect the electrical charge resulting from neuronal activity (Cajal, 1909–1911). He also proposed that spines substantially increase the receptive surface of the dendritic arbor, which may represent an important factor in receiving the contacts made by the axonal terminals of other neurons. It has been calculated that the approximately 20,000 spines of a pyramidal neuron account for more than 40% of its total surface area (Peters, Palay, & Webster, 1991).

More recent analyses of spine electrical properties have demonstrated that spines are dynamic structures that can regulate many neurochemical events related to synaptic transmission and modulate synaptic efficacy. Spines are also known to undergo pathologic alterations and have a reduced density in a number of experimental manipulations (such as deprivation of a sensory input) and in many developmental, neurologic, and psychiatric conditions (such as dementing illnesses, chronic alcoholism, schizophrenia, and trisomy 21). Morphologically, spines are characterized by a narrower portion emanating from the dendritic shaft, the neck, and an ovoid bulb or head, although spine morphology may vary from large mushroom-shaped bulbs to small bulges barely discernable on the surface of the dendrite. Spines have an average length of ~2 μm, but there is considerable variability in their dimensions. At the ultrastructural level (Fig. 3.3), spines are characterized by the presence of asymmetric synapses and contain fine and quite indistinct filaments. These filaments most likely consist of actin and α- and β-tubulins. Microtubules and neurofilaments present in dendritic shafts do not enter spines. Mitochondria and free ribosomes are infrequent, although many spines contain polyribosomes in their neck. Interestingly, most polyribosomes in dendrites are located at the bases of spines, where they are associated with endoplasmic reticulum, indicating that spines possess the machinery necessary for the local synthesis of proteins. Another

feature of the spine is the presence of confluent tubular cisterns in the spine head that represent an extension of the dendritic smooth endoplasmic reticulum. Those cisterns are referred to as the *spine apparatus*. The function of the spine apparatus is not fully understood but may be related to the storage of calcium ions during synaptic transmission.

SPECIFIC EXAMPLES OF DIFFERENT NEURONAL TYPES

Inhibitory Local Circuit Neurons

Inhibitory Interneurons of the Cerebral Cortex

The study of cortical interneurons dates back to the original work of Camillo Golgi when he applied the new technique he had discovered, the *reazione nera* (black reaction: Golgi, 1873). This method allowed all the components of a neuron to be visualized in histological sections (soma, dendrites, and axon). Golgi proposed that neurons could generally be considered to be of two different morphological and physiological types: motor (type I) and sensory (type II) neurons. These motor neurons had long axons that sprout collaterals, and they could project beyond the gray matter, whereas by contrast, sensory neurons had short axons that arborized near the parent cell and did not leave the gray matter. This hypothesis was challenged when Cajal entered the scene following his masterful studies of brain structure based on the Golgi method. Cajal argued that it was not physiologically possible to maintain such a distinction, and he designated Golgi's two types as cells with a long axon (projection neurons) and cells with a short axon (intrinsic neurons), avoiding any consideration of their possible physiological roles (Fig. 3.4). Since then, the term short-axon cell has commonly been used as synonymous with *interneurons* (DeFelipe, 2002).

In general, cortical interneurons have been subdivided into two large groups: spiny non-pyramidal cells and aspiny or sparsely spiny non-pyramidal cells. Spiny non-pyramidal cells represent the typical neurons (including spiny stellate cells) of the middle cortical layers (especially layer IV). These spiny non-pyramidal cells are morphologically heterogeneous, with ovoid, fusiform, and triangular somata, and most of them are excitatory (probably glutamatergic). Their axons are found within layer IV or in the layers adjacent to that in which their soma is located, either above or below. Aspiny or sparsely spiny non-pyramidal cells have axons that remain close to the parental cell body, although prominent collaterals may run out from some of these in the horizontal (parallel to the cortical surface) or vertical dimension (ascending and/or descending to other cortical layers). These interneurons constitute approximately 15 to 30% of the total population of cortical neurons, and they appear to be mostly GABAergic, representing the main components of inhibitory cortical circuits (Jones, 1993) (Fig. 3.4). Indeed, they can be found in all cortical layers, and they characteristically display a tremendous variety of morphological, biochemical, and physiological features (Markram et al., 2004; Kubota et al., 2011). However, a general consensus

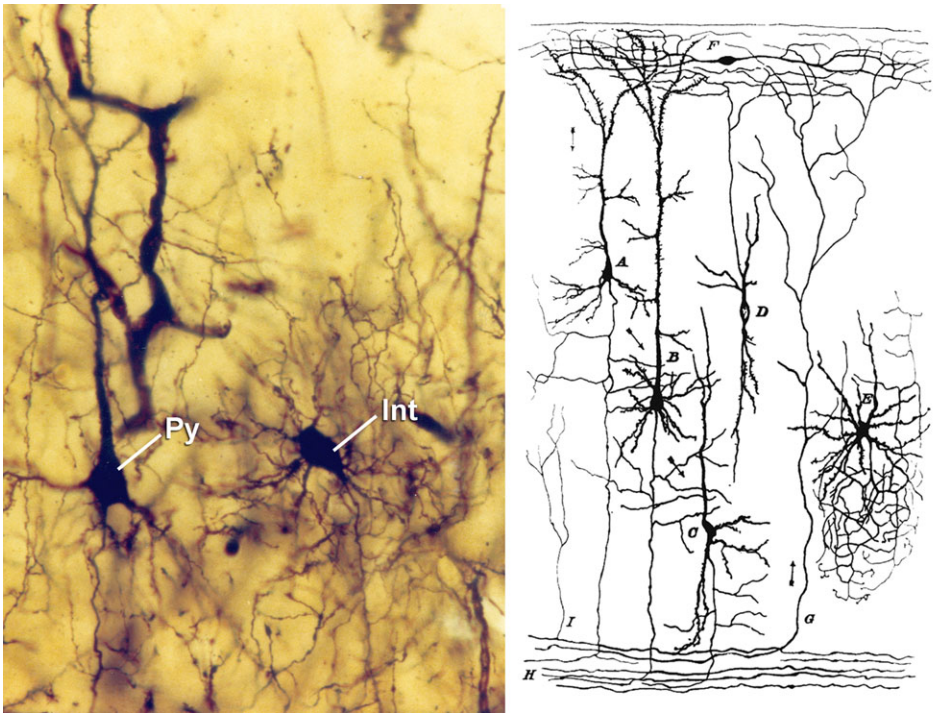

FIGURE 3.4 *Left*, photomicrograph from one of the Cajal's preparations of the "occipital pole" of an eighteen-day-old cat, showing the soma of a pyramidal cell (Py) and a neurogliaform cell (interneuron; Int) stained with the Golgi method. *Right*, the principal cellular types based on the works of Cajal on the cerebral cortex of small mammals (rabbit, guinea pig, rat, and mouse). *A*, pyramidal cell of medium size; *B*, giant pyramidal cell; *C*, polymorphic cell; *D*, cell whose axon is ascending; *E*, cell of Golgi; *F*, special cell of the molecular layer. *Copyright © Herederos de Santiago Ramón y Cajal.*

to name and classify cortical neurons has yet to emerge. This is in part due to the fact that, with some exceptions, there are no rules to establish the essential characteristics that define whether an individual neuron belongs to a given cell type. Indeed, this characterization is also hindered by the fact that most studies of these neurons are generally based on either morphological, physiological, or molecular approaches, rather than any combination of these features.

In a more recent attempt to classify these neurons, the Petilla Interneuron Nomenclature Group (Ascoli et al., 2008) proposed a set of terms to organize and describe the anatomical, molecular, and physiological features of GABAergic interneurons of the cerebral cortex based on existing data. The anatomical, molecular, and physiological classifications divided GABAergic cortical interneurons into several main types of interneurons, which in turn were further subdivided depending on distinct properties. Briefly, the anatomical classification identified three major neuronal types: cells that target pyramidal cells; cells that do not show target specificity; and cells that specifically target other interneurons. The molecular classification includes five main groups based on the expression of specific biochemical markers: parvalbumin, somatostatin, neuropeptide Y in the absence of somatostatin, vasointestinal peptide, and cholecystokinin in the absence of somatostatin and vasointestinal peptide. Finally, the physiological classification identified six main types of interneurons: fast spiking neurons, nonadapting/nonfast spiking neurons, adapting neurons, accelerating cells, irregular spiking neurons, and intrinsic bursting neurons. Each of these attempts to classify these neurons has its limitations, and the scientific community still lacks a general catalogue of accepted neuron types and names. Nevertheless, standardizing the nomenclature based on the properties of GABAergic interneurons proposed by the Petilla Interneuron Nomenclature Group represents a step in the right direction towards a more comprehensive classification of cortical GABAergic interneurons.

In general, GABAergic interneurons control the timing and flow of information in the cerebral cortex (Fig. 3.5), although there does seem to be some division of labor between the different types of interneurons (Klausberger & Somogyi, 2008). One such example is the class of basket and chandelier cells that are considered as fast-spiking GABAergic interneurons and that express the calcium binding protein parvalbumin. These cells appear to play important roles in controlling the timing of pyramidal cell firing, shaping the network output and the rhythms generated in different states of consciousness (Klausberger et al., 2003; Howard, Tamas, & Soltesz, 2005; Yizhar, Fenno,

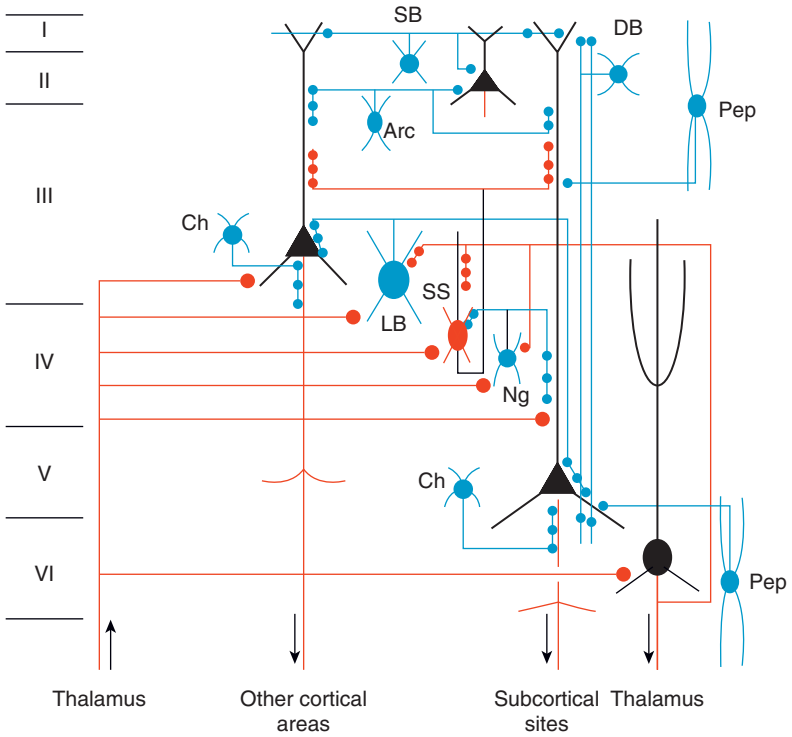

FIGURE 3.5 A schematic circuit based upon the known cortical cells upon which thalamic afferent fibers terminate in cats and monkeys. The GABAergic interneurons (blue) are identified by the names that they have received in these species. *Arc*, neuron with arciform axon; *Ch*, chandelier cell; *DB*, double bouquet cell; *LB*, large basket cell; *Ng*, neurogliaform cell; *Pep*, peptidergic neuron; *SB*, small basket cell. Excitatory neurons (black) include pyramidal cells of layers II–VI and the spiny stellate cells (*SS*) of layer IV. *Courtesy of Dr. E. G. Jones.*

Davidson, Mogri, & Deisseroth, 2011). By contrast, other interneurons containing nitric oxide synthase and various neuropeptides are implicated in the neurovascular coupling (Rossier, 2009). In addition, some types of interneurons have been directly implicated in disease, which is particularly evident when we consider that certain alterations to chandelier and basket cells seem to be critical in establishing some forms of human epilepsy (DeFelipe, 1999; Magloczky & Freund, 2005). Finally, the proportion of GABAergic neurons in the cerebral cortex of rodents is lower than in primates, and there are interneurons in primates that are not found in rodents (Jones, 1975, 1993; DeFelipe, 2002; Markram et al., 2004; Ascoli et al., 2008). These observations, together with the existence of differences in the developmental origins of GABAergic interneurons in rodents and primates, including humans, seem to indicate that more GABA interneurons and newer forms of GABA interneurons appeared in the primate cortex during the course of evolution (Rakic, 2009; Raghanti, Spocter, Butti, Hof, & Sherwood, 2010; DeFelipe, 2011). These features of GABAergic interneurons make their study one of the most exciting and active research fields in relation to the cerebral cortex.

Inhibitory Projection Neurons

Medium-sized Spiny Cells

These neurons are unique to the striatum, a part of the basal ganglia that comprises the caudate nucleus and putamen (see Chapter 31). Medium-sized spiny cells are scattered throughout the caudate nucleus, the putamen, and the nucleus accumbens, and are recognized by their relatively large size, compared with other cellular elements of the basal ganglia. They differ from all other neurons in the striatum in that they have a highly ramified dendritic arborization radiating in all directions, which is densely covered with spines. They furnish a major output from the striatum and receive a highly diverse input from, among other sources, the cerebral cortex, thalamus, and certain dopaminergic neurons of the substantia nigra. These neurons are neurochemically quite heterogeneous, contain GABA, and may contain several neuropeptides and the calcium-binding protein calbindin. In Huntington disease, a neurodegenerative disorder of the striatum characterized by involuntary movements and progressive dementia, an early and dramatic loss of medium-sized spiny cells occurs.

Purkinje Cells

Purkinje cells are the most morphologically striking cellular elements of the cerebellar cortex. They are arranged in a single row throughout the entire cerebellar cortex between the molecular (outer) layer and the granular (inner) layer. Purkinje cells are among the largest neurons in the brain and have a round perikaryon, classically described as shaped "like a chianti bottle," with a highly branched dendritic tree resembling a candelabrum and extending into the molecular layer where they are contacted by incoming systems of afferent fibers from granule neurons and the brainstem (see Chapter 32). Their apical dendrites have an enormous number of spines (more than 80,000 per cell). A particular feature of the dendritic tree of the Purkinje cell is that it is distributed in one plane, perpendicular to the longitudinal axes of the cerebellar folds, and each dendritic arbor determines a separate domain of cerebellar cortex (Fig. 3.1). The axons of Purkinje neurons course through the cerebellar white matter and contact cerebellar nuclei or vestibular nuclei. These neurons contain the inhibitory neurotransmitter GABA and the calcium-binding protein calbindin. Spinocerebellar ataxia, a severe disorder combining ataxic gait and impairment of fine hand movements, accompanied by dysarthria and tremor, has been documented in some families and is related directly to Purkinje cell degeneration.

Excitatory Local Circuit Neurons

Spiny Stellate Cells

Spiny stellate cells are small multipolar neurons with local dendritic and axonal arborizations. These neurons resemble pyramidal cells in that they are the only other cortical neurons with large numbers of dendritic spines, but they differ from pyramidal neurons in that they lack an elaborate apical dendrite. The relatively restricted dendritic arbor of these neurons is presumably a manifestation of the fact that they are high-resolution neurons that gather afferents to a very restricted region of the cortex. Dendrites rarely leave the layer in which the cell body resides. The spiny stellate cell also resembles the pyramidal cell in that it provides asymmetric synapses that are presumed to be excitatory, and is thought to use glutamate as its neurotransmitter (Peters & Jones, 1984).

The axons of spiny stellate neurons have primarily intracortical targets and a radial orientation, and appear to play an important role in forming links among layer IV, the major thalamorecipient layer, and layers III, V, and VI, the major projection layers. The spiny stellate neuron appears to function as a high-fidelity relay of thalamic inputs, maintaining strict topographic organization and setting up initial vertical links of information transfer within a given cortical area (Peters & Jones, 1984).

Excitatory Projection Neurons

Pyramidal Cells

All cortical output is carried by pyramidal neurons, and the intrinsic activity of the neocortex can be viewed

simply as a means of finely tuning and coordinating their output. A pyramidal cell is a highly polarized neuron, with a major orientation axis perpendicular (or orthogonal) to the pial surface of the cerebral cortex. In cross section, the cell body is roughly triangular (Fig. 3.1), although a large variety of morphologic types exist with elongate, horizontal, or vertical fusiform, or inverted perikaryal shapes. Pyramidal cells are the major excitatory type of neurons and use glutamate as their neurotransmitter. A pyramidal neuron typically has a large number of dendrites that emanate from the apex and form the base of the cell body. The span of the dendritic tree depends on the laminar localization of the cell body, but it may, as in giant pyramidal neurons, spread over several millimeters. The cell body and dendritic arborization may be restricted to a few layers or, in some cases, may span the entire cortical thickness (Jones, 1984).

In most cases, the axon of a large pyramidal cell extends from the base of the perikaryon and courses toward the subcortical white matter, giving off several collateral branches that are directed to cortical domains generally located within the vicinity of the cell of origin (as explained later). Typically, a pyramidal cell has a large nucleus, and a cytoplasmic rim that contains, particularly in large pyramidal cells, a collection of granular material chiefly composed of *lipofuscin*. Although all pyramidal cells possess these general features, they can also be subdivided into numerous classes based on their morphology, laminar location, and connectivity with cortical and subcortical regions (Fig. 3.6) (Jones, 1975).

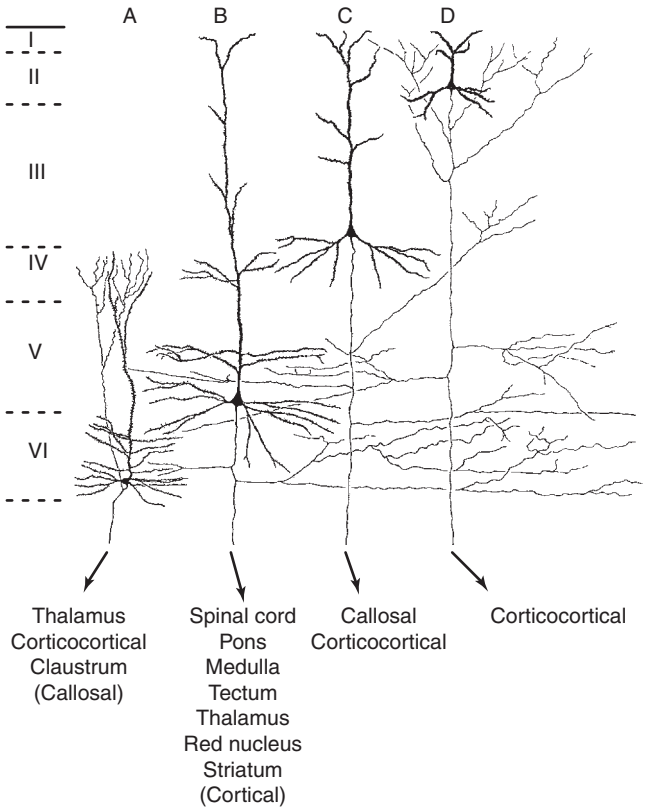

FIGURE 3.6 Morphology and distribution of neocortical pyramidal neurons. Note the variability in cell size and dendritic arborization, as well as the presence of axon collaterals, depending on the laminar localization (I–VI) of the neuron. Also, different types of pyramidal neurons with a precise laminar distribution project to different regions of the brain (less important projections zones are indicated by parentheses). *Adapted from Jones (1984).*

Spinal Motor Neurons

Motor cells of the ventral horns of the spinal cord, also called motoneurons, have their cell bodies within the spinal cord and send their axons outside the central nervous system to innervate the muscles. Different types of motor neurons are distinguished by their targets. The α motoneurons innervate skeletal muscles, but smaller motor neurons (the γ motoneurons, forming about 30% of the motor neurons) innervate the spindle organs of the muscles (see Chapter 28). Alpha motor neurons are some of the largest neurons in the entire central nervous system and are characterized by a multipolar perikaryon and a very rich cytoplasm that renders them very conspicuous in histological preparations. They have a large number of spiny dendrites that arborize locally within the ventral horn. The α motoneuron axon leaves the central nervous system through the ventral root of the peripheral nerves. Their distribution in the ventral horn is not random and corresponds to a somatotopic representation of the muscle groups of the limbs and axial musculature (Brodal, 1981). Spinal motor neurons use acetylcholine as their neurotransmitter. Large motor neurons are severely affected in lower motor neuron disease, a neurodegenerative disorder characterized by progressive muscular weakness that affects, at first, one or two limbs but involves more and more of the body musculature, which shows signs of wasting as a result of denervation.

Neuromodulatory Neurons

Dopaminergic Neurons of the Substantia Nigra

Dopaminergic neurons are large neurons that reside mostly within the pars compacta of the substantia nigra and in the ventral tegmental area (van Domburg & ten Donkelaar, 1991). A distinctive feature of these cells is the presence of a pigment, *neuromelanin*, in compact granules in the cytoplasm. These neurons are medium-sized to large, fusiform, and frequently elongated. They have several large radiating dendrites. The axon emerges from the cell body or from one of the dendrites and projects to large expanses of cerebral cortex and to the basal ganglia. These neurons contain the catecholamine-synthesizing

enzyme *tyrosine hydroxylase*, as well as the monoamine dopamine as their neurotransmitter. Some of them contain both calbindin and calretinin. These neurons are affected severely and selectively in Parkinson disease—a movement disorder different from Huntington disease and characterized by resting tremor and rigidity—and their specific loss is the neuropathologic hallmark of this disorder.

NEUROGLIA

The term *neuroglia*, or "nerve glue," was coined in 1859 by Rudolph Virchow, who conceived of the neuroglia as an inactive "connective tissue" holding neurons together in the central nervous system. The metallic staining techniques developed by Cajal and del Rio-Hortega allowed these two great pioneers to distinguish, in addition to the ependyma lining the ventricles and central canal, three types of supporting cells in the CNS: oligodendrocytes, astrocytes, and microglia. In the peripheral nervous system (PNS), the Schwann cell is the major neuroglial component. These cells are much smaller than the neurons—usually glial cells are 4–10 μm across—yet their size depends on their state of maturation and their possible involvement in a pathological process.

Oligodendrocytes and Schwann Cells Synthesize Myelin

Most brain functions depend on rapid communication between circuits of neurons. As shown in depth later, there is a practical limit to how fast an individual bare axon can conduct an action potential. Organisms developed two solutions for enhancing rapid communication between neurons and their effector organs. In invertebrates, the diameters of axons are enlarged. In vertebrates, the myelin sheath (Fig. 3.7) evolved to permit rapid nerve conduction.

Axon enlargement accelerates action potential propagation in proportion to the square root of axonal diameter. Thus larger axons conduct faster than small ones, but substantial increases in conduction velocity require huge axons. The largest axon in the invertebrate kingdom is the squid giant axon, which is about the thickness of a mechanical pencil lead. This axon conducts the action potential at speeds of 10 to 20 m/s. As the axon mediates an escape reflex, firing must be rapid if the animal is to survive. Bare axons and continuous conduction obviously provide sufficient rates of signal propagation for even very large invertebrates, and many human axons also remain bare. However, in the human brain with 10 billion neurons, axons cannot be as thick as pencil lead, or heads would weigh one hundred pounds or more.

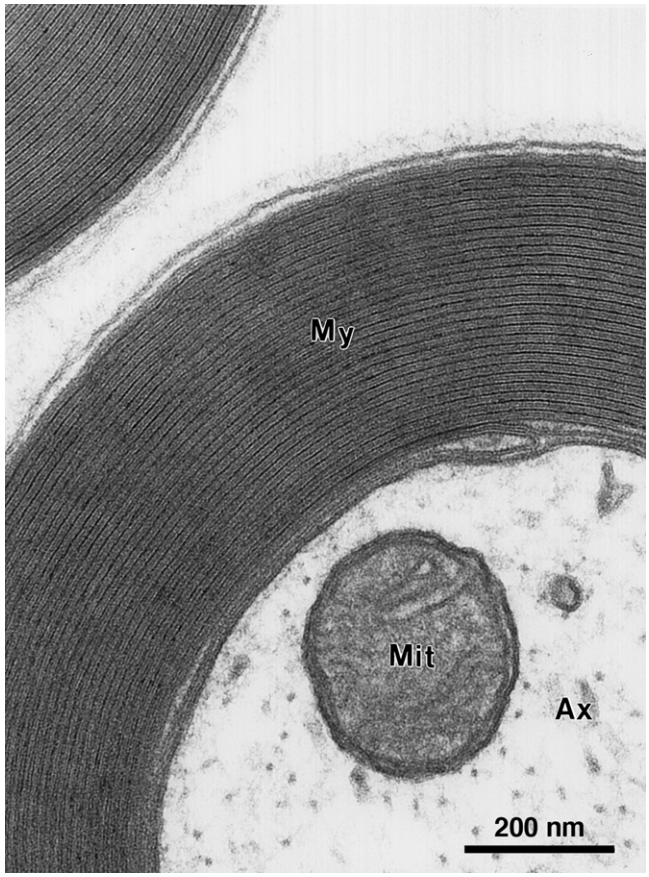

FIGURE 3.7 An electron micrograph of a transverse section through part of a myelinated axon from the sciatic nerve of a rat. The tightly compacted multilayer myelin sheath (My) surrounds and insulates the axon (Ax). Mit, mitochondria. Scale bar = 200 nm.

Thus, along the invertebrate evolutionary line, the use of bare axons imposes a natural, insurmountable limit—a constraint of axonal size—to increasing the processing capacity of the nervous system. Vertebrates, however, get around this problem through evolution of the myelin sheath, which allows 10- to 100-fold increases in conduction of the nerve impulse along axons with fairly minute diameters.

In the central nervous system, myelin sheaths (Fig. 3.8) are elaborated by oligodendrocytes. During brain development, these glial cells send out a few cytoplasmic processes that engage adjacent axons and form myelin around them (Bunge, 1968). Myelin consists of a long sheet of oligodendrocyte plasma membrane, which is spirally wrapped around an axonal segment. At the end of each myelin segment, there is a bare portion of the axon, the node of Ranvier. Myelin segments are thus called *internodes*. Physiologically, myelin has insulating properties such that the action potential can "leap" from node to node and therefore does not have to be regenerated continually along the axonal segment that is covered by the myelin membrane sheath. This leaping of the action

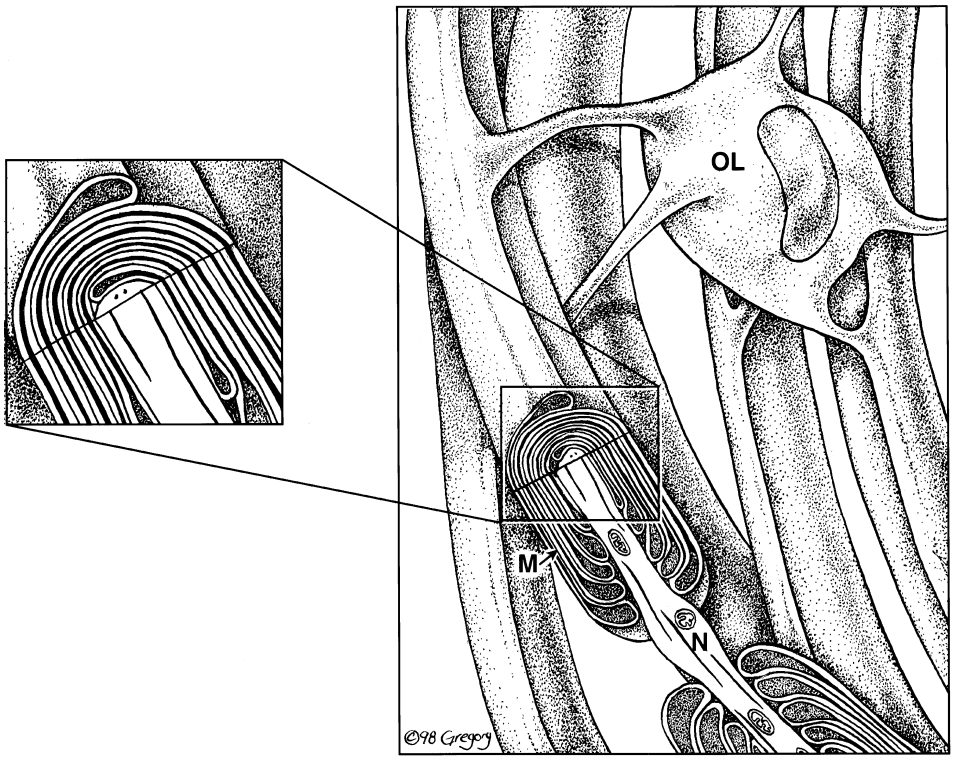

FIGURE 3.8 An oligodendrocyte (OL) in the central nervous system is depicted myelinating several axon segments. A cutaway view of the myelin sheath is shown (M). Note that the internode of myelin terminates in paranodal loops that flank the node of Ranvier (N). (Inset) An enlargement of compact myelin with alternating dark and light electron-dense lines that represent intracellular (major dense lines) and extracellular (intraperiod line) plasma membrane appositions, respectively.

potential from node to node allows axons with fairly small diameters to conduct extremely rapidly (Ritchie, 1984), and is called *saltatory conduction*.

Because the brain and spinal cord are encased in the bony skull and vertebrae, evolution has promoted compactness among the supporting cells of the CNS. Each oligodendrocyte cell body is responsible for the construction and maintenance of several myelin sheaths (Fig. 3.8), thus reducing the number of glial cells required. In both PNS and CNS myelin, cytoplasm is removed between each turn of the myelin, leaving only the thinnest layer of plasma membrane. Due to protein composition differences, CNS lamellae are approximately 30% thinner than in PNS myelin. In addition, there is little or no extracellular space or extracellular matrix between the myelinated axons passing through CNS white matter. Brain volume is thus reserved for further expansion of neuronal populations.

Peripheral nerves pass between moving muscles and around major joints and are routinely exposed to physical trauma. A hard tackle, slipping on an icy sidewalk, or even just occupying the same uncomfortable seating posture for too long can painfully compress peripheral nerves and potentially damage them. Thus, evolutionary pressures shaping the PNS favor robustness and regeneration rather than conservation of space. Myelin in the PNS is generated by Schwann cells (Fig. 3.9), which are different to oligodendrocytes in several ways. Individual myelinating Schwann cells form a single internode.

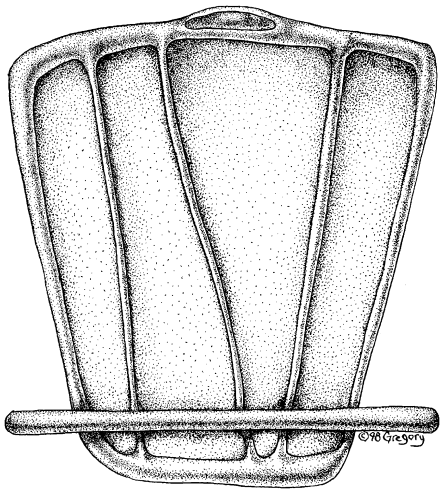

FIGURE 3.9 An "unrolled" Schwann cell in the PNS is illustrated in relation to the single axon segment that it myelinates. The broad stippled region is compact myelin surrounded by cytoplasmic channels that remain open even after compact myelin has formed, allowing an exchange of materials among the myelin sheath, the Schwann cell cytoplasm, and perhaps the axon as well.

The biochemical composition of PNS and CNS myelin differs, as discussed later. Unlike oligodendrocytes, Schwann cells secrete copious extracellular matrix components and produce a basal lamina "sleeve" that runs the entire length of myelinated axons. Schwann cell and fibroblast-derived collagens prevent normal wear-and-tear compression

damage. Schwann cells also respond vigorously to injury, in common with astrocytes but unlike oligodendrocytes. Schwann cell growth factor secretion, debris removal by Schwann cells after injury, and the axonal guidance function of the basal lamina are responsible for the exceptional regenerative capacity of the PNS compared with the CNS.

The major integral membrane protein of peripheral nerve myelin is protein zero (P0), a member of a very large family of proteins termed the immunoglobulin gene superfamily. This protein makes up about 80% of the protein complement of PNS myelin. Interactions between the extracellular domains of P0 molecules expressed on one layer of the myelin sheath with those of the apposing layer yield a characteristic regular periodicity that can be seen by thin section electron microscopy (Fig. 3.7). This zone, called the intraperiod line, represents the extracellular apposition of the myelin bilayer as it wraps around itself. On the other side of the bilayer, the cytoplasmic side, the highly charged P0 cytoplasmic domain probably functions to neutralize the negative charges on the polar head groups of the phospholipids that make up the plasma membrane itself, allowing the membranes of the myelin sheath to come into close apposition with one another. In electron microscopy, this cytoplasmic apposition appears darker than the intraperiod line and is termed the major dense line. In peripheral nerves, although other molecules are present in small quantities in compact myelin and may have important functions, compaction (i.e., the close apposition of membrane surfaces without intervening cytoplasm) is accomplished solely by P0–P0 interactions at both extracellular and intracellular (cytoplasmic) surfaces.

Curiously, P0 is present in the CNS of lower vertebrates such as sharks and bony fish, but in terrestrial vertebrates (reptiles, birds, and mammals), P0 is limited to the PNS. CNS myelin compaction in these higher organisms is subserved by proteolipid protein (PLP) and its alternate splice form, DM-20. These two proteins are generated from the same gene, both span the plasma membrane four times, and differ only in that PLP has a small, positively charged segment exposed on the cytoplasmic surface. Why did PLP/DM-20 replace P0 in CNS myelin? Manipulation of PLP and P0 in CNS myelin established an axonotrophic function for PLP in CNS myelin. Removal of PLP from rodent CNS myelin altered the periodicity of compact myelin and produced a late onset axonal degeneration (Griffiths et al., 1998). Replacing PLP with P0 in rodent CNS myelin stabilized compact myelin but enhanced the axonal degeneration (Yin et al., 2006). These observations indicate that myelination provides trophic support that is essential for axon survival. Studies of primary demyelinating diseases, such as multiple sclerosis, and genetic dysmyelinating diseases (e.g., Charcot-Marie-Tooth diseases) indicate that axonal degeneration is the major cause of permanent disability (Nave & Trapp, 2008).

Myelin membranes also contain a number of other proteins such as the myelin basic protein, which is a major CNS myelin component, and PMP-22, a protein that is involved in a form of peripheral nerve disease. A large number of naturally occurring gene mutations can affect the proteins specific to the myelin sheath and cause neurological disease. In animals, these mutations have been named according to the phenotype that is produced: the shiverer mouse, the shaking pup, the rumpshaker mouse, the jumpy mouse, the myelin-deficient rat, the quaking mouse, and so forth. Many of these mutations are well characterized and have provided valuable insights into the role of individual proteins in myelin formation and axonal survival.

Astrocytes Play Important Roles in CNS Homeostasis

As the name suggests, astrocytes were first described as star-shaped, process-bearing cells distributed throughout the central nervous system. They constitute from 20 to 50% of the volume of most brain areas. Astrocytes appear stellate when stained using reagents that highlight their intermediate filaments but have complex morphologies when their entire cytoplasm is visualized (Fig. 3.10). The two main forms, protoplasmic and fibrous astrocytes, predominate in gray and white matter, respectively (Fig. 3.11). Embryonically, astrocytes develop from radial glial cells, which transversely compartmentalize the neural tube. Radial glial cells serve as scaffolding for the migration of neurons and play a critical role in defining the cytoarchitecture of the CNS (Fig. 3.12). As the CNS matures, radial glia retract their processes and serve as progenitors of astrocytes. However, some specialized astrocytes of a radial nature are still found in the adult cerebellum and the retina and are known as Bergmann glial cells and Müller cells, respectively.

Astrocytes "fence in" neurons and oligodendrocytes. Astrocytes achieve this isolation of the brain parenchyma by extending long processes projecting to the pia mater and the ependyma to form the glia limitans by covering the surface of capillaries and by making a cuff around the nodes of Ranvier. They also ensheath synapses and dendrites and project processes to cell somas (Fig. 3.13). Astrocytes are connected to each other, and to oligodendrocytes, by gap junctions, forming a syncytium that allows ions and small molecules to diffuse across the brain parenchyma. Astrocytes have in common unique cytological and immunological properties that make them easy to identify, including their star shape, the glial end feet on capillaries, and a unique population of large bundles of intermediate filaments. These filaments are composed of an astroglial-specific protein commonly referred to as glial

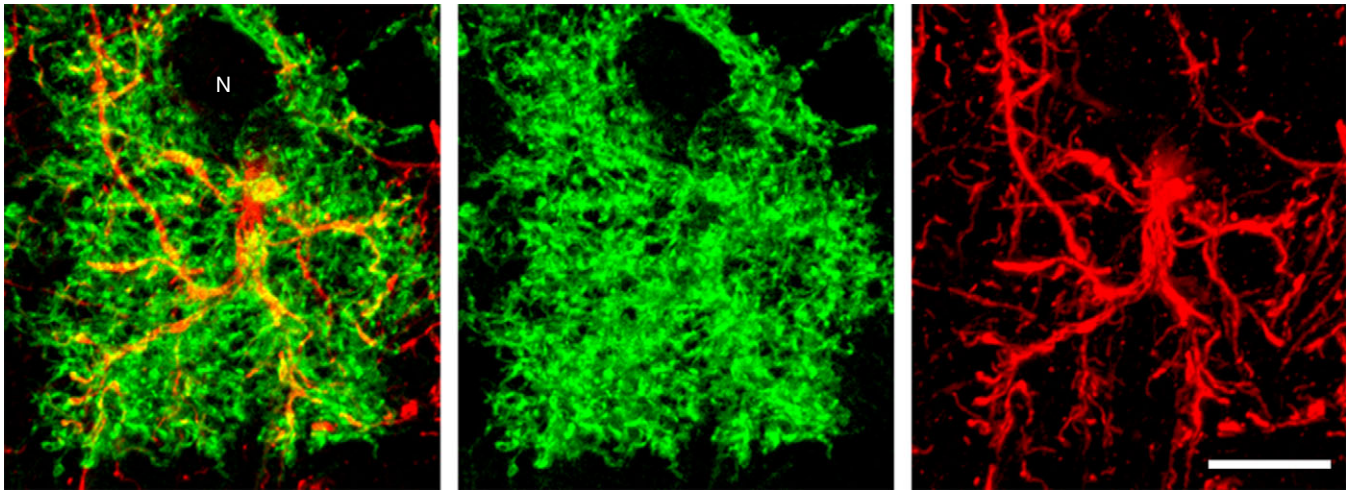

FIGURE 3.10 Astrocytes appear stellate when their intermediate filaments are stained (red, GFAP), but membrane labeling (green, membrane-associated EGFP) highlights the profusion of fine cellular processes that intercalate among other neuropil elements such as synapses and neurons (N). Scale bar = 10 μm. *Image courtesy of Dr. M. C. Smith.*

fibrillary acidic protein (GFAP). S-100, a calcium-binding protein, and glutamine synthetase are also astrocyte markers. Ultrastructurally, gap junctions (connexins), desmosomes, glycogen granules, and membrane orthogonal arrays are distinct features used by morphologists to identify astrocytic cellular processes in the complex cytoarchitecture of the nervous system.

For a long time, astrocytes were thought to physically form the blood–brain barrier (considered later in this chapter), which prevents the entry of cells and diffusion of molecules into the CNS. In fact, astrocytes are indeed the blood–brain barrier in lower species. However, in higher species, astrocytes are responsible for inducing and maintaining the tight junctions in endothelial cells that effectively form the barrier. Astrocytes also take part in angiogenesis, which may be important in the development and repair of the CNS. Their role in this important process is still poorly understood.

Astrocytes Have a Wide Range of Functions

There is strong evidence for the role of radial glia and astrocytes in the migration and guidance of neurons in early development. Astrocytes are a major source of extracellular matrix proteins and adhesion molecules in the CNS; examples are nerve cell–nerve cell adhesion molecule (N-CAM), laminin, fibronectin, cytotactin, and the J-1 family members janusin and tenascin. These molecules participate not only in the migration of neurons, but also in the formation of neuronal aggregates, so-called nuclei, as well as networks.

Astrocytes produce, *in vivo* and *in vitro*, a very large number of growth factors. These factors act singly or in combination to selectively regulate the morphology, proliferation, differentiation, or survival, or all four, of distinct neuronal subpopulations. Most of the growth factors also act in a specific manner on the development and functions of astrocytes and oligodendrocytes. The production of growth factors and cytokines by astrocytes and their responsiveness to these factors is a major

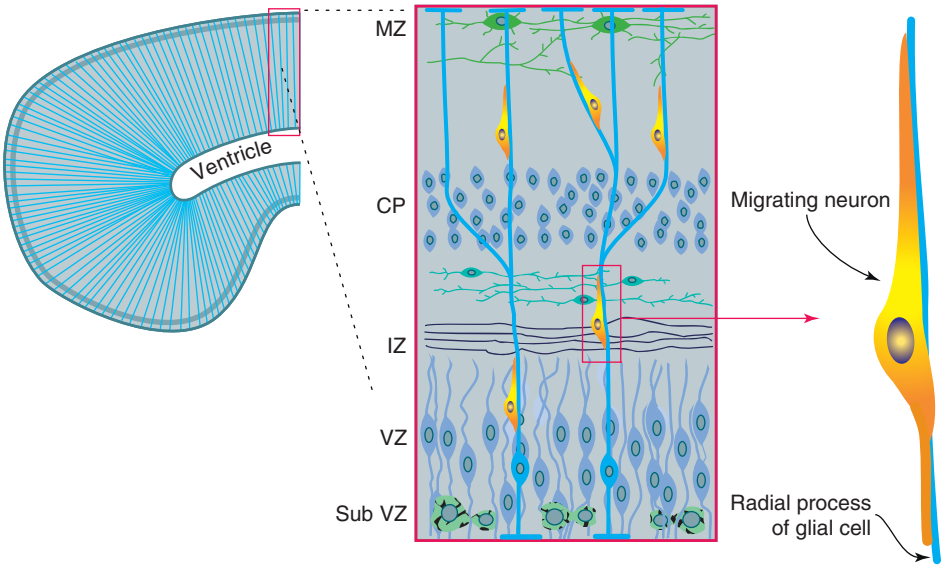

FIGURE 3.12 Radial glia perform support and guidance functions for migrating neurons. In early development, radial glia span the thickness of the expanding brain parenchyma. (Inset) Defined layers of the neural tube from the ventricular to the outer surface: VZ, ventricular zone; IZ, intermediate zone; CP, cortical plate; MZ, marginal zone. The radial process of the glial cell is indicated in blue, and a single attached migrating neuron is depicted at the right.

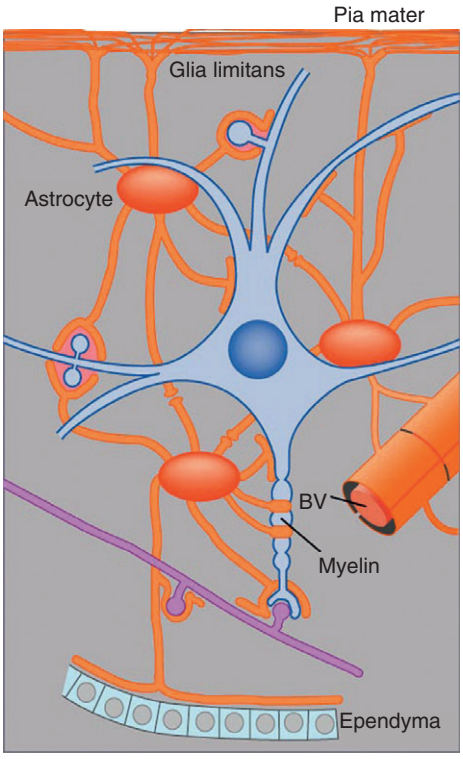

FIGURE 3.13 Astrocytes (in orange) are depicted *in situ* in schematic relationship with other cell types with which they are known to interact. Astrocytes send processes that surround neurons and synapses, blood vessels, and the region of the node of Ranvier and extend to the ependyma, as well as to the pia mater, where they form the glial limitans.

mechanism underlying the developmental function and regenerative capacity of the CNS. During neurotransmission, neurotransmitters and ions are released at high concentration in the synaptic cleft. The rapid removal of these substances is important so that they do not interfere with future synaptic activity. The presence of astrocyte processes around synapses positions them well to regulate neurotransmitter uptake and inactivation (Kettenman & Ransom, 1995). These possibilities are consistent with the presence in astrocytes of transport systems for many neurotransmitters. For instance, glutamate reuptake is performed mostly by astrocytes, which convert glutamate into glutamine and then release it into the extracellular space. Glutamine is taken up by neurons, which use it to generate glutamate and GABA, potent excitatory and inhibitory neurotransmitters, respectively (Fig. 3.14). Astrocytes contain ion channels for K^+, Na^+, Cl^-, HCO_3^-, and Ca^{2+}, as well as displaying a wide range of neurotransmitter receptors. K ions released from neurons during neurotransmission are soaked up by astrocytes and moved away from the area through astrocyte gap junctions. This is known as *spatial buffering*. Astrocytes play a major role in detoxification of the CNS by sequestering metals and a variety of neuroactive substances of endogenous and xenobiotic origin.

In response to stimuli, intracellular calcium waves are generated in astrocytes. Propagation of the Ca^{2+} wave can be visually observed as it moves across the cell soma and from astrocyte to astrocyte. The generation of Ca^{2+} waves from cell to cell is thought to be mediated by second messengers, diffusing through gap junctions (see Chapter 10). In the adult brain, gap junctions are present in all astrocytes. Some gap junctions also have been detected between astrocytes and neurons. Thus, they may participate, along with astroglial neurotransmitter receptors, in the coupling of astrocyte and neuron physiology.

In a variety of CNS disorders—neurotoxicity, viral infections, neurodegenerative disorders, HIV, AIDS, dementia, multiple sclerosis, inflammation, and trauma—astrocytes react by becoming hypertrophic and, in a few

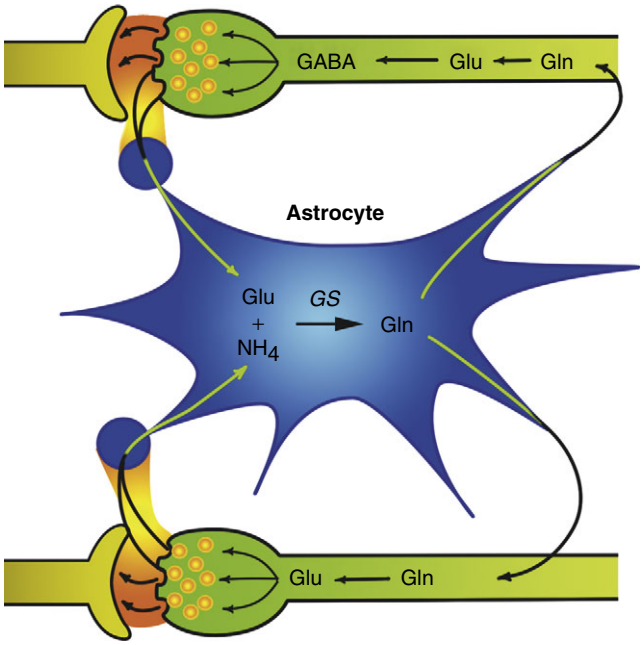

FIGURE 3.14 The glutamate–glutamine cycle is an example of a complex mechanism that involves an active coupling of neurotransmitter metabolism between neurons and astrocytes. The systems of exchange of glutamine, glutamate, GABA, and ammonia between neurons and astrocytes are highly integrated. The postulated detoxification of ammonia and the inactivation of glutamate and GABA by astrocytes are consistent with the exclusive localization of glutamine synthetase in the astroglial compartment.

cases, hyperplastic. A rapid and huge upregulation of GFAP expression and filament formation is associated with astrogliosis. The formation of reactive astrocytes can spread very far from the site of origin. For instance, a localized trauma can recruit astrocytes from as far as the contralateral side, suggesting the existence of soluble factors in the mediation process. Tumor necrosis factor (TNF) and ciliary neurotrophic factors (CNTF) have been identified as key factors in astrogliosis.

Microglia Are Mediators of Immune Responses in Nervous Tissue

The brain traditionally has been considered an "immunologically privileged site," mainly because the blood–brain barrier normally restricts the access of immune cells from the blood. However, it is now known that immunological reactions do take place in the central nervous system, particularly during cerebral inflammation. Microglial cells have been termed the tissue macrophages of the CNS, and they function as the resident representatives of the immune system in the brain. A rapidly expanding literature describes microglia as major players in CNS development and in the pathogenesis of CNS disease.

The first description of microglial cells can be traced to Franz Nissl (1899), who used the term "rod cell" to describe a population of glial cells that reacted to brain pathology. He postulated that rod-cell function was similar to that of leukocytes in other organs. Cajal described microglia as part of his "third element" of the CNS—cells that he considered to be of mesodermal origin and distinct from neurons and astrocytes (Cajal, 1913).

Del Rio-Hortega (1932) distinguished this third element into microglia and oligodendrocytes. He used silver impregnation methods to visualize the ramified appearance of microglia in the adult brain, and he concluded that ramified microglia could transform into cells that were migratory, ameboid, and phagocytic. Indeed, a hallmark of microglial cells is their ability to become reactive and to respond to pathological challenges in a variety of ways. A fundamental question raised by del Rio-Hortega's studies was the origin of microglial cells. Some questions about this remain even today.

Microglia Have Diverse Functions in Developing and Mature Nervous Tissue

On the basis of current knowledge, it appears that most ramified microglial cells are derived from bone marrow–derived monocytes, which enter the brain parenchyma during early stages of brain development. These cells help phagocytosis degenerating cells that undergo programmed cell death as part of normal development. They retain the ability to divide and have the immunophenotypic properties of monocytes and macrophages. In addition to their role in remodeling the CNS during early development, microglia secrete cytokines and growth factors that are important in fiber tract development, gliogenesis, and angiogenesis. They are also the major CNS cells involved in presenting antigens to T lymphocytes. After the early stages of development, ameboid microglia transform into the ramified microglia that persist throughout adulthood (Altman, 1994).

Little is known about microglial function in the healthy adult vertebrate CNS. Microglia constitute a formidable percentage (5–20%) of the total cells in the mouse brain. Microglia are found in all regions of the brain, and there are more in gray than in white matter. The neocortex and hippocampus have more microglia than the brainstem or cerebellum. Species variations also have been noted, as human white matter has three times more microglia than rodent white matter.

Microglia usually have small rod-shaped somas from which numerous processes extend in a rather symmetrical fashion. Processes from different microglia rarely overlap or touch, and specialized contacts between microglia and other cells have not been described in the normal brain. Although each microglial cell occupies its own territory, microglia collectively form a network

that covers much of the CNS parenchyma. Because of the numerous processes, microglia present extensive surface membrane to the CNS environment. Regional variation in the number and shape of microglia in the adult brain suggests that local environmental cues can affect microglial distribution and morphology. On the basis of these morphological observations, it is likely that microglia play a role in tissue homeostasis. The nature of this homeostasis remains to be elucidated. It is clear, however, that microglia can respond quickly and dramatically to alterations in the CNS microenvironment.

Microglia Become Activated in Pathological States

"Reactive" microglia can be distinguished from resting microglia by two criteria: (1) change in morphology and (2) upregulation of monocyte–macrophage molecules (Fig. 3.15). Although the two phenomena generally occur together, reactive responses of microglia can be diverse and restricted to subpopulations of cells within a microenvironment. Microglia not only respond to pathological conditions involving immune activation, but also become activated in neurodegenerative conditions that are not considered immunity-mediated (Graeber, 2010; Naert & Rivest, 2011). This latter response is indicative of the phagocytic role of microglia. Microglia change their morphology and antigen expression in response to almost any form of CNS injury.

CEREBRAL VASCULATURE

The cerebral vasculature supports the development and function of the brain. It is composed of a dense network of arterioles, veinules, and capillaries. Figure 3.16 provides an example of the microvascular density across neocortical layers in a mouse brain. During embryogenesis, the brain vasculature develops via the process of angiogenesis from a preformed perineural vascular plexus. The formation of closed neurovascular networks requires the ordered and coordinated action of neural and endothelial signaling factors, such as vascular endothelial growth factor (VEGF), which is produced in the neuroepithelium and attracts vessel growth into the brain. Other factors, including insulin-like growth factor-1 (IGF-1), basic fibroblast growth factors (bFGFs), interleukin-8 (IL-8), erythropoietin, and angiopoietin-1, promote the recruitment, proliferation, and survival of endothelial cells while simultaneously promoting the proliferation of neural progenitors, neurogenesis, synaptogenesis, and axonal growth. Many neurogenic factors, including nerve growth factor (NGF), brain derived growth factor (BDNF), neuropilin, glial derived growth factor (GDNF), and artemin, as well as components of the extracellular matrix (ECM), affect both neurons and endothelial cells. The vasculature also contributes to neurogenesis by providing a vascular niche for the resident neural progenitor population that exists in neurogenic regions of the adult brain (Ihrie & Alvarez-Buylla, 2011).

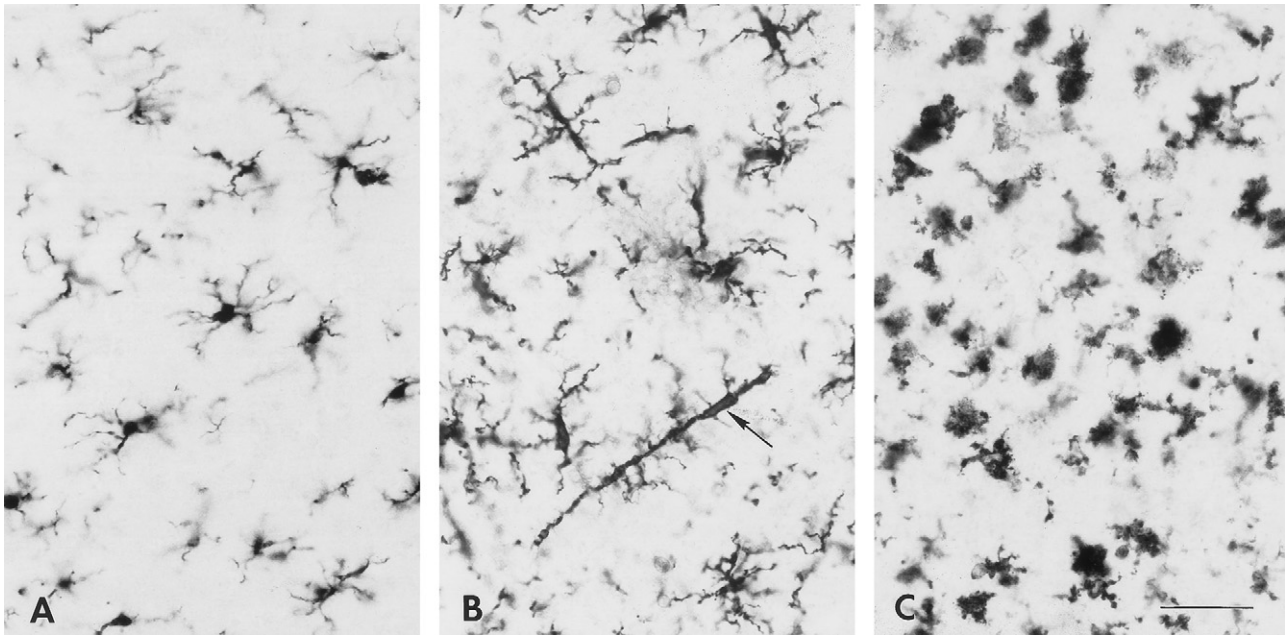

FIGURE 3.15 Activation of microglial cells in a tissue section from human brain. Resting microglia in normal brain (A). Activated microglia in diseased cerebral cortex (B) have thicker processes and larger cell bodies. In regions of frank pathology (C) microglia transform into phagocytic macrophages, which can also develop from circulating monocytes that enter the brain. Arrow in B indicates rod cell. Sections stained with antibody to ferritin. Scale bar = 40 μm.

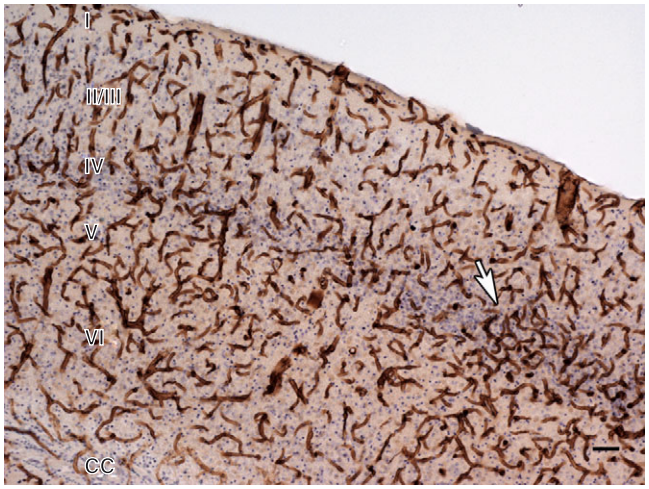

FIGURE 3.16 Microvasculature of the adult mouse somatosensory barrel field (S1BF) cortex. Microvessels were stained with antibodies against collagen type IV, a protein component of the extracellular matrix, and lightly counter-stained with cresyl violet (Nissl). Cortical layers (I–VI) and the corpus callosum (CC) are indicated. An area of increased vascular density in layer IV, where contralateral somatosensory inputs from the thalamus terminate, is indicated by an arrow. Scale bar = 50 μm.

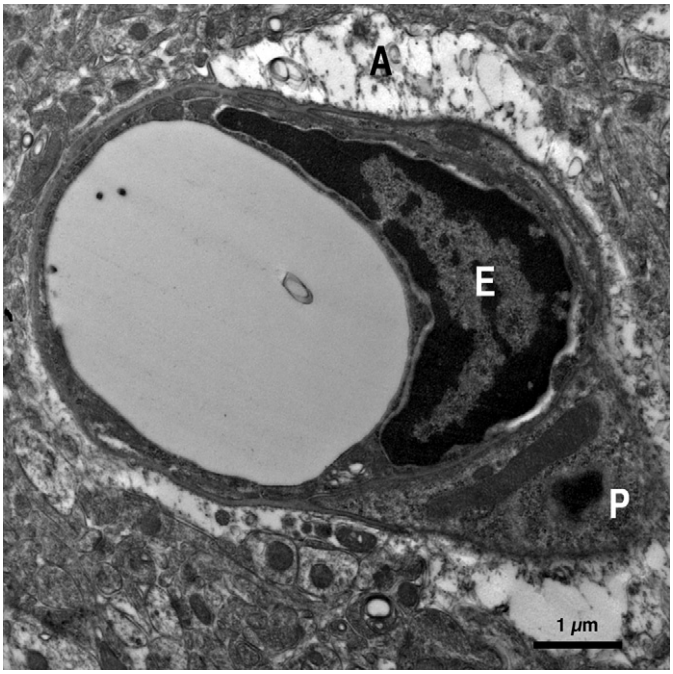

FIGURE 3.17 Ultrastructural analysis of the cerebral microvasculature of a 10-month-old wild-type mouse. A transversely sectioned capillary is shown from the prefrontal cortex. An endothelial cell (E) surrounding the lumen, a pericyte (P), and an astrocytic end-foot process (A) are indicated. Scale bar = 1 μm.

During angiogenesis, endothelial cells proliferate and migrate to form capillary networks, initially aligning into multicellular, precapillary cord-like structures that form an integrated polygonal network. As the vascular cords mature, lumens form and allow blood flow, and endothelial cells become sequestered from the interstitial matrix by a continuous lamina of ECM that forms a basement membrane or basal lamina. The vascular ECM is a hyaline rich and amorphous substance containing laminins, which are thought to be the primary glycoprotein determinants of basement membrane assembly, along with collagen type IV, perlecan (heparan sulfate proteoglycan-2), nidogens, collagen type XVIII, and fibronectin. Structurally, the ECM supports vascular organization as well as playing a mechanosensing role.

Endothelial cells adhere to the ECM through both integrin and nonintegrin receptors. These interactions result in activation of a complex set of signaling pathways that include Rho GTPases (including Cdc42 and Rac1), focal adhesion kinase (FAK), protein kinase Cε (PKCε), and Src. MAPK signaling is particularly important in the regulation of endothelial cell proliferation, migration, and survival. Although these pathways have diverse targets, one common theme is that most affect directly or indirectly the endothelial cytoskeleton. Regulation of ECM structure and function is primarily achieved through the action of matrix metalloproteases (MMPs), which degrade ECM components and release ECM-bound factors such as cytokines that affect vascular cell behavior (Davis, Stratman, Sacharidou, & Koh, 2011).

Transport of Molecules into the Brain

As an extension of the systemic circulation, the cerebral vasculature delivers oxygen and nutrients into the brain and removes carbon dioxide and other metabolic wastes. Endothelial cells interact with neurons, astrocytes, and microglia, as well as other perivascular cells, including smooth muscle cells and pericytes, to form a neurovascular unit (Lecrux & Hamel, 2011) (Fig. 3.17). This structural organization maintains cerebral homeostasis and also forms a blood–brain barrier (BBB) that restricts exchange of solutes between the systemic circulation and brain. Unlike the fenestrated capillaries most often found in the periphery, the spaces between endothelial cells in brain capillaries are occluded by tight junctions (also known as zonula occludens) that form the physical basis for the BBB by restricting the paracellular movement of molecules into the brain. The tight junctions between endothelial cells are localized at cholesterol-rich regions along the plasma membrane containing caveolin-1 (Cav-1) and are composed of tetraspan transmembrane proteins (claudins and occludin) and single-span cytoplasmic proteins (junction adhesion molecules or JAM proteins). Adaptor proteins, such as ZO-1, link both classes of proteins to the actin cytoskeleton as well as to other signaling molecules. These junctions seal the paracellular space, although they remain

capable of rapid modulation and regulation. Consequently, the only solutes that can passively enter the brain are lipid soluble and able to freely diffuse across endothelial cell membranes.

The presence of a functional BBB means that most substances entering the brain must do so by carrier- or receptor-mediated mechanisms. Some molecules cross the BBB by clathrin-mediated endocytosis. However, in addition to clathrin-mediated transport, the plasma membranes of brain endothelia are enriched in membrane lipid rafts, called caveolae, that participate in potocytosis, a type of endocytosis by which small molecules are transported across the plasma membrane by caveolae rather than clathrin-coated vesicles. Select plasma proteins are, for example, taken up and transported across endothelial cell membranes by both receptor-mediated and receptor-independent transcytosis (transport across the interior of the cell from blood to interstitial fluid or vice versa) involving caveolae. Caveolar membranes, in addition to containing structural proteins including the caveolins (Cav-1 and 2 in endothelial cells and Cav-3 in astrocytes) and cavin (abundant at the cytoplasmic face of caveolae), also contain a variety of signaling molecules (G-protein-coupled receptors, G-proteins, non-receptor tyrosine kinases, nonreceptor Ser/Thr kinases, GTPases, and adaptor proteins). Caveolae are also enriched in *β*-D-galactosyl and *β*-*N*-acetylglucosaminyl residues, cholesterol, sphingolipids (sphingomyelin and glycosphingolipids), as well as palmitoleic and stearic acids. Following the BBB breakdown that occurs with acute injuries to the brain, caveolae can fuse to form transendothelial channels that extend from the luminal to the abluminal plasma membrane, which allows passage of macromolecules from the blood to the brain and vice versa, a phenomenon that has not been observed in normal brain endothelium (Nag, Kapadia, & Stewart, 2011; Redzic, 2011).

The high metabolic rate within the brain is dependent on a continuous supply of glucose from the circulation; under normal conditions, glucose is the main source of metabolic energy. Because glucose does not readily cross the BBB, mechanisms have evolved for the transcellular transport of glucose from the blood to the brain interstitial fluid. In the brain, the main glucose transporters are glucose transporter 1 (GLUT-1) in microvascular endothelial cells and glia, and GLUT-3 in neurons. These insulin-insensitive glucose transporters are constitutively expressed on the cell surface. In endothelial cells, the concentration of GLUT-1 is higher on the abluminal surface. Capillary densities in different brain regions are directly related to local blood flow, and close correlations exist between local cerebral glucose utilization, local densities of GLUT-1 and GLUT-3, and local capillary density. Moreover, the pericytes, which are contractile cells, regulate the distribution of the capillary blood flow to match the local cerebral metabolic need (Dalkara, Gursoy-Ozdemir, & Yemisci, 2011).

The BBB also limits the diffusion of other circulating solutes, and independent carrier systems exist for neutral, basic, and acidic amino acids, as well as purines, nucleosides, and monocarboxylic acids, including lactate and pyruvate. Aromatic amino acids serve as precursors for the synthesis of the neurotransmitters serotonin, dopamine, and histamine, and the synthesis of these neurotransmitters is substrate limited. Cerebral endothelial cells express specific solute carrier proteins (SLCs) that mediate the entry and efflux of amino acids across the luminal and abluminal surfaces of the BBB. Both Na^+-dependent and -independent systems have been identified. Na^+-independent amino acid transport systems that have been identified in brain capillary endothelium are system L (or a high-affinity isoform L1) for large neutral amino acids (including L-leucine, L-phenylalanine, L-isoleucine, L-methionine, L-valine); system y^+ for the transport of cationic amino acids (L-arginine, L-lysine, L-ornithine), and system x_c^- for anionic amino acids (cystine/glutamate exchange transporter system). Na^+-dependent transport systems present in brain endothelial cells include systems A and ASC, which show preference for small neutral amino acids (L-alanine, L-serine, L-cysteine), system $B^{o,+}$ for both neutral and basic amino acids, system X_{AG}^- for L-glutamate and L-aspartate, and system *β* (Cl^--dependent) for *β*-amino acids *β*-alanine and taurine. The anionic amino acid transport systems are important in the inactivation of glutamatergic neurotransmission in the brain and for the synthesis of glutathione. The high-affinity Na^+-dependent transporters are located principally in the abluminal membrane of the cerebral endothelium (Broer & Palacin, 2011; Mann, Yudilevich, & Sobrevia, 2003).

The Cerebral Vasculature in Disease States

Many disease states affect the cerebral vasculature. Occlusive cerebral vascular disease can affect both large and small cerebral vessels, causing ischemia of cerebral tissue and resulting acutely in stroke. By contrast, more chronic cerebral ischemia can result in slow, progressive cognitive impairment and vascular dementia. The integrity of the BBB is also affected in a variety of conditions (Nag et al., 2011). For example, brain tumors often disrupt the BBB, causing fluid to leak into brain tissue. The vasogenic edema that results is often associated with neurological impairment beyond the effects of the tumor itself. A variety of inflammatory and infectious conditions also disrupt the BBB. In multiple sclerosis, inflammatory T lymphocytes cross the BBB and initiate an autoimmune attack on central nervous system (CNS) myelin. Treatment modalities often target the effects of an altered BBB, such as the use of corticosteroids in patients with brain tumors or CNS disorders associated with autoimmunity.

CHAPTER

4

Subcellular Organization of the Nervous System: Organelles and Their Functions

Cells have many features in common, but each cell type also possesses a functional architecture related to its unique physiology. In fact, cells may become so specialized in fulfilling a particular function that virtually all subcellular components may be devoted to that function. For example, the machinery inside mature mammalian erythrocytes is completely dedicated to the delivery of oxygen to the tissues and the removal of carbon dioxide. Toward this end, this cell has evolved a specialized plasma membrane, an underlying cytoskeletal matrix that molds the cell into a biconcave disk, and a cytoplasm rich in hemoglobin. Modification of the cell machinery extends even to the discarding of structures such as the nucleus and the protein synthetic apparatus, which are not needed after the red blood cell matures. In many respects, the terminally differentiated, highly specialized cells of the nervous system exhibit comparable commitment; the extensive development of subcellular components reflects the roles that each plays (Brady & Tai, 2012).

The neuron serves as the cellular correlate of information processing, and, in aggregate, all neurons act together to integrate responses of the entire organism to the external world. It is therefore not surprising that the specializations found in neurons are more diverse and complex than those found in any other cell type. Single neurons commonly interact in specific ways with hundreds of other cells—other neurons, astrocytes, oligodendrocytes, immune cells, muscle, and glandular cells (see Chapter 3). Some of these other cell types in the nervous system, such as the myelinating glia (oligodendrocytes and Schwann cells) or astrocytes are inextricably linked to the neuron both functionally and structurally, representing critical partners in building and maintaining a nervous system, with highly specialized subcellular architecture. Here, we define the major functional domains of the neuron, describe the subcellular elements that compose the building blocks of these domains, and examine the processes that create and maintain neuronal functional architecture.

AXONS AND DENDRITES: UNIQUE STRUCTURAL COMPONENTS OF NEURONS

Neurons and glial cells are remarkable for their size and complexity, but they do share many features with other eukaryotic cells (Peters, Palay, & Webster, 1991). As discussed in Chapter 3, the perikaryon, or cell body, contains a nucleus and its associated protein synthetic machinery. Most neuronal nuclei are large and typically contain a preponderance of euchromatin. This is consistent with the need to create and maintain a large cellular volume. Because protein synthesis must be kept at a high level just to maintain the extensive volume and surface area comprising the perikaryon, dendrites, and axon, transcription levels in neurons are generally high. In turn, the wide variety of different polypeptide constituents associated with cellular domains in a neuron requires that a large number of different genes be transcribed constantly.

When specific mRNAs have been synthesized and processed, they move from the nucleus into a subcellular region that can be termed the translational cytoplasm (Lasek & Brady, 1982) comprising cytoplasmic ("free") and membrane-associated polysomes, the intermediate compartment of the smooth endoplasmic reticulum, and

© 2013 Elsevier Inc. All rights reserved.

the Golgi complex. The constituents of translational cytoplasm are thus associated with the synthesis and processing of proteins. Neurons in particular have relatively large amounts of translational cytoplasm to accommodate a high level of protein synthesis. This protein synthetic machinery is arranged in discrete intracellular "granules" termed Nissl substance, after the histologist who first discovered these structures in the nineteenth century. The Nissl substance is actually a combination of stacks of rough endoplasmic reticulum (RER), interposed with rosettes of free polysomes (Fig. 4.1). This arrangement is unique to neurons, and its functional significance is unknown. Most, but by no means all, proteins used throughout the neuron are synthesized in the perikaryon. During or after synthesis and processing, proteins are packaged into membrane-limited organelles in the Golgi complex, incorporated into cytoskeletal elements, or remain as soluble constituents of the cytoplasm. After proteins have been packaged appropriately, they are transported to their sites of function.

With a few exceptions, vertebrate neurons have two discrete functional domains or compartments, the axonal and the somatodendritic compartments, each of which encompasses a number of distinct microdomains. The axon is perhaps the most familiar functional domain of a neuron and is classically defined as the cellular process by which a neuron makes contact with a target cell to transmit information, providing a conducting structure for transmitting the action potential to a synapse, a specialized subdomain for transmission of a signal from neuron to target cell (neuron, muscle, etc.), most often by release of appropriate neurotransmitters. Consequently, most axons end in presynaptic terminal specializations, although a single axon may have many (hundreds or even thousands in some cases) presynaptic specializations known as en passant synapses along its length. Characteristics of presynaptic terminals are presented in greater detail later.

The axon is the first neuronal process to differentiate during development. A typical neuron has only a single axon that proceeds some distance from the cell body before branching extensively. Usually the longest process of a neuron, axons come in many sizes. In a human adult, axons range in length from a few micrometers for small interneurons to a meter or more for large motor or sensory neurons, and they may be even longer in large animals (such as giraffes, elephants, and whales). In mammals and other vertebrates, the longest axons generally extend approximately half the body length.

Axonal diameters also are quite variable, ranging from 0.1 to 20 μm for large myelinated fibers in vertebrates. Invertebrate axons grow to even larger diameters, with the giant axons of some squid species achieving diameters in the millimeter range. Invertebrate axons reach such large diameters because they lack the myelinating glia that speed conduction of the action potential. As a result, axonal caliber must be large to sustain the high rate of conduction needed for the reflexes that permit escape from predators and capture of prey. Although axonal caliber is closely regulated in both myelinated and nonmyelinated fibers, this parameter is critical for those organisms that are unable to produce myelin.

The region of the neuronal cell body where the axon originates has several specialized features. This domain, called the axon hillock, is distinguished most readily by a deficiency of Nissl substance. Therefore, protein synthesis cannot take place to any appreciable degree in this region. Cytoplasm in the vicinity of the axon hillock may have a few polysomes but is dominated by the cytoskeletal and membranous organelles that are being delivered to the axon. Microtubules and neurofilaments begin to align roughly parallel to each other, helping to organize membrane-limited organelles destined for the axon. The hillock is a region where materials either are committed to the axon (cytoskeletal elements, synaptic vesicle precursors, mitochondria, etc.) or are excluded from the axon (RER and free polysomes, dendritic microtubule-associated proteins). The molecular basis for this sorting is not understood, although recent studies suggest that actin and microtubule-based cytoskeletal elements may play a role in this sorting at the protein level (Arnold, 2009). Cytoplasm in the axon hillock does not appear to contain a physical "sizing" barrier (like a filter) because large organelles such as mitochondria enter the axon readily, whereas only a small number of essentially excluded structures such as polysomes are occasionally seen only in the initial segment of the axon and not in the axon proper. A known exception to this general rule is during development when local protein synthesis does take place at the axon terminus or growth cone. Nevertheless, new methods of detecting gene transcripts, including so-called "deep sequencing," are beginning to suggest that even in mature axons mRNAs may be more abundant than originally thought, in spite of the fact that classical ribosomes or even polysomes are difficult to detect. In the mature neuron,

FIGURE 4.1 Basic elements of neuronal subcellular organization. The neuron consists of a soma, or cell body, in which the nucleus, multiple cytoplasm-filled processes termed dendrites, and the (usually single) axon are placed. The neuron is highly extended in space; a neuron with a cell body of the size shown here could easily maintain an axon several miles in length! The unique shape of each neuron is the result of a cooperative interplay between plasma membrane components (the lipid matrix and associated proteins) and cytoskeletal elements. Most large neurons in vertebrates are myelinated by oligodendrocytes in the CNS and by Schwann cells in the PNS. The compact wraps of myelin encasing the axon distal to the initial segment permit the rapid conduction of the action potential by a process termed "saltatory conduction" (see Chapter 3).

the physiological significance of this barrier must be considerable because axonal structures are found to accumulate in this region in many neuropathologies, including those due to degenerative diseases (such as amyotrophic lateral sclerosis) and to exposure to neurotoxic compounds (such as acrylamide).

The initial segment of the axon is the region of the axon adjacent to the axon hillock (Palay, Sotelo, Peters & Orkand, 1968; Grubb & Burrone, 2010). Microtubules generally form characteristic fascicles, or bundles, in the initial segment of the axon. These fascicles are not seen elsewhere in the neuron. The initial segment and, to some extent, the axon hillock also have a distinctive specialized plasma membrane. Initially, the plasmalemma was thought to have a thick electrondense coating actually attached to the inner surface of the membrane, but this dense undercoating is in reality separated by 5–10 nm from the plasma membrane inner surface and has a complex ultrastructure. Neither the composition nor the function of this undercoating is known. Curiously, the undercoating is present in the same regions of the initial segment as the distinctive fasciculation of microtubules, although the relationship is not understood. The plasma membrane is specialized in the initial segment and axon hillock in that it contains voltage-sensitive ion channels in large numbers together with several other proteins known to play a part in either clustering the voltage-gated sodium channels (ankyrin G), or stabilizing them (Neurofascin 186). It has generally been thought that most action potentials are initiated in this domain, but it may also have a role in modulating action potentials that arise elsewhere.

Ultimately, axonal structure is geared toward the efficient conduction of action potentials at a rate appropriate to the function of that neuron. This can be seen from both the ultrastructure and the composition of axons. Axons are roughly cylindrical in cross section with little or no taper. As discussed later, this diameter is maintained by regulation of the cytoskeleton. Even at branch points, daughter axons are comparable in diameter to the parent axon. This constant caliber helps ensure a consistent rate of conduction. Similarly, the organization of membrane components is regulated to this end. Voltage-gated ion channels are distributed to maximize conduction. Sodium channels are distributed more or less uniformly in small nonmyelinated axons, but are concentrated at high density in the regularly spaced unmyelinated gaps, known as nodes of Ranvier (Sherman & Brophy, 2005; Susuki & Rasband, 2008). The nodes are flanked by specialized domains known as the paranodal axoglial junctions, which, as their name suggests, are sites where junctional complexes form between the terminal loops of the myelin sheath and the axolemma. These play an important role in both clustering sodium channels at the node and restricting them there in mature nerve fibers. Disruption of the septate junctions between the paranodal loops of myelin and the axonal membrane impair rapid nerve impulse conduction. An axon so organized will conduct an action potential or train of spikes long distances with high fidelity at a defined speed. These characteristics are essential for maintaining the precise timing and coordination seen in neuronal circuits.

Most vertebrate neurons have multiple dendrites arising from their perikarya. Unlike axons, dendrites branch continuously and taper extensively with a reduction in caliber in daughter processes at each branching. In addition, the surface of dendrites is covered with small protrusions, or spines, that are postsynaptic specializations. Although the surface area of a dendritic arbor may be quite extensive, dendrites in general remain in the relative vicinity of the perikaryon. A dendritic arbor may be contacted by the axons of many different and distant neurons or innervated by a single axon making multiple synaptic contacts.

The base of a dendrite is continuous with the cytoplasm of the cell body. In contrast to the axon, Nissl substance extends into dendrites, and certain proteins are synthesized predominantly in dendrites (Martin & Zukin, 2006). There is evidence for the selective placement of some mRNAs in dendrites as well. For example, whereas RER and polysomes extend well into the dendrites, the mRNAs that are transported and translated in dendrites are a subset of the total neuronal mRNA, deficient in some mRNA species (such as neurofilament mRNAs) and enriched in mRNAs with dendritic functions (such as microtubule-associated protein, MAP2, mRNAs). Also, certain proteins appear to be targeted, postsynthesis, to the dendritic compartment as well.

The shapes and complexity of dendritic arborizations may be remarkably plastic. Dendrites appear relatively late in development and initially have only limited numbers of branches and spines. As development and maturation of the nervous system proceed, the size and number of branches increase. The number of spines increases dramatically, and their distribution may change. This remodeling of synaptic connectivity may continue into adulthood, and environmental effects can alter this pattern significantly. Eventually, in the aging brain, there is a reduction in complexity and size of dendritic arbors, with fewer spines and thinner dendritic shafts. These changes correlate with changes in neuronal function during development and aging.

As defined by classical physiology, axons are structural correlates for neuronal output, and dendrites constitute the domain for receiving information. The functional and morphological hallmarks of axons and dendrites are listed in Table 4.1. A neuron without an axon or one without dendrites might therefore seem paradoxical, but such neurons do exist. Certain amacrine and horizontal cells in the vertebrate retina have no identifiable axons, although they do have dendritic processes

TABLE 4.1 Functional and Morphological Hallmarks of Axons and Dendrites[a]

Axons	Dendrites
With rare exceptions, each neuron has a single axon	Most neurons have multiple dendrites arising from their cell bodies
Axons appear first during neuronal differentiation	Dendrites begin to differentiate only after the axon has formed
Axon initial segments are distinguished by a specialized plasma membrane containing a high density of ion channels and distinctive cytoskeletal organization	Dendrites are continuous with the perikaryal cytoplasm, and the transition point cannot be distinguished readily
Axons typically are cylindrical in form with a round or elliptical cross section	Dendrites usually have a significant taper and small spinous processes that give them an irregular cross section
Large axons are myelinated in vertebrates, and the thickness of the myelin sheath is proportional to the axonal caliber	Dendrites are not myelinated, although a few wraps of myelin may occur rarely
Axon caliber is a function of neurofilament and microtubule numbers with neurofilaments predominating in large axons	The dendritic cytoskeleton may appear less organized, and microtubules dominate even in large dendrites
Microtubules in axons have a uniform polarity with plus ends distal from the cell body	Microtubules in proximal dendrites have mixed polarity, with both plus and minus ends oriented distal to the cell body
Axonal microtubules are enriched in tau protein with a characteristic phosphorylation pattern	Dendritic microtubules may contain some tau protein, but MAP2 is not present in axonal compartments and is highly enriched in dendrites
Ribosomes are excluded from mature axons, although a few may be detectable in initial segments	Both rough endoplasmic reticulum and cytoplasmic polysomes are present in dendrites, with specific mRNAs being enriched in dendrites
Axonal branches tend to be distal from the cell body	Dendrites begin to branch extensively near the perikaryon and form extensive arbors in the vicinity of the perikaryon
Axonal branches form obtuse angles and have diameters similar to the parent stem	Dendritic branches form acute angles and are smaller than the parent stem
Most axons have presynaptic specializations that may be *en passant* or at the ends of axonal branches	Dendrites are rich in postsynaptic specializations, particularly on the spinous processes that project from the dendritic shaft
Action potentials are usually generated at the axon hillock and conducted away from the cell body	Some dendrites can generate action potentials, but more commonly they modulate the electrical state of the perikaryon and initial segment
Traditionally, axons are specialized for conduction and synaptic transmission—that is, neuronal output	Dendritic architecture is most suitable for integrating synaptic responses from a variety of inputs—that is, neuronal input

[a]*Neurons typically have two classes of cytoplasmic extensions that may be distinguished using electrophysiological, morphological, and biochemical criteria. Although some neuronal processes may lack one or more of these features, enough parameters can generally be defined to allow unambiguous identification.*

that are morphologically distinct from axons. Such dendritic processes may have both pre- and postsynaptic specializations or may have gap junctions that act as direct electrical connections between two cells. Similarly, the pseudounipolar sensory neurons of dorsal root ganglia (DRG) have no dendrites. In their mature form, these DRG sensory neurons give rise to a single axon that extends a few hundred micrometers before branching. One long branch extends to the periphery, where it may form a sensory nerve ending in muscle spindles or skin. Large DRG peripheral branches are myelinated and have the morphological characteristics of an axon, but they contain neither pre- nor postsynaptic specializations. The other branch extends into the central nervous system, where it forms synaptic contacts. In DRG neurons, the action potential is generated at distal sensory nerve endings and is then transmitted along the peripheral branch to the central branch and the appropriate central nervous system (CNS) targets, bypassing the cell body.

Summary

Neurons are polarized cells that are specialized for membrane and protein synthesis, as well as for conduction of the nerve impulse. In general, neurons have a cell body, a dendritic arborization that is usually located near the cell body, and an extended axon that may branch considerably before terminating to form synapses with other neurons.

PROTEIN SYNTHESIS IN NERVOUS TISSUE

Both neurons and glial cells have strikingly extended morphologies. This cytoarchitecture is ideal for a tissue whose functions depend on multiple intercellular contacts locally and at great distances. Protein and lipid components are synthesized and assembled into the membranes of these cell extensions through pathways of membrane biogenesis that have been elucidated primarily in other cell types, including the yeast *Saccharomyces cerevisiae*. However, some adaptations of these general mechanisms have been necessary, due to the specific requirements of cells in the nervous system. Neurons, for example, have devised mechanisms for ensuring that the specific components of the axonal and dendritic plasma membranes are selectively delivered (targeted) to each plasma membrane subdomain.

The distribution to specific loci of organelles, receptors, and ion channels is critical to normal neuronal function. In turn, these loci must be "matched" appropriately to the local microenvironment and specific cell–cell interactions. Similarly, in myelinating glial cells during the narrow developmental window when the myelin sheath is being formed, these cells synthesize vast sheets of insulating plasma membrane at an unbelievably high rate. To understand how the plasma membrane of neurons and glia might be modeled to fit individual functional requirements, it is necessary to review the progress that has been made so far in our understanding of how membrane components and organelles are generated in eukaryotic cells.

There are two major categories of membrane proteins: integral and peripheral. Integral membrane proteins, which include receptors for neurotransmitters (e.g., acetylcholine receptor subunits) and polypeptide growth factors (e.g., the dimeric insulin receptor) as well as ion channels, have segments that are either embedded in the lipid bilayer or bound covalently to molecules that insert into the membrane, such as those proteins linked to glycosyl phosphatidylinositol at their C termini (e.g., Thy–1). A protein with a single membrane-embedded segment and an N terminus exposed at the extracellular surface is said to be of type I, whereas type II proteins retain their N termini on the cytoplasmic side of the plasma membrane. Peripheral membrane proteins are localized on the cytoplasmic surface of the membrane and do not cross any membrane during their biogenesis. They interact with the membrane either by means of their associations with membrane lipids or the cytoplasmic tails of integral proteins or by means of their affinity for other peripheral proteins (e.g., platelet-derived growth factor receptor-Grb2-Sos-Ras complex). In some cases, they may bind directly to the polar head groups of the lipid bilayer (e.g., myelin basic protein).

Integral Membrane and Secretory Polypeptides Are Synthesized *de Novo* in the Rough Endoplasmic Reticulum

Subcellular destinations for integral and peripheral membrane proteins may be determined by their sites of synthesis. In the secretory pathway, integral membrane proteins and secretory proteins are synthesized in the rough endoplasmic reticulum, whereas the mRNAs encoding peripheral proteins are translated on cytoplasmic "free" polysomes, which are not membrane associated but may interact with cytoskeletal structures.

The pathway by which secretory proteins are synthesized and exported was first postulated through the elegant ultrastructural studies on the pancreas by George Palade and colleagues (Palade, 1975). Pancreatic acinar cells were an excellent choice for this work because they are extremely active in secretion, as revealed by the abundance of their RER network, a property they share with neurons. Nissl deduced, in the nineteenth century, that pancreatic cells and neurons would be found to have common secretory properties (Fig. 4.2), because of similarities in the distribution of the Nissl substance.

Pulse–chase autoradiography revealed that newly synthesized secretory proteins move from the RER to the Golgi apparatus, where the proteins are packaged

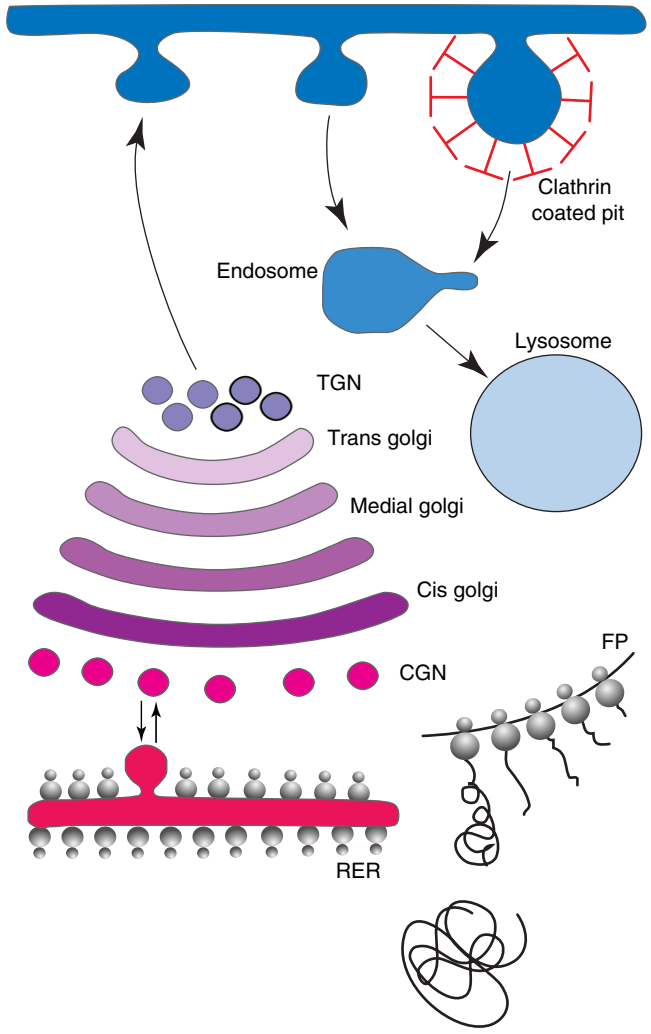

FIGURE 4.2 The secretory pathway. Transport and sorting of proteins in the secretory pathway occur as they pass through the Golgi complex before reaching the plasma membrane. Sorting occurs in the *cis*-Golgi network (CGN), also known as the intermediate compartment, and in the *trans*-Golgi network (TGN). Proteins exit from the Golgi complex at the TGN. The default pathway is the direct route to the plasma membrane. Proteins bound for regulated secretion or for transport to endosomes and from there to lysosomes are diverted from the default path by means of specific signals. In endocytosis, one population of vesicles is surrounded by a clathrin cage and is destined for late endosomes.

into secretory granules and transported to the plasma membrane, from which they are released by exocytosis. Pulse–chase studies in neurons reveal a similar sequence of events for proteins transported into the axon (Brady, 1985). Unraveling the detailed molecular mechanisms of the pathway began with the successful reconstitution of secretory protein biosynthesis *in vitro* and the direct demonstration that, very early during synthesis, secretory proteins are translocated into the lumen of RER vesicles, prepared by cell fractionation, termed microsomes. A key observation here was that the fate of the protein was sealed as a result of encapsulation in the lumen of the RER at the site of synthesis. This cotranslational insertion model provided a logical framework for understanding the synthesis of integral membrane proteins with a transmembrane orientation.

The process by which integral membrane proteins are synthesized closely follows the secretory pathway, except that integral proteins are of course not released from the cell, but instead remain within cellular membranes (Rapoport, 2007). Synthesis of integral proteins begins with synthesis of the nascent chain on a polysome that is not yet bound to the RER membrane (Fig. 4.3). Emergence of the N terminus of the nascent protein from the protein synthesizing machinery allows a ribonucleoprotein, a signal recognition particle (SRP), to bind to an emergent hydrophobic signal sequence and prevent further translation (Walter & Johnson, 1994). Translation arrest is relieved when SRP docks with its cognate receptor in the RER and dissociates from the signal sequence in a process that requires GTP. Synthesis of transmembrane proteins on RER is an extremely energy-efficient process. The passage of a fully formed and folded protein through a membrane is, thermodynamically, formidably expensive; it is infinitely "cheaper" for cells to thread amino acids, in tandem, through a membrane during initial protein synthesis.

Protein synthesis then resumes, and the emerging polypeptide chain is translocated into the RER membrane through a conceptualized "aqueous pore" termed the translocon. Several proteins have been identified in cross-linking experiments as possible components of the translocon, including translocating chain-associating membrane protein (TRAM) and translocon-associated protein a (TRAP), which is a component of the mammalian homologue of the yeast sec 61 complex. Many others are strikingly similar to proteins that were originally discovered in yeast, revealing the common conserved nature of this process in organisms as diverse as yeasts and humans.

A few polypeptides deviate from the common pathway for secretion. For example, certain peptide growth factors, such as basic fibroblast growth factor and ciliary neurotrophic factor, are synthesized without signal peptide sequences but are potent biological modulators of

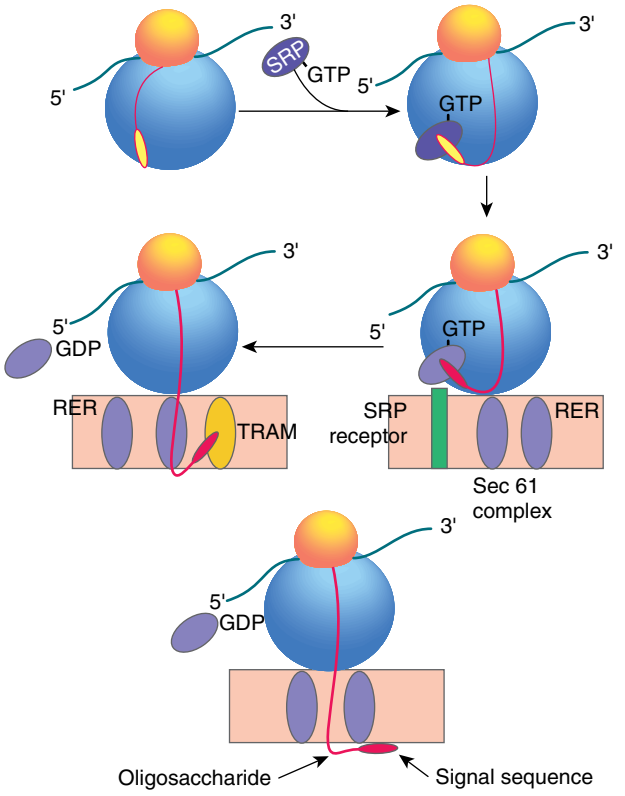

FIGURE 4.3 Translocation of proteins across the rough endoplasmic reticulum (RER). Integral membrane and secretory protein synthesis begins with partial synthesis on a free polysome not yet bound to the RER. The N terminus of the nascent protein emerges and allows a ribonucleoprotein, signal recognition particle (SRP), to bind to the hydrophobic signal sequence and prevent further translation. Translation arrest is relieved once the SRP docks with its receptor at the RER and dissociates from the signal sequence in a process that requires GTP. Once protein synthesis resumes, translocation occurs through an aqueous pore termed the translocon, which includes translocating chain-associating membrane protein (TRAM) and translocon-associated protein (TRAP). The signal sequence is removed by a signal peptidase located in the lumen of the RER.

cell survival and differentiation. These growth factors appear to be released under certain conditions, although the mechanisms for such release are still controversial. One possibility is that release of these factors may be associated primarily with cellular injury.

Two cotranslational modifications are commonly associated with the emergence of the polypeptide on the luminal face of the RER (Fig. 4.3). First, an N-terminal hydrophobic signal sequence that is used for insertion into the RER is usually removed by a signal peptidase. Second, oligosaccharides rich in mannose sugars are transferred from a lipid carrier, dolichol phosphate, to the side chains of asparagine residues (Kornfeld & Kornfeld, 1985). The asparagines must be in the sequence N X T (or S), and they are linked to mannose sugars by two molecules of *N*-acetylglucosamine. Although the prevention of glycosylation of some proteins causes their aggregation and

accumulation in the RER and Golgi apparatus, for most glycoproteins, the significance of glycosylation is not apparent. Neither is it a universal feature of integral membrane proteins: some proteins, such as the proteolipid proteins of CNS myelin, neither lose their signal sequence nor become glycosylated, although they do appear to be posttranslationally modified by the addition of the fatty acid, palmitic acid. One clear case of a proved function for a carbohydrate moiety is the targeting of proteins to lysosomes in the *trans*-Golgi by means of the mannose 6-phosphate receptor (Braulke & Bonifacino, 2009). Intercellular adhesion molecules, such as selectins, which affect the sticking of lymphocytes to blood vessel walls, appear to interact with lectin-like proteins through their oligosaccharide chains. Similarly, the sialic acid side chains of the neural cell adhesion molecule (NCAM) are essential for modulation of cell–cell adhesion mediated by NCAMs. Thus, for the vast majority of polypeptides destined for release from the cell (secretory polypeptides), an N-terminal "signal sequence" first mediates the passage of the protein into the RER and is cleaved immediately from the polypeptide by a signal peptidase residing on the luminal side of the RER. For proteins destined to remain as permanent residents of cellular membranes (and these form a particularly important and diverse category of plasma membrane proteins in neurons and myelinating glial cells), however, many variations on this basic theme have been found. Simply stated:

1. Signal sequences for membrane insertions need not be only N-terminal; those that lie within a polypeptide sequence are not cleaved.
2. A second type of signal, a "halt" or "stop" transfer signal, functions to arrest translocation through the membrane bilayer. The halt transfer signal is also hydrophobic and is usually flanked by positive charges. This arrangement effectively stabilizes a polypeptide segment in the RER membrane bilayer.
3. The sequential display in tandem of insertion and halt transfer signals in a polypeptide as it is being synthesized ultimately determines its disposition with respect to the phospholipid bilayer, and thus its final topology in its target membrane. By synthesizing transmembrane polypeptides in this way, virtually any topology may be generated.

Newly Synthesized Polypeptides Exit from the RER and Are Moved through the Golgi Apparatus

When the newly synthesized protein has established its correct transmembrane orientation in the RER, it is incorporated into vesicles and must pass through the Golgi complex before reaching the plasma membrane (Fig. 4.2). For membrane proteins, the Golgi serves two major functions: it sorts and targets proteins, and it performs further posttranslational modifications, particularly on the oligosaccharide chains that were added in the RER (Glick & Nakano, 2009). Sorting takes place in the *cis*-Golgi network (CGN), also known as the intermediate compartment, and in the *trans*-Golgi network (TGN), whereas sculpting of oligosaccharides is primarily the responsibility of the *cis*-, *medial*-, and *trans*-Golgi stacks. The TGN is a tubulovesicular network wherein proteins are targeted to the plasma membrane or to organelles.

In addition to the processing of carbohydrates in the Golgi, posttranslational modifications can take place in other subcellular compartments. Some protein glycosylations are modified further post-Golgi in components of the smooth endoplasmic reticulum or transport vesicles, as described later in this section. Finally, some neuropeptides (vasopressin, enkephalins, etc.) are synthesized as sequence domains in large precursor proteins that must be cleaved in transit by specific proteases to form the biologically active form.

The CGN serves an important sorting function for proteins entering the Golgi from the RER. Because most proteins that move from the RER through the secretory pathway do so by default, any resident endoplasmic reticulum proteins must be restrained from exiting or returned promptly to the RER from the CGN should they escape (Dudek et al., 2009). Although no retention signal has been demonstrated for the endoplasmic reticulum, two retrieval signals have been identified: a Lys-Asp-Glu-Leu or KDEL sequence in type I proteins and the Arg-Arg or RR motif in the first five amino acids of proteins with a type II orientation in the membrane. The KDEL tetrapeptide binds to a receptor called Erd 2 in the CGN, and the receptor–ligand complex is returned to the RER. There may also be a receptor for the N arginine dipeptide; alternatively, this sequence may interact with other components of the retrograde transport machinery, such as microtubules.

Movement of proteins between Golgi stacks proceeds by means of vesicular budding and fusion (Glick & Nakano, 2009). Through the use of a cell-free assay containing Golgi-derived vesicles, the essential mechanisms for budding and fusion have been shown to require coat proteins (COPs) in a manner that is analogous to the role of clathrin in endocytosis. Currently, two main types of COP complex, COPI and COPII, have been distinguished. Although both have been shown to coat vesicles that bud from the endoplasmic reticulum, they may have different roles in membrane trafficking. Coat proteins provide the external frame-work into which a region of a flattened Golgi cisternae can bud and vesiculate. A complex of these COPs forms the coatomer (coat protomer) together with a p200 protein, and a family of

GTP-binding proteins called ADP-ribosylation factors (ARFs), originally named for their role in the action of cholera toxin. Immunolocalization of one of the coatamer proteins, β-COP, predominantly to the CGN and *cis*-Golgi indicates that these proteins may also take part in vesicle transport into the Golgi (Fig. 4.4A). The function of ARF is to drive the assembly of the coatamer and therefore vesicle budding in a GTP-dependent fashion. Dissociation of the coat is triggered when a GTPase-activating protein (GAP) in the Golgi membrane stimulates hydrolysis of the GTP bound to ARF. The cycle of coat assembly and disassembly can continue when the replacement of GDP on ARF by GTP is catalyzed by a guanine nucleotide exchange factor (GEF). The importance of this GDP–GTP exchange to normal vesicular traffic is illustrated dramatically by the effects of brefeldin A, a fungal metabolite that specifically inhibits GTP exchange and disperses the Golgi complex by preventing the return of Golgi components from the intermediate compartment.

Fusion of vesicles with their target membrane in the Golgi apparatus is regulated by a series of proteins, *N*-ethylmaleimide-sensitive factor (NSF), soluble NSF attachment proteins (SNAPs), and SNAP receptors (SNAREs), which together assist the vesicle in docking with its target membrane. In addition, Rabs, a family of membrane-bound GTPases, act in concert with their own GAPs, GEFs, and a cytosolic protein that dissociates Rab–GDP from membranes after fusion called guanine-nucleotide dissociation inhibitor. Rabs are believed to regulate the action of SNAREs, the proteins directly engaged in membrane–membrane contact prior to fusion. The tight control necessary for this process and the importance of ensuring that vesicle fusion takes place only at the appropriate target membrane may explain why eukaryotic cells contain so many Rabs, some of which are known to specifically take part in the internalization of endocytic vesicles at the plasma membrane (Fig. 4.2).

Exocytosis of the neurotransmitter at the synapse must occur in an even more finely regulated manner than endocytosis (Sudhof, 2004). The proteins first identified in vesicular fusion events in the secretory pathway (namely NSF, SNAPs, and SNAREs or closely related homologues) appear to play a part in the fusion of synaptic vesicles with the active zones of the presynaptic neuronal membrane (Fig. 4.4B).

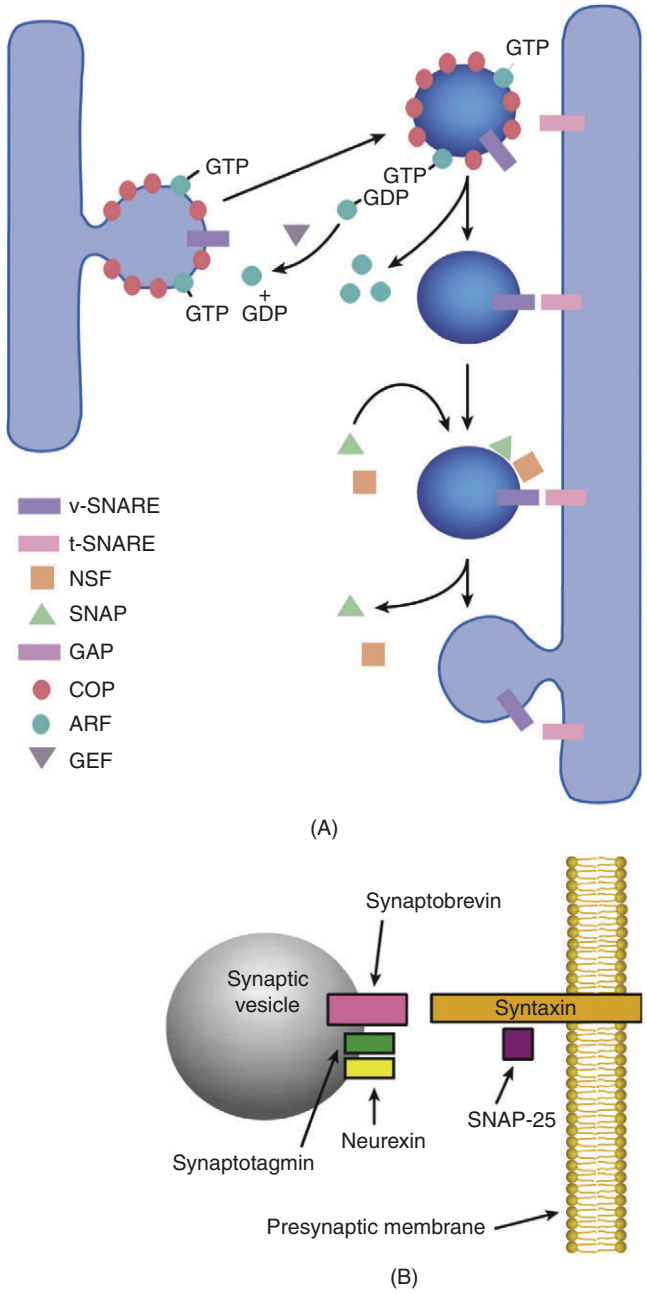

FIGURE 4.4 **A.** General mechanisms of vesicle targeting and docking in the ER and Golgi. The assembly of coat proteins (COPs) around budding vesicles is driven by ADP-ribosylation factors (ARFs) in a GTP-dependent fashion. Dissociation of the coat is triggered when hydrolysis of the GTP bound to ARF is stimulated by a GTPase activating protein (GAP) in the Golgi membrane. The cycle of coat assembly and disassembly can continue when the replacement of GDP on ARF by GTP is catalyzed by a guaninenucleotide exchange factor (GEF). Fusion of vesicles with their target membrane in the Golgi is regulated by a series of proteins, *N*-ethyl-maleimide-sensitive factor (NSF), soluble NSF attachment proteins (SNAPs), and SNAP receptors (SNAREs), which together assist the vesicle in docking with its target membrane. SNAREs on the vesicle (v-SNAREs) are believed to associate with corresponding t-SNAREs on the target membrane. **B.** Mechanisms of vesicle targeting and docking in the synaptic terminal. The synaptic counterpart of v-SNARE is synap-tobrevin (also known as vesicle-associated membrane protein), and syntaxin corresponds to t-SNARE. SNAP-25 is an accessory protein that binds to syntaxin. Synaptotagmin is believed to be the Ca^{2+} sensitive regulatory protein in the complex that binds to syntaxin. Neurexins appear to have a role in conferring Ca^{2+} sensitivity to these interactions.

The synaptic counterpart of vSNARE is synaptobrevin [also known as vesicle-associated membrane protein (VAMP)], and syntaxin corresponds to t-SNARE. SNAP-25 is an accessory protein that binds to syntaxin. In the constitutive pathway, such as between the RER and Golgi apparatus, assembly of the complex at the target membrane promotes fusion. However, at the presynaptic membrane, Ca^{2+} influx is required to stimulate membrane fusion at the presynaptic membrane. Synaptotagmin is believed to be the Ca^{2+}-sensitive regulatory protein in the complex that binds syntaxin. Neurexins appear to have a role in regulation as well, because, in addition to interacting with synaptotagmin, they are the targets of black widow spider venom (α)-latrotoxin, which deregulates the Ca^{2+}-dependent exocytosis of the neurotransmitter.

The comparison between secretion in slow-releasing cells, such as the pancreatic β-cell, and neurotransmitter release at the neuromuscular junction is much like the comparison between a hand-held pocket calculator for balancing a checkbook and a state-of-the-art desktop computer. Two differences stand out. First, the speed of neurotransmitter release is much greater both in release from a single vesicle and in total release in response to a specific signal. Releasing the contents of a single synaptic vesicle at a mouse neuromuscular junction takes from 1 to 2 ms, and the response to an action potential involving the release of many synaptic vesicles is over in approximately 5 ms. In contrast, releasing the insulin in a single secretory granule by a pancreatic β-cell takes from 1 to 5 s, and the full release response may take from 1 to 5 min. A 103- to 105-fold difference in rate is an extraordinary range, making neurotransmitter release one of the fastest biological events routinely encountered, but this speed is critical for a properly functioning nervous system.

A second major difference between slow secretion and fast secretion is seen in the recycling of vesicles. In the pancreas, secretory vesicles carrying insulin are used only once, and so new secretory vesicles must be assembled *de novo* and released from the TGN to meet future requirements. In the neuron, the problem is that the synapse may be at a distance of 1 m or more from the protein synthetic machinery of the perikaryon, and so newly assembled vesicles even traveling at rapid axonal transport rates (see later) may take more than a day to arrive. Now, the number of synaptic vesicles released in 15 min of constant stimulation at a single frog neuromuscular junction has been calculated to be on the order of 105 vesicles, but a single terminal may have only a few hundred vesicles at any one time. These measurements would make no sense if synaptic vesicles had to be replaced constantly through new synthesis in the perikaryon, as is the case with insulin-carrying vesicles. The reason that these numbers are possible is that synaptic vesicles are taken up locally by endocytosis, refilled with neurotransmitter, and reutilized at a rate fast enough to keep up with normal physiological stimulation levels. This takes place within the presynaptic terminal, and evidence shows that these recycled synaptic vesicles are used preferentially (Sudhof, 2004). Such recycling does not require protein synthesis because the classical neurotransmitters are small molecules, such as acetylcholine, or amino acids, such as glutamate, that can be synthesized or obtained locally. Significantly, neurons have fast and slow secretory pathways operating in parallel in the presynaptic terminal (Sudhof, 2004). Synapses that release classical neurotransmitters (acetylcholine, glutamate, etc.) with these fast kinetics also contain dense core granules containing neuropeptides (calcitonin gene related peptide, substance P, etc.) that are comparable to the secretory granules of the pancreatic β-cell. These are used only once because neuropeptides are produced from large polypeptide precursors that must be made by protein synthesis in the cell body. The release of neuropeptides is relatively slow; as is the case in endocrine release, neuropeptides serve primarily as modulators of synaptic function. The small, clear synaptic vesicles containing the classic neurotransmitters can in fact be depleted pharmacologically from the presynaptic terminal, while the dense core granules remain. These observations indicate that even though fast and slow secretory mechanisms have many similarities and may even have common components, in neurons they can operate independent of one another (Xu & Xu, 2008).

Proteins Exit the Golgi Complex at the *trans*-Golgi Network

Transport of cargoes in vesicles beyond the TGN is believed to involve coat proteins other than the classical COPs. These are the adaptins, which form Adaptor Protein (AP) complexes. The APs were until recently considered to comprise four families (AP-1-4) where AP-1 and AP-2 segregated their cargoes to clathrin-coated vesicles, whereas AP-3 and AP-4 did not appear to require clathrin. In general it is believed that AP-1 and AP-4 are involved in moving vesicles between the TGN and endosomes, AP-2 is specialized for endocytosis, and AP-3 ferries cargoes from endosomes to lysosomes. Interestingly, mutations in AP-4 cause cerebral palsy, intellectual disability, and spastic paraplegia. Recently a fifth AP complex, AP-5, has been identified that also appears to be involved in endosomal trafficking. Defects in AP-5 have been linked to spastic paraplegia (Hirst et al., 2011).

Most of the N-linked oligosaccharide chains acquired at the RER are remodeled in the Golgi cisternae, and while the proteins are in transit, another type of glycosyl

linkage to serine or threonine residues through *N*-acetylgalactosamine can also be made. Modification of existing sugar chains by a series of glycosidases and the addition of further sugars by glycosyl transferases occur from the *cis* to the *trans* stacks. Some of these enzymes have been localized to particular cisternae. For example, the enzymes (β)-1,4-galactosyltransferase and (α)-2,6-sialyltransferase are concentrated in the *trans*-Golgi. How they are retained there is a matter of some debate. One idea is that these proteins are anchored by oligomerization. Another view is that the progressively rising concentration of cholesterol in membranes more distal to the ER in the secretory pathway increases membrane thickness, which in turn anchors certain proteins and causes an arrest in their flow along the default route.

The default or constitutive pathway seems to be the direct route to the plasma membrane taken by vesicles that bud from the TGN (Fig. 4.2). This is how, in general, integral plasma membrane proteins reach the cell surface. Proteins bound for regulated secretion or for transport to endosomes and from there to lysosomes are diverted from the default path by means of specific signals. It has been assumed that the sorting of proteins for their eventual destination takes place at the TGN itself. However, recent analyses of the three-dimensional structure of the TGN have provoked a revision of this view. These studies have shown that the TGN is tubular, with two major types of vesicles that bud from distinct populations of tubules. The implication is that sorting may already have occurred in the *trans*-Golgi prior to the proteins' arrival at the TGN. One population of vesicles consists of those surrounded by the familiar clathrin cage, which are destined for late endosomes. The β-COP protein and related coatomer proteins active in more proximal regions of the secretory pathway are absent from the TGN.

Endocytosis and Membrane Cycling Occurs in the *trans*-Golgi Network

Two types of membrane invagination occur at the surface of mammalian cells and are clearly distinguishable by electron microscopy (Doherty & McMahon, 2009). The first type is a caveola, which has a thread-like structure on its surface made of the protein caveolin. Caveolae mediate the uptake of small molecules such as vitamin folic acid by a process called potocytosis. They may also have a role in concentrating proteins linked to the plasma membrane by the glycosylphosphatidylinositol anchor. Demonstration of the targeting of protein tyrosine kinases to caveolae by the tripeptide signal MGC (Met-Gly-Cys) also suggests that caveolae may function in signal transduction cascades.

The other type of endocytic vesicle at the cell surface is that coated with the distinctive meshwork of clathrin triskelions (Doherty & McMahon, 2009). The triskelion comprises three copies of a clathrin heavy chain and three copies of a clathrin light chain. The ease with which these triskelions can assemble into a cage structure demonstrates how they promote the budding of a vesicle from a membrane invagination. Clathrin binds selectively to regions of the cytoplasmic surface of membranes that are selected by adaptins. The AP-2 complex, which is primarily active at the plasma membrane, consists of 100-kDa α and β subunits and two subunits of 50 and 17 kDa each. AP-1 complexes localize to the TGN and have γ and subunits of 100 kDa together with smaller polypeptides of 46 and 19 kDa. Adaptins bind to the cytoplasmic tails of membrane proteins, thus recruiting clathrin for budding at these sites.

A further component of the endocytic complex at the plasma membrane is GTPase dynamin, which seems to be required for the normal budding of coated vesicles during endocytosis. Dynamins are a family of 100-kDa GTPases found in both neuronal and nonneuronal cells and may interact with the AP-2 component of a clathrin-coated pit (Doherty & McMahon, 2009). Dynamin I is found primarily in neurons, whereas dynamin II has a widespread distribution. Oligomers of dynamin form a ring at the neck of a budding clathrin-coated vesicle, and GTP hydrolysis appears to be necessary for the coated vesicle to pinch off from the plasma membrane. The existence of a specific neuronal form of dynamin may be a manifestation of the unusually rapid rate of synaptic vesicle recycling.

The primary function of clathrin-coated vesicles at the plasma membrane is to deliver membrane proteins together with any ligands bound to them to the early endosomal apparatus. The other major site of action of clathrin is in vesicles that bud from the TGN carrying lysosomal enzymes en route to late endosomes. Early endosomes have a tubulovesicular morphology. Receptors that will be recycled back to the plasma membrane partition into the tubules; those endocytosed proteins destined for lysosomes concentrate in the vesicular regions. Recycling seems to be the default pathway, whereas proteins must be actively targeted to lysosomes. However, the precise signals for this are unknown.

Regulation of membrane cycling in the endosomal compartment is likely to include the Rab family of small GTP-binding proteins (Zerial & McBride, 2001). Indeed, each stage of the endocytic pathway may have its own Rab protein to ensure efficient targeting of the vesicle to the appropriate membrane. Rab6 is believed to have a role in transport from the TGN to endosomes, whereas Rab9 may regulate vesicular flow in the reverse direction. In neurons, Rab5a has a role in regulating the fusion of endocytic vesicles and early endosomes and appears to function in endocytosis from both somatodendritic domains and the axon. The association of the

protein with synaptic vesicles in nerve terminals, attached presumably by means of its isoprenoid tail, also suggests that early endosomal compartments may have a role in the packaging and recycling of synaptic vesicles.

Lysosome Is the Target Organelle in Several Inherited Diseases that Affect the Nervous System

Lysosomes were first isolated and characterized as a distinct organelle fraction bounded by a single membrane and separable from mitochondria by differential and sucrose gradient centrifugation. Because of their high content of acid hydrolases, the classic view is that lysosomes are organelles of terminal degradation. Indeed, the latency of hydrolase activity before membrane permeabilization by agents such as nonionic detergents has been used biochemically as a measure of the purity and intactness of lysosomal preparations. However, in addition to their well-established function in lipid and protein breakdown, tubulovesicular lysosomes may overlap in sorting functions with early endosomes, particularly during antigen processing in macrophages.

Inherited deficiencies in lipid metabolism in the lysosome often have particularly devastating consequences on the nervous system because of the abundance of the lipid-rich membrane myelin. Metachromatic leukodystrophy is an autosomal recessive disease caused by a deficiency in arylsulfatase A activity, which is also responsible for degrading the myelin lipid cerebroside sulfate (sulfatide). Oligodendrocytes accumulate sulfatide in metachromatic granules, causing severe disruption of myelination. Peripheral nerve myelination is also affected, as are other organs that normally contain much lower amounts of sulfatide, such as the kidney, the liver, and the endocrine system. Krabbe disease, or globoid cell leukodystrophy, is also a dysmyelinating disease in which there is an almost complete lack of oligodendrocytes and therefore myelin, caused by a deficiency in the β-galactosidase responsible for hydrolyzing galactocerebroside to ceramide and galactose. Galactocerebroside is particularly abundant in myelin, constituting about 25% of myelin lipid. Mice that lack galactocerebroside have the ability to assemble multilamellar myelin; however, this myelin does not support adequate nerve conduction, and is not stable. Unlike metachromatic leukodystrophy, Krabbe disease is limited to the CNS and peripheral nervous system (PNS). However, why a buildup of galactocerebroside should prove particularly toxic to oligodendrocytes is not entirely clear. One hypothesis is that a metabolite of galactocerebroside, galactosphingosine (psychosine), is the primary culprit.

How are proteins destined to operate in lysosomes targeted to these organelles? Soluble lysosomal hydrolase enzymes acquire a phosphorylated mannose on their oligosaccharide chains by a two-step process in the Golgi apparatus (Braulke & Bonifacino, 2009). This mannose 6-phosphate label is recognized by specific mannose 6-phosphate receptors, which carry the proteins to late endosomes. In contrast, lysosomal membrane proteins are targeted by means of cytoplasmic tail signals that contain either leucine or tyrosine of type LJ or type YXXJ or NXXY, where J is any hydrophobic amino acid. The LJ signal seems to be essential for efficient delivery directly to endosomes, whereas the second type of signal seems to be more important in the recovery of proteins destined for lysosomes from the plasma membrane. The majority of lysosomal membrane proteins have the YXXJ but do not have the LJ signal. The implication of these observations is that many of the lysosomal membrane proteins make their way to lysosomes from the TGN endosomes through the plasma membrane.

What are the receptors for the type LJ or the type YXXJ or NXXY motifs at the TGN? Because transport from the TGN to the endosomes occurs in clathrin-coated vesicles, the proteins that link such vesicles to membranes, the adaptins, may play a role. The weight of the evidence suggests that AP-1 recognizes the LJ sequence, whereas AP-2 identifies the YXXJ and NXXY motifs. Once the ligands are bound, these adaptins would direct transport of their respective ligands to the endosomes from the TGN or through the plasma membrane, respectively. At present, it is not clear how proteins in the late endosome, such as mannose 6-phosphate receptors, that cycle back to the Golgi are sorted from those whose ultimate destination is a lysosome.

How are Peripheral Membrane Proteins Targeted to Their Appropriate Destinations?

Peripheral membrane proteins are synthesized in the same type of free polysome in which the bulk of the cytosolic proteins are made. However, the cell must ensure that these membrane proteins are sent to the plasma membrane rather than allowed to attach in a haphazard way to other intracellular organelles. The fact that complex machinery has evolved to ensure the correct delivery of integral membrane proteins suggests that some equivalent targeting mechanism must exist for proteins that attach to the cytoplasmic surface of the plasma membrane. Such proteins are translated on "free" polysomes, but these polysomes are associated with cytoskeletal structures and are not distributed uniformly throughout the cell body. In a number of cases, mRNAs that encode soluble cytosolic proteins are

concentrated in discrete regions of the cell, resulting in a local accumulation of the translated protein close to the site of action. For some peripheral membrane proteins, this is the plasma membrane.

Evidence that this mechanism might operate in peripheral membrane protein synthesis came from studies showing biochemically and by *in situ* hybridization that mRNAs encoding the myelin basic proteins are concentrated in the myelinating processes that extend from the cell body of oligodendrocytes (Colman, Kreibich, Frey, & Sabatini, 1982). Myelin basic protein may be a special case because of its very strong positive charge and consequent propensity for binding promiscuously to the negatively charged polar head groups of membrane lipids. Nevertheless, the fact that actin mRNAs are localized to the leading edge of cultured myocytes and mRNA for the microtubule-associated protein MAP2b is concentrated in the dendrites of neurons suggest that targeting by local synthesis is more common than originally thought. This mechanism is probably less important for peripheral membrane proteins that associate with the cytoplasmic surface of the plasma membrane by means of strong specific associations with proteins already located at the membrane because such proteins would act as specific receptors. Because only selected cytoplasmic mRNAs are localized to the periphery, the process is specific. However, no mRNAs are localized exclusively to the periphery, and a significant fraction is typically localized proximal to the nucleus in a region rich with translational and protein-processing machinery of the cell (the Nissl substance or translational cytoplasm).

Special Mechanisms Are Used to Target Proteins to Mitochondria and Peroxisomes

The inner membrane of the mitochondrion is the site of oxidative phosphorylation in which the step-by-step transfer of electrons from oxygen intermediary metabolites to molecular oxidation is coupled to proton transport and ATP synthesis. Thus, this organelle has an essential role in providing the large amount of ATP required for the electrical activity of neurons. The fact that, in a resting adult, about 40% of the total energy consumption is required for ion pumping in the CNS accounts for the exquisite sensitivity of the brain to damage from oxygen deprivation. The sensitivity of neurons to interruptions in the provision of ATP by the mitochondrion is also seen in cases of uremia, where a buildup of ammonium ions depletes the Krebs cycle of α-oxoglutaric acid by converting it into glutamate.

Although the mitochondrion has its own circular DNA that encodes some proteins, most mitochondrial proteins are synthesized in the nucleocytoplasmic system (Endo & Yamano, 2009). This poses the problem of how these proteins once made in the cytoplasm gain entry into the mitochondrion. Furthermore, because the mitochondrion has an inner and an outer membrane, some proteins must cross two membranes to gain access to the inner matrix. This group of proteins includes the enzymes of the Krebs cycle and the fatty acid β-oxidation pathway.

Unlike proteins inserted into the RER, mitochondrial proteins can be imported either posttranslationally or cotranslationally with the use of a cleavable amphipathic helical signal sequence usually at the N terminus. At the RER, the signal sequence of a nascent polypeptide chain can be translocated across the membrane because the polypeptide remains small and unfolded due to the arrest of translation caused by a signal recognition particle. However, mitochondrial proteins are typically synthesized on cytoplasmic or free polysomes and must be folded at least partially to prevent degradation. For posttranslational import, mitochondria rely on a group of molecular chaperones to prevent complete folding of the polypeptides. These hsp70 and hsp60 proteins were originally identified because they are upregulated during heat shock. Their role in binding to proteins and maintaining them in specific conformations helps explain why these proteins have an important function in protecting proteins against the stress of elevated temperatures, as well as facilitating the proper folding of newly synthesized polypeptides. In yeast, a second protein, Ydj1p, whose bacterial homologue DnaJ regulates chaperone function has been identified. Ydj1p possesses an isoprenoid tail linked to its C-terminal amino acid, which may serve to anchor the protein to the outer membrane. The third factor that has been implicated is the mitochondrial stimulation factor, which is a heterodimer possessing an ATP-dependent protein "unfoldase" activity. This factor may be more important in cotranslational import where polysomes are known to be associated with the mitochondrial outer membrane.

Most of our current understanding of protein translocation from the mitochondrial outer membrane inward has come from studies on either the fungus *Neurospora crassa* or the yeast *S. cerevisiae*. In both yeast and higher eukaryotes, the partially folded polypeptide targeted for the mitochondrion may be stabilized by a cytoplasmic chaperone that is a member of the hsp70 family, but this interaction is not required for import. However, several proteins in the outer membrane form an essential complex that acts as a receptor and pore for protein translocation. This complex can in turn interact with an inner membrane complex at specialized contact sites that minimize the distance across the two membranes, thereby facilitating the movement of proteins to the inner matrix. Although both pores can function independently, they contact and cooperate when there is

a transmembrane potential across the inner membrane. This accounts for early observations showing that importation of subunits of the F1-ATPase, an inner membrane protein, required an active electron transport chain but did not need ATP synthesis. The mitochondrial import sequence extends through the pore into the inner matrix, where a second member of the hsp70 family binds and facilitates movement into the inner matrix. After proteins have crossed into the inner matrix, they must dissociate from hsp70 in order to fold properly, a process that requires another kind of molecular chaperone, hsp60.

Peroxisomes are so named because they contain oxidases that generate H_2O_2 and the enzyme catalase, which is responsible for detoxifying it. In addition, these organelles contain many other enzymes that take part in lipid, purine, and amino acid metabolism. Peroxisomes are of interest because of the number of inherited diseases associated with defects either in certain enzymes or indeed in the assembly of the organelle itself. Some of these diseases manifest as particularly damaging to the nervous system and include adrenoleukodystrophy (accumulation of very long chain fatty acids due to insufficient lignoceryl-CoA ligase activity caused by inefficient import of the protein) and Refsum disease (buildup of phytanic acid due to defective α-oxidation), both of which cause demyelination.

Like many mitochondrial proteins, peroxisomal proteins are imported posttranslationally (Ma, Agrawal, & Subramani, 2011). Although cytosolic factors are implicated in peroxisomal biogenesis, no peroxisomal chaperones analogous to the hsp70 family have yet been shown to function in protein import. Therefore, unfolding and refolding are assumed not to play a role in the accumulation of proteins inside the peroxisome. Among these cytosolic proteins is presumed to be the receptor for the tripeptide C-terminal import signal SKL (Ser-Lys-Leu) known as peroxisomal targeting signal 1 (PTS1). In addition to C-terminal PTS1, some peroxisomal proteins have a cleavable N-terminal sequence called PTS2, which signals their import. A quite distinct translocation machinery appears to operate for PTS1 and PTS2 proteins. Two possible receptor proteins in the peroxisomal membrane, one of which is the adrenoleukodystrophy protein (ALDP), have been identified. ALDP is a member of a larger family known as ABC ATP-dependent membrane transporters.

A characteristic feature of peroxisomal biogenesis is that it is stimulated by drugs whose detoxification requires peroxisomal activity. It is possible that mature peroxisomes are recruited from a pool of precursor organelles, and there is some evidence for the existence of such a population in rat liver. Although the mature organelle appears to be spherical, electron microscopic evidence suggests a peroxisomal reticulum in which synthesis and protein import may take place. Mature peroxisomes might then arise from this reticulum by a process of budding.

Cytoplasmic Proteins Are also Compartmentalized

Membrane-bound organelles are the most familiar form of compartmentation in cells, but cytoplasmic regions of the cell containing metabolic compartments exist as well. Regions of the neuronal or glial cytoplasm may have highly specialized polypeptide compositions that are important for function. For example, the neuronal phosphoprotein synapsin is highly enriched in presynaptic terminals, where it participates in the localization and targeting of synaptic vesicles. Similarly, calmodulin and the glycolytic enzyme aldolase have been localized in muscle cells to the region of the I-band, where they are thought to facilitate coupling of ATP production to contractility.

As mentioned earlier, cytoplasmic proteins are synthesized on cytoplasmic polysomes, termed "free" polysomes to reflect an absence of underlying ER membrane, even though they may be restricted to specific domains of the cell cytoplasm. This restriction is particularly obvious in the neuronal perikaryon, where both cytoplasmic polysomes and membrane-associated polysomes are concentrated in areas near the nucleus and Golgi complex. In addition, cytoplasmic polysomes containing specific mRNAs may be localized to certain regions of the cell, such as the proximal dendrite (those encoding the microtubule-associated protein MAP-2) and the processes of oligodendrocytes (those encoding myelin basic protein). In contrast, the protein synthetic machinery of the polysome appears to be effectively excluded from the mature axon. Therefore, cytoplasmic polysomes are representative of cytoplasmic compartmentation for proteins and nucleic acids.

In most cases, localized cytoplasmic proteins interact with cytoskeletal structures in the cytoplasm (see next section), but macromolecular complexes that form in order to make a cellular process more efficient or free from error have been described. Evidence exists that glycolytic enzymes of neurons and muscle cells may be organized in a labile complex that facilitates energy metabolism, but the existence of such complexes remains controversial.

Perhaps the best characterized cytoplasmic macromolecular complex is the proteasome, which is a large protein complex (2×10^6 Da, sedimenting as a 20S particle) that contains several distinct enzymatic activities, including catalytic sites for both ubiquitin-dependent and ubiquitin-independent proteolysis (Hochstrasser, 1995). Ubiquitin is a small, highly conserved polypeptide that is added covalently to cytoplasmic proteins

targeted for degradation. The catalytic core of the proteasome is a barrel-shaped structure formed by four heptameric stacked rings, but additional proteins (about 16 polypeptides) may interact with the 20S core to form a larger 26S particle. Because proteasomes constitute the primary cytoplasmic pathway for protein degradation (i.e., nonlysosomal pathways), they serve a number of important physiological functions, including regulation of cell proliferation and processing of antigens for presentation. In the nervous system, however, proteasomes are likely to be most important for homeostasis, allowing turnover of cytoplasmic polypeptides at specific sites so that the elaborate cellular extensions of neurons and glia may be maintained.

Cytoplasmic proteins may also be compartmentalized effectively by posttranslational modification. Two types of modification may be particularly important for this kind of compartmentalization. Local activation of kinases can lead to the phosphorylation of proteins in specific domains of the neuron. For example, the reversible phosphorylation of synapsin in the presynaptic terminal appears to be responsible for the targeting of synaptic vesicles to the terminal and for the mobilization of vesicles during prolonged stimulation. An impressive variety of cytoplasmic protein kinases that may be selectively activated to modify serines or threonines presented in distinctive consensus sequences have been described. Distinct from these serine or threonine kinases, a number of other kinases that specifically modify tyrosines can be found in the brain. In some cases, the tyrosine kinase is linked directly to a membrane-spanning receptor and phosphorylates cytoplasmic proteins in the vicinity of the receptor after activation. Completing the cycle of phosphorylation and dephosphorylation are a number of phosphatases with varying specificities. The properties and physiological roles for kinases and phosphatases are discussed in greater detail later.

A second common posttranslational modification of cytoplasmic proteins is the addition of carbohydrate moieties. Whereas modification of membrane-associated proteins in the Golgi complex proceeds by the addition of complex carbohydrates through N linkages on selected asparagines, glycosylated cytoplasmic proteins have simpler carbohydrates added through O linkages to serine or threonine hydroxyls. This modification was first recognized as a feature of many nuclear proteins and components of the nuclear membrane, but subsequent studies showed that a number of cytoplasmic proteins also have O-linked carbohydrates. Unlike phosphorylation, relatively little is known about the functional significance of cytoplasmic glycosylation. Remarkably, however, serines and threonines subject to O-linked glycosylation would also be good sites for phosphorylation by various kinases as well. This congruence raises the possibility that glycosylation and phosphorylation of some cytoplasmic proteins may serve complementary functions.

Summary

Membrane biogenesis and protein synthesis in neurons and glial cells are accomplished by the same mechanisms that have been worked out in great detail in other cell types. Integral membrane proteins are synthesized in the rough endoplasmic reticulum, and peripheral membrane proteins are products of cytoplasmic-free ribosomes that are found in the cell sap. For transmembrane proteins and secretory polypeptides, synthesis in the RER is followed by transport to the Golgi apparatus, where membranes and proteins are sorted and targeted for delivery to precise intracellular locations. It is likely that the neuron and glial cell have evolved additional highly specialized mechanisms for membrane and protein sorting and targeting because these cells are so greatly extended in space, although these additional mechanisms have yet to be fully described. The basic features of the process of secretion, which includes neurotransmitter delivery to presynaptic terminals, are beginning to be understood as well. The key features of this process are apparently common to all cells, including yeast, although the neuron has developed certain specializations and modifications of the secretory pathway that reflect its unique properties as an excitable cell.

CYTOSKELETONS OF NEURONS AND GLIAL CELLS

The cytoskeleton of eukaryotic cells is an aggregate structure formed by three classes of cytoplasmic structural proteins: microtubules (tubulins), microfilaments (actins), and intermediate filaments. Each of these elements exists concurrently and independently in overlapping cellular domains. Most cell types contain one or more examples of each class of cytoskeletal structure, but there are exceptions. For example, mature mammalian erythrocytes contain no microtubules or intermediate filaments, but they do have highly specialized actin cytoskeletons. Among cells of the nervous system, the oligodendrocyte is unusual in that it contains no cytoplasmic intermediate filaments. Typically, each cell type in the nervous system has a unique complement of cytoskeletal proteins that are important for the differentiated function of that cell type (Pigino, Song, Kirkpatrick, & Brady, 2011).

Although the three classes of cytoskeletal elements interact with each other and with other cellular structures, all three are dynamic structures rather than passive structural elements. Their aggregate properties

form the basis of cell morphologies and plasticity in the nervous tissue. In many cases, biochemical specialization in the cytoskeleton is characteristic of a particular cell type, function, and developmental stage. Each type of cytoskeletal element has unique functions that are essential for a working nervous system.

Microtubules Are an Important Determinant of Cell Architecture

Microtubules are nearly ubiquitous components of the cytoskeleton in eukaryotes. They play key roles in intracellular transport, are a primary determinant of cell morphology, are the structural correlate of the mitotic spindle, and form the functional core of cilia and flagella. Microtubules are very abundant in the nervous system, and tubulin subunits of microtubules may constitute more than 10% of total brain protein. As a result, many fundamental properties of microtubules have been defined by using microtubule protein prepared from brain extracts. At the same time, the microtubule cytoskeleton of the neuron has a variety of biochemical specializations that meet the unique demands imposed by the size and shape of the neuron.

Of the various functions defined for microtubules, intracellular transport and the generation of cellular morphology are the most important roles played by microtubules in cells of the nervous system. In part, this comes from their ability to organize cytoplasmic polarity. Microtubules *in vitro* are dynamic, polar structures with plus and minus ends that correspond to the fast- and slow-growing ends, respectively. In contrast, both stable and labile microtubules can be identified *in vivo*, where they help define both microscopic and macroscopic aspects of intracellular organization in cells. Microtubule organization, stability, and composition in nervous tissue are all highly regulated in the nervous system.

By electron microscopy, microtubules appear as hollow tubes 25 nm in diameter and in axons can be up to hundreds of micrometers in length. High resolution electron micrographs also reveal that the walls of microtubules typically comprise 13 protofilaments formed by a linear arrangement of globular subunits, although microtubules with 12 to 14 protofilaments exist in some tissues and organisms. Globular subunits in the walls of a microtubule are heterodimers of α- and β-tubulin, whereas a variety of microtubule-associated proteins bind to the surface of microtubules.

Neuronal microtubules are remarkable for their genetic and biochemical diversity. Multiple genes exist for both α-and β-tubulins. These genes are expressed differentially according to cell type and developmental stage. Some of these genetic isotypes are expressed ubiquitously, whereas others are only turned on at specific times in development, in specific cell types, or both. Most tubulin genes are expressed in nervous tissue, and some appear to be enriched or specific to neurons. When specific isotypes are prepared in a pure form, they show variability in assembly kinetics and ability to bind ligands. However, when more than one isotype is expressed in a single cell, such as a neuron, they coassemble into microtubules with mixed composition.

A variety of posttranslational modifications of tubulins have been described, the most common of which are tyrosination–detyrosination, acetylation–deacetylation, and phosphorylation. The first two of these pathways are associated intimately with the assembly of microtubules, but relatively little is known about physiological functions for any of these modified tubulins. Most α-tubulin isotypes are synthesized with a Glu-Tyr dipeptide at the C terminus (Tyr-tubulin), but the tyrosine can be removed by a specific tubulin carboxypeptidase after assembly into a microtubule, leaving a terminal glutamate (Glu-tubulin). When microtubules containing detyrosinated α-tubulins are disassembled, the liberated α-tubulins are retyrosinated rapidly by a specific tubulin tyrosine ligase. The result is that microtubules that have been assembled for an extended period of time will tend to be rich in Glu-tubulin. The tyrosination state of α-tubulin does not affect its assembly–disassembly kinetics *in vitro*, but evidence suggests that detyrosination may affect the interaction of microtubules with other cellular structures. In parallel with detyrosination, α-tubulins are also substrates for a specific acetylation reaction. Acetylation of tubulin was initially described for flagellar tubulins, but subsequent work demonstrated that this modification was widespread in neurons and many other cell types. Because the acetylase acts preferentially on α-tubulin assembled into microtubules, long-lived or stable microtubules tend to be rich in acetylated α-tubulin. However, the distribution of microtubules rich in acetylated tubulin may not be identical with that of Glu-tubulin. Acetylated α-tubulin is also deacetylated rapidly upon disassembly of microtubules, although acetylation does not alter the stability of microtubules *in vitro*.

In contrast with these modifications, tubulin phosphorylation involves a β-tubulin and appears to be restricted to an isotype expressed preferentially in neurons and neuron-like cells. A variety of kinases have been shown to phosphorylate tubulin *in vitro*, but the endogenous kinase has not been identified. The effect of phosphorylation on assembly is unknown, but phosphorylation is upregulated during neurite outgrowth. As with α-tubulin modifications, the physiological role of phosphorylation on neuronal β-tubulin has yet to be determined. A variety of additional posttranslational modifications have been reported, but their significance

and distribution in the nervous system are not well documented.

The biochemical diversity of microtubules is increased through the association of different MAPs with different populations of microtubules (Table 4.2). The significance of microtubule diversity is not completely understood, but it may include functional differences as well as variations in assembly and stability. In particular, MAP composition may be used to define specific neuronal domains. For example, one type of MAP, MAP-2, appears to be restricted to dendritic regions of the neuron, whereas another class of MAPs, tau proteins, are modified differentially in axons. A recently identified isoform of MAP-2 is similar to MAP-2c but includes an additional repeat within the microtubule-binding site; hence it is known as 4-repeat MAP-2c, or MAP-2d.57. Oligodendrocyte progenitors transiently express this novel isoform of MAP-2c in their cell bodies but not in their processes, suggesting that MAP-2d might have a role separate from its known capacity to bundle microtubules (Vouyiouklis & Brophy, 1995).

MAPs in nervous tissue fall into two heterogeneous groups: tau proteins and high molecular weight MAPs. Tau proteins have been the subject of intense interest because posttranslationally modified tau proteins are the primary polypeptide constituents of neurofibrillary tangles from the brains of Alzheimer patients. Tau proteins appear to be neuronal MAPs, although reports of tau immunoreactivity outside neurons have appeared. Tau proteins bind to microtubules during assembly–disassembly cycles with a constant stoichiometry and can promote microtubule assembly and stabilization. However, recent evidence suggests a role for tau protein as a scaffold for signaling molecules and localizing these pathways to the microtubule that may be more important than stabilization in the mature neuron. Tau exists in a number of molecular weight isoforms that vary with region of the nervous system and developmental stage. For example, tau proteins in the adult CNS are typically from 60 to 75 kDa, whereas PNS axons contain a higher molecular mass tau of approximately 100 kDa. The different isoforms of tau protein are generated from a single mRNA by alternative splicing, and additional heterogeneity is produced by phosphorylation.

In contrast with tau MAPs, high molecular weight MAPs are a diverse group of largely unrelated proteins found in a variety of tissues, although some are brain specific. Most have apparent molecular mass of 1300 kDa or more and form side arms protruding from the walls of microtubules. Many of them may participate in microtubule assembly and cytoskeletal organization but may also serve as scaffolds. Traditionally, the high molecular weight MAPs comprise five polypeptides: MAPs 1a, 1b, 1c, 2a, and 2b. MAP-2 proteins are closely related and are located primarily in dendrites. In contrast, the three polypeptides known as MAP-1 are unique polypeptides with little sequence homology. MAP-1c is a cytoplasmic form of dynein (see the section on molecular motors later in this chapter). MAPs 1a and 1b are widespread and appear to be regulated developmentally. MAPs 1a, 1b, and 2 are all thought to play important roles in stabilizing and organizing the microtubule cytoskeleton.

TABLE 4.2 Major Microtubule Proteins and Microtubule Motors in Mammalian Brain

	Location and Function
Tubulins	
α-and β-tubulins	Neurons, glia, and nonneuronal cells except mature mammalian erythrocytes. Multigene family with some genes expressed preferentially in brain, whereas others are ubiquitous. Primary structural polypeptides of microtubules
γ-Tubulin	Present near microtubule-organizing center in all microtubule-containing cells. Needed for nucleation of microtubules
	Microtubule-Associated Proteins (MAPs)
MAP-1a/1b	Widely expressed in neurons and glia, including both axons (MAP-1b) and dendrites (MAP-1a); developmentally regulated phosphoproteins.
MAP-2a/2b MAP-2c	Dendrite-specific MAPs. The smaller MAP-2c is regulated developmentally, becoming restricted to spines in adults, whereas 2a and 2b are major phosphoproteins in adult brain
LMW tau HMW tau	Tau proteins are enriched in axons with a distinctive phosphorylation pattern. A single tau gene is alternatively spliced to give multiple isoforms. LMW tau is found in the CNS and HMW tau is seen in the mature PNS
Katanin and Spastin	Microtubule severing proteins that release MTs from the microtubule organizing center (K) or play a role in branching of neurites (K and S)
	Motor Proteins
Kinesin-1	Plus-end directed motors associated with membrane-bound organelles to move them along microtubules in fast axonal transport.
Kinesin-related proteins	A diverse set of motor proteins with a kinesin-related motor domain and varied tails. Many are regulated developmentally and some are mitotic motors, restricted to dividing cells. May be plus- or minus-end-directed motors
Axonemal dynein	A set of minus-end-directed microtubule motors associated with cilia and flagella, such as ependymal cells.
Cytoplasmic dynein (MAP-1c)	Cytoplasmic form of minus-end-directed microtubule-based motor may be involved in the axonal transport of both organelles or cytoskeletal elements

In most cell types, cytoplasmic microtubules appear to be relatively dynamic structures, although stable microtubules or microtubule segments are found in all cells. In nonneuronal cells such as astrocytes and other glial cells, microtubules are typically anchored in centrosomal regions that serve as microtubule organizing centers. As a result, their cytoplasmic microtubules are oriented so that plus ends are distal to the cell center. The biochemistry of microtubule organizing centers is not fully understood, but they contain a novel tubulin subunit, γ-tubulin, which is thought to function as a nucleating site for microtubules. In contrast, dendritic and axonal microtubules of neurons are not continuous with the microtubule organizing center, so alternate mechanisms must exist for stabilization and organization of these microtubules. The situation is complicated further by the fact that dendritic and axonal microtubules differ in both composition and organization. Studies show that both axonal and dendritic microtubules are nucleated at the microtubule-organizing center but are subsequently released for delivery to the appropriate compartment through the action of the microtubule severing protein, katanin (Roll-Mecak & McNally, 2010). Surprisingly, axonal and dendritic compartments are not equivalent. There are two striking differences. First, MAPs of dendritic and axonal microtubules are different in both identity and phosphorylation state. Second, microtubule orientation in axons is similar to that seen in other cell types with the plus end distal, but microtubules in dendrites may exhibit both polarities. Perhaps due to these differences, dendritic microtubules are less likely to be aligned with one another and appear less regular in their spacing.

Stabilization of axonal and dendritic microtubules is essential because of the volume of cytoplasm and distance from sites of protein synthesis for tubulin. Because microtubules play critical roles in both dendritic and axonal function, mechanisms to ensure their proper extent and organization must exist. A common side effect of one class of antineoplastic drugs, the vinca alkaloids, underscores the importance of microtubule stability in axons. Vincristine and other vinca alkaloids act by destabilizing spindle microtubules, but dosage must be monitored carefully to prevent the development of peripheral neuropathies due to loss of axonal microtubules.

Axonal microtubules contain a particularly stable subset of microtubule segments that are resistant to depolymerization by antimitotic drugs, cold, and calcium. The stable microtubule segments are biochemically distinct and may constitute more than half of the axonal tubulin. Stable domains in microtubules may serve to regulate the axonal cytoskeleton by nucleating and organizing microtubules as well as stabilizing them. The biochemical basis of microtubule stability is not completely understood but probably includes posttranslational modification of the tubulin, the presence of stabilizing proteins, or both. There are indications that levels of cold-insoluble tubulin correlate with axonal plasticity. In contrast, relatively little is known about the regulation of dendritic microtubules, but local synthesis of MAP-2 in dendrites may play a role in regulating their stability.

Microfilaments and the Actin-Based Cytoskeleton Are Involved in Intracellular Transport and Cell Movement

The actin cytoskeleton is universally present in eukaryotes, although actin microfilaments are most familiar as the thin filaments of skeletal muscle. Microfilaments (Table 4.3) play a critical role in contractility for both muscle and nonmuscle cells. Actin and its contractile partner myosin are particularly abundant in nervous tissue relative to other nonmuscle tissues (Letourneau, 2009). In fact, one of the earliest descriptions of nonmuscle actin and myosin was in brain (Berl, Puszkin, & Nicklas, 1973). In neurons, actin microfilaments are most abundant in presynaptic terminals, dendritic spines, growth cones, and the subplasmalemmal cortex. Although concentrated in these regions, microfilaments are also present throughout the cytoplasm of both neurons and glia in the form of short filaments from 4 to 6 nm in diameter and from 400 to 800 nm in length.

As with tubulin, multiple actin genes exist in both vertebrates and invertebrates. Four α-actin human genes have been cloned. Each of these α-actin genes is expressed specifically in a different muscle cell type (skeletal, cardiac, vascular smooth, and enteric smooth muscle). In addition to α-actins, two nonmuscle actin genes (β-and γ-actin) are present in humans. β-Actin

TABLE 4.3 Selected Proteins of the Microfilament Cytoskeleton in Brain

Actins
α-actin (smooth and skeletal muscle)
β-actin and γ-actin (neuronal and nonneuronal cells)
Actin monomer-binding proteins
Profilin
Thymosin 4 and 10
Capping proteins
EB1, EB3
Ezrin/radixin/moesin
Schwannomin/merlin
Gelsolin and other microfilament severing proteins
Gelsolin
Villin
Cross-linking and bundling proteins
Spectrin (fodrin)
Dystrophin, utrophin, and related proteins
α-Actinin
Tropomyosin
Myosins I, II, V, VI, VII

and γ-actin genes are expressed ubiquitously, and both are abundant in nervous tissue. The functional significance of these different genetic isotypes is not clear because the actins are highly conserved proteins. Across the range of known actin sequences, the amino acids are identical at approximately two of three positions. Even the positions of introns within different actin genes are highly conserved across many species and genes. Despite this high degree of conservation, differences in the distribution of specific isotypes within a single neuron have been reported. For example, β-actin may be enriched in growth cones. The prominent actin bundles seen in fibroblasts and some other nonneuronal cells in culture are not characteristic of neurons, and most neuronal actin microfilaments are less than 1 μm in length.

Many microfilament-associated proteins have been described in nervous tissue (myosin, tropomyosin, spectrin, α-actinin, etc.), but less is known about their distribution and normal function in neurons and glia. Myosins and myosin-associated proteins are considered later in the section on molecular motors, but several categories of actin-binding proteins can be defined (Table 4.3). Monomer actin-binding proteins such as profilin and thymosin β4 or β10 are abundant in the developing brain and are thought to help regulate the amount of actin assembled into microfilaments by sequestering actin monomers. These monomers can be mobilized rapidly in response to appropriate signals. For example, phosphatidylinositol 4,5-bisphosphate causes the actin–profilin complex to dissociate, freeing the monomer for microfilament assembly. Such regulation may play a key role in growth cone motility, where actin assembly is an important mechanism for filopodial extension.

Several proteins that can cap actin microfilaments, serving to anchor them to other structures or to regulate microfilament length, have been identified. The ezrin–radixin–moesin gene family encodes barbed-end capping proteins that are concentrated at sites where the microfilaments meet the plasma membrane, suggesting a role in anchoring microfilaments or linking them to extracellular components through membrane proteins. A mutation in a member of this family expressed in Schwann cells, merlin or schwannomin, is responsible for the human disease neurofibromatosis type 2. Development of numerous tumors with a Schwann cell lineage in neurofibromatosis type 2 suggests that this microfilament-binding protein acts as a tumor suppressor.

Whereas some membrane proteins can interact directly with actin microfilaments of the membrane cytoskeleton, others interact with the actin cytoskeleton through intermediaries such as spectrin. Proteins such as spectrin (fodrin), α-actinin, and dystrophins cross-link, or bundle, microfilaments, giving rise to higher order complexes. Spectrin is enriched in the cortical membrane cytoskeleton and is thought to have a role in the localization of integral membrane proteins such as ion channels and receptors. Dystrophin is the best-known member of a family of related proteins that all appear to be essential for the clustering of receptors in muscle and nervous tissue. A mutation in dystrophin is responsible for Duchenne muscular dystrophy. Positioning of integral membrane proteins on the cell surface is likely to be an essential function of the actin-rich membrane cytoskeleton, acting in concert with a class of proteins that contain the protein-binding module, the PDZ domain, a motif that typically interacts with the C-terminus of transmembrane proteins.

Members of the gelsolin family have multiple activities. They cannot only cap the barbed end of a microfilament, but also sever microfilaments and nucleate microfilament assembly under some circumstances. These severing-capping proteins may be essential for reorganizing the actin cytoskeleton. Because gelsolin severing activity is Ca^{2+} activated, it may provide a mechanism for altering the membrane cytoskeleton in response to Ca^{2+} transients. Other second messengers, such as phosphatidylinositol 4,5-bisphosphate, may also serve as regulators of gelsolin function, suggesting an interplay between different classes of actin-binding proteins such as gelsolin and profilin. Oligodendrocytes are the only nonneuronal cells in the CNS that express significant amounts of the actin-binding and microfilament-severing protein gelsolin (Tanaka & Sobue, 1994).

Proteins with other functions may also interact directly with actin or actin microfilaments. For example, the enzyme DNase I binds actin tightly, inhibiting both DNase activity and actin assembly. The physiological function of this interaction is unclear, but it has proved a useful tool for probing actin structure and function. Some membrane proteins, such as the epidermal growth factor receptor, bind actin microfilaments directly, which may be important in anchoring these membrane components at a particular location on the cell surface. Other cytoskeletal structures may have specific interactions. Both MAP-2 and tau microtubule-associated proteins have been shown to interact with actin microfilament *in vitro* and have the potential to mediate interactions between microtubules and microfilaments. Finally, the synaptic vesicle-associated phosphoprotein, synapsin I, has a phosphorylation-sensitive interaction with microfilaments that appears to be important for the targeting and storage of synaptic vesicles in the presynaptic terminal. Many of these interactions have been defined by *in vitro*–binding studies, and their physiological significance is not always clearly established. However, there is little doubt that interactions occur between the actin cytoskeleton and a variety of other cellular structures.

The presence of actin as a major component of both pre- and postsynaptic specializations, as well as in the growth cone, gives the actin cytoskeleton special significance in

the nervous system. The enrichment of microfilaments and associated proteins in the membrane cytoskeleton means that they are the cytoskeletal components most subject and most responsive to changes in the local external environment of the neuron.

Microfilaments also play a critical role in positioning the various receptors and ion channels at specific locations on the neuronal surface, such as the initial segment (Grubb & Burrone, 2010). Although many studies have emphasized enrichment of the microfilament cytoskeleton at the plasma membrane, microfilaments are also abundant in the deep cytoplasm. In many respects, the microfilaments may be best regarded as a uniquely plastic component of the neuronal cytoskeleton that plays a critical role in local trafficking of both cytoskeletal and membrane components.

Intermediate Filaments Are Prominent Constituents of Nervous Tissue

Intermediate filaments of the nervous system appear as solid, ropelike fibrils from 8 to 12 nm in diameter that may be many micrometers long (Herrmann, Bar, Kreplak, Strelkov, & Aebi, 2007). Intermediate filament proteins constitute a superfamily of five classes, which have distinctive patterns of expression specific to cell type and developmental stage (Table 4.4).

Type I and type II intermediate filament proteins are keratins, which are hallmarks of epithelial cells. Keratins are not associated with nervous tissue and will not be considered further here. In contrast, all nucleated cells contain type V intermediate filament proteins, the nuclear lamins. Lamins are encoded by the most evolutionarily divergent of the intermediate filament genes, with a distinctive pattern of introns and exons, as well as having a different polypeptide domain structure. Intermediate filaments in the nervous system are all produced by either type III or type IV intermediate filament proteins.

Type III intermediate filaments are a diverse family that includes, among others, vimentin (characteristic of fibroblasts and many embryonic tissues such as embryonic neurons) and glial fibrillary acidic protein (GFAP, a marker for astrocytes and Schwann cells). Type III intermediate filament subunits typically have a molecular mass between 45 and 60 kDa and consist of a conserved rod domain and relatively small gene-specific amino- and carboxy-terminal sequences. As a result, intermediate filaments formed from type III subunits form smooth filaments without side arms. Type III polypeptides can form homopolymers but may also coassemble with other type III intermediate filament subunits.

Another type III intermediate filament protein, peripherin, is unique to neurons and may be coexpressed with neurofilament triplet proteins. Peripherin has a characteristic expression during development and regeneration in specific neuronal populations. It has been shown to coassemble with neurofilament triplet proteins both *in vitro* and *in vivo*, where presumably it can substitute for the low molecular weight neurofilament (NFL). However, whether coassembly is generally the case is not known. Physiological roles for neuron-specific type III intermediate filament polypeptides are uncertain. Unlike type IV intermediate filaments, intermediate filaments made from type III subunits tend to disassemble more readily under physiological conditions. Thus, the presence of type III intermediate filament subunit proteins may produce more dynamic structures, which could be important during development or regeneration.

Although other type III intermediate filament proteins are found in the nervous system, they are generally restricted to glia or to neurons at early stages of differentiation. Vimentin is abundant in a wide variety of cells during early development, including both glioblasts and neuroblasts. Some Schwann cells and astrocytes contain vimentin. Curiously, mature oligodendrocytes do not appear to have any cytoplasmic intermediate filaments; an exception to the general rule that metazoan cells contain all three classes of cytoskeletal structures. Oligodendrocyte precursors do, however, express vimentin and may express GFAP transiently.

In neurons, intermediate filaments typically have side arms that limit packing density, whereas glial intermediate filaments lack side arms and may be very tightly packed. Neuronal intermediate filaments have

TABLE 4.4 Intermediate Filament Proteins of the Nervous System

Class and Name	Cell Type
Types I and II	
Acidic and basic keratins	Epithelial and endothelial cells
Type III	
Glial fibrillary acidic protein	Astrocytes and nonmyelinating Schwann cells
Vimentin	Neuroblasts, glioblasts, fibroblasts, etc.
Desmin	Smooth muscle
Peripherin	Asubset of peripheral and central neurons
Type IV	
NF triplet (NFH, NFM, NFL)	Most neurons, expressed at highest level in large myelinated fibers
α-Internexin	Developing neurons, parallel fibers of cerebellum
Nestin	Early neuroectodermal cells. The most divergent member of this class; some have classified it as a sixth type
Type V	
Nuclear lamins	Nuclear membranes

an unusual degree of metabolic stability, which makes them well suited to the role of stabilizing and maintaining neuronal morphology. The existence of neurofilaments was established for many years before much was known about their biochemistry or function. Neurofilaments could be seen in early electron micrographs, and many traditional histological procedures visualize neurons as a result of a specific interaction of metals with neurofilaments. Recent work on the biochemistry and molecular genetics of intermediate filaments has illuminated many aspects of their function in the nervous system.

The primary type of intermediate filament in neurons is formed from three subunits, the neurofilament triplet, each encoded by a separate gene. Neurofilament triplet proteins are type IV intermediate filament proteins, which are generally expressed only in neurons and have a characteristic domain structure seen in both primary sequence and gene structure. The polypeptides were initially identified from axonal transport studies. Apparent molecular mass for the neurofilament subunits vary widely across species, but mammalian forms typically range from 180 to 200 kDa for the high molecular weight subunit (NFH), from 130 to 170 kDa for the medium subunit (NFM), and from 60 to 70 kDa for the NFL. Interestingly, Schwann cells in damaged peripheral nerves also transiently express NFM and NFL. Neurofilament subunits are phosphorylated in axons, with NFM and NFH having unusually high levels of phosphorylation. In some species, NFH has 50 or more repeats of a consensus phosphorylation site at its carboxy terminus, and levels of NFH phosphorylation indicate that most of these sites are phosphorylated *in vivo*. This high level of phosphorylation in neurofilament subunit tail domains is a distinctive characteristic of neurofilaments.

A second motif characteristic of neurofilaments is the presence of a glutamate-rich region in the tail adjacent to the core rod domain. This glutamate region has particular significance for neuroscientists because it appears to be the basis for the reaction of the classic neurofibrillary silver stains for neurons. These stains were first introduced in the late nineteenth century and have been used extensively by neurohistologists and neuroanatomists from Ramon y Cajal's time to the present day. However, the molecular basis of these neurofibrillary stains was not known until 1968, when F. O. Schmitt showed that neurofibrils were formed by 10-nm-diameter neurofilaments. Remarkably, the ability of isolated neurofilament subunits to react with silver histological stains is retained even after separation in gel electrophoresis for neurofilaments from organisms as diverse as humans, squid, and the marine fanworm, *Myxicola*. Conservation of the glutamate-rich domain suggests both an important functional role for this motif and the early divergence of neurofilaments from the other intermediate filament families.

Neurofilaments formed from neurofilament triplet proteins play a critical role in determining axonal caliber. As mentioned earlier, neurofilaments have characteristic side arms, unique among intermediate filaments; these side arms are formed by NFM and NFH carboxy-terminal regions. Although all three neurofilament subunits contribute to the neurofilament central core, the side arms are formed only by the NFM and NFH subunits. Phosphorylation of NFH and NFM side arms alters charge density on the neurofilament surface, repelling adjacent neurofilaments with a similar charge. The high density of surface charge due to phosphate groups on neurofilaments makes it difficult to imagine a stable interaction between neurofilaments and other structures of like charge. Although many reports refer to cross bridges between neurofilaments, direct studies of interactions between neurofilaments provide little evidence of stable crosslinks between neurofilaments or between neurofilaments and other cytoskeletal structures. However, dynamic interactions between neurofilaments and cellular structures or proteins may be critical for many aspects of neurofilament function and metabolism.

Alteration in expression levels for neurofilament subunits or mutations in neurofilament genes can lead to specific neuropathologies. Overexpression of genes encoding normal NFH or expression of some mutant NFL genes in transgenic mouse models leads to the accumulation of neurofilaments in the cell body and proximal axon of spinal motor neurons. These accumulations are similar to those seen in amyotrophic lateral sclerosis and related motor neuron diseases, leading to the hypothesis that the disruption of normal neurofilament function is a common intermediate in the pathogenesis of motor neuron disease. Similarly, an early indicator of neuropathies caused by neurotoxins such as acrylamide and hexanedione is the accumulation of neurofilaments in either proximal or distal regions of the axon. Disruption of neurofilament organization is a hallmark of pathology for many degenerative diseases of the nervous system, particularly those affecting large myelinated axons such as those of spinal motor neurons. Although altering neurofilament organization can produce pathology, the question of whether neurofilament defects are a primary event in pathogenesis or a manifestation of an underlying metabolic pathology remains controversial in most cases.

Another member of the type IV intermediate filament family, α-internexin, is also expressed only in neurons. Unlike the triplet proteins, α-internexin is expressed preferentially early in development of the nervous system and then disappears from most neurons during maturation. Intermediate filaments containing α-internexin do

persist in portions of the adult nervous system, such as the branched axons of granule cells in the cerebellar cortex. Evidence show that α-internexin can coassemble with members of the neurofilament triplet, but it also forms homopolymeric filaments. The primary sequence of α-internexin has features in common with both NFL and NFM that are thought to form the basis for assembly properties distinct from those of other type IV intermediate filaments.

The final type of intermediate protein present in the nervous system is nestin, which is expressed transiently during early development. Nestin is also expressed in Schwann cells and in the progenitors of oligodendrocytes, which appear late in the development of the embryonic nervous system. Remarkably, nestin appears to be expressed almost exclusively in ectodermal cells after commitment to the neuroglial lineage, but prior to terminal differentiation. At 1250 kDa, nestin is the largest intermediate filament subunit and is the most divergent in sequence with several distinctive features, leading some to classify nestin as a sixth type of intermediate filament protein, whereas others group it with type IV intermediate filaments. Relatively little is known about the assembly properties of nestin *in vivo* or the physiological function of nestin intermediate filaments in neuroectodermal cells.

How Do the Various Cytoskeletal Systems Interact?

Each class of cytoskeletal structures may be found without the others in some cellular domains, but all three classes—microtubules, microfilaments, and intermediate filaments—coexist in many domains. As a result, they inevitably interact. This is not to say that individual cytoskeletal elements are necessarily cross-linked to one another. As mentioned earlier, microtubules and neurofilaments have highly phosphorylated side arms that project from their surfaces. The high density of negative charge on the surface tends to repel structures with a like charge such as other microtubules and neurofilaments. This does not mean that microtubules and neurofilaments do not interact with each other, but it does suggest that such interactions may be transient.

One location containing longer microfilaments and more elaborate organization is the growth cone, which contains bundles of microfilaments in the filopodia, as well as a more dispersed actin network. Neurofilaments are largely excluded from the growth cone, typically extending no further than the neck of the growth cone. In contrast, microtubules and microfilaments play complementary roles in the growth cone itself. Microfilaments are critical in sprouting but appear less critical for elongation, at least over short distances. Disruption of microtubules in the distal neurite does not affect sprouting but does inhibit neurite elongation. It seems likely that microtubules and microfilaments also act synergistically in the function of the axon initial segment. The tips of microtubules are often associated with proteins that appear to regulate their interaction with sub-plasma membrane structures. At the axon initial segment the proteins EB1 and EB3 appear to link microtubules with ankyrin-G, a key interactor with the spectrin-actin cytoskeleton and that is known to play a crucial role in the assembly of this critical neuronal domain.

Summary

The intracellular framework that gives shape to the neuron and glial cell is the cytoskeleton, a complicated set of filaments and tubules and their associated proteins. These organelles are responsible as well for intracellular movement of materials and, during development, for cell migration and plasma membrane extension within nervous tissue.

MOLECULAR MOTORS IN THE NERVOUS SYSTEM

Until 1985, our knowledge of molecular motors in vertebrate cells of any type was restricted to myosins and flagellar dyneins. Myosins had been identified in nervous tissue, but their functions were uncertain. Because the preponderance of evidence indicated that fast axonal transport was microtubule based, there was considerable interest in dyneins in cell cytoplasm. Despite a number of studies, no evidence for a functional cytoplasmic dynein emerged. Worse yet, the characteristic properties of fast organelle movements appeared inconsistent with both myosins and dyneins. Over the past decade, however, we have developed a good but still incomplete understanding of how these motors may work inside cells.

Myosins and dyneins can be distinguished pharmacologically by their differential susceptibility to inhibitors of ATPase activity, but the spectrum of inhibitors active against fast axonal transport fails to match the properties of either myosin or dynein. The most striking difference between inhibitor effects on axonal transport and on myosin or dynein motors was seen in the effect of a non-hydrolyzable analog of ATP. Adenylyl-imidodiphosphate (AMP-PNP) is a weak competitive inhibitor of both myosin and dynein, requiring a 10- to 100-fold excess of analog. In contrast, within minutes of AMP-PNP perfusion into isolated axoplasm, both anterograde and retrograde axonal transport stop. Inhibition by AMP-PNP occurs even in the presence of stoichiometric concentrations of

ATP. Organelles moving in both directions freeze in place and remain attached to microtubules. AMP-PNP weakens the interaction of myosin with microfilaments and of dynein with microtubules, but stabilizes the binding of membrane-bound organelles to microtubules. Thus, the effects of AMP-PNP indicate that movement of membrane-bound organelles in fast axonal transport must require another type of motor, distinct from myosins and dyneins.

The effects of AMP-PNP both demonstrated the existence of a new type of mechanochemical ATPase and provided a basis for identifying its constituent polypeptides. Binding of ATPase to microtubules should be increased by AMP-PNP and decreased by ATP. Polypeptides meeting this criterion were soon identified. The new ATPase was named kinesin, based initially on an ability to move microtubules across glass coverslips as first described in axoplasmic extracts. Studies soon established that kinesin was a microtubule-activated ATPase with minimal basal activity. This combination of ATPase activity and motility *in vitro* confirmed that kinesin was a new class of microtubule-based motor (Brady & Sperry, 1995).

Kinesin has now been identified in a variety of organisms and tissues, leading to an extensive characterization of many biochemical, pharmacological, immunochemical, and molecular properties. Electron microscopic and biophysical analyses reveal kinesin as a long, rod-shaped protein, approximately 80 nm in length. Neuronal kinesin is a heterotetramer with two heavy chains (molecular mass 115–130 kDa) and two light chains (62–70 kDa). Localization of antibodies specific for kinesin subunits by high-resolution electron microscopy of bovine brain kinesin indicates that the two heavy chains are arranged in parallel, forming the heads and much of the shaft, whereas light chains are localized to the fan-shaped tail region (Fig. 4.5).

A variety of approaches have demonstrated that the ATP-binding and microtubule-binding domains of kinesin are in the head regions of the heavy chains, whereas the light chains in the tail region of kinesin appear to bind to membranes. When *in vitro* motility assays are employed for analysis of brain kinesins, movements are directed toward the plus ends of microtubules. Because axonal microtubules are oriented with their plus ends distal from the cell body, this movement would be appropriate for a motor that moves organelles in the anterograde direction.

Neuronal kinesin appears associated with a variety of membrane-bound organelles, including synaptic vesicles, mitochondria, coated vesicles, and lysosomes. The interaction of kinesin and other molecular motors with membrane surfaces is not well understood. In the case of kinesin, the interaction is thought to involve the light chains of kinesin along with the carboxy termini of the heavy chains.

Kinesins have now been shown to be a family of related proteins with a highly conserved domain that includes ATP- and microtubule-binding domains (Hirokawa, Noda, Tanaka, & Niwa, 2009). Many of these kinesin-related polypeptides appear associated with cell division, and kinesin-related proteins in vertebrate tissues are not well characterized. However, multiple members of the kinesin superfamily are expressed in both adult and developing brains. This proliferation of motor proteins has dramatically altered the questions being asked about motor function in the brain. The discovery that ncd, a kinesin-related protein from *Drosophila*, can move structures toward the minus end of microtubules increases the number of potential functions that kinesin family members might serve in nervous tissue still further, perhaps including a role in retrograde transport. Further study is needed to establish specific functions for each member of the kinesin superfamily expressed in neurons or glial cells.

As an indirect result of the discovery of kinesin, one of the high molecular weight microtubule-associated proteins of brain, MAP-1c, was found to be the long sought cytoplasmic form of dynein (Allan, 2011). Both MAP-1c dynein and kinesin can be isolated from bovine brain by incubation of microtubules with nucleotide-free soluble extracts. Both are bound to microtubules under these conditions and released by ATP. MAP-1c dynein moved microtubules *in vitro* with a polarity opposite that seen with kinesin and was identified as a two-headed cytoplasmic dynein using both structural and biochemical criteria. Concurrently, a similar protein was identified in nematodes.

MAP-1c dyneins form a 40-nm-long complex of molecular mass 1.6×10^6 Da, which includes two heavy chains and a number of light chains (Figs. 4.8 and 4.9). Less information is available about the distribution and properties of MAP-1c dyneins than about kinesin. Immunocytochemical studies in nonneuronal cells showed immunoreactivity on mitotic spindles. In addition, a punctate pattern of immunoreactivity also present in interphase cells was thought to be due to dynein bound to membrane-bound organelles. Dyneins are widely thought to be the motor for fast retrograde axonal transport but are also a candidate for a motor in slow axonal transport.

Myosins from muscle were the first molecular motors identified, but in recent years interest in nonmuscle myosins has increased (Foth, Goedecke, & Soldati, 2006). Nonmuscle myosins may be categorized as belonging to one of eight classes, but only a subset has been clearly demonstrated in the nervous system. Nonmuscle myosins in this subset share considerable homology in their motor domains but diverge widely in other domains.

The most familiar of the myosins are the myosin II proteins (Fig. 4.6), which are found in the thick filaments

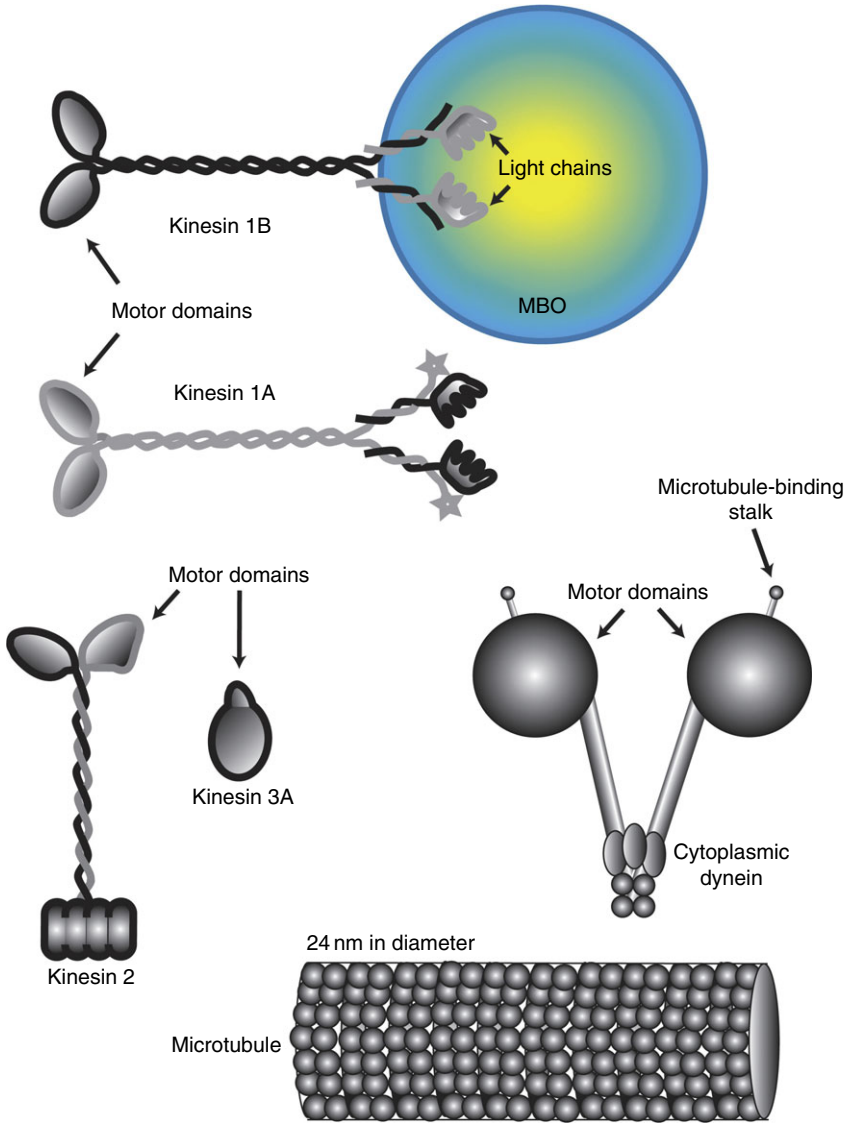

FIGURE 4.5 Examples of microtubule motor proteins in the mammalian nervous system. The first microtubule motor identified in nervous tissue was a kinesin 1, but showed 3 kinesin 1 genes including a neuron-specific form (kinesin 1A). Motor domains are well conserved by tail domains and appear to be specialized for interaction with various targets, such as different membrane-bound organelles. After the sequence of the kinesin heavy chain was established, the presence of additional genes that contained sequences homologous to the motor domain of kinesin was soon recognized. The molecular organization of these various motor proteins is diverse, including monomers (Kinesin 3A), trimers (Kinesin 2), and tetramers (ubiquitous and neuron-specific kinesins). Cytoplasmic dynein may interact with membrane-bound organelles and cytoskeletal structures. Genetic methods have established that there may be more than 40 kinesin-related genes and 16 dynein heavy chains genes in a single organism.

of smooth and skeletal muscle but are also present in nonmuscle cells. Two heavy chains of myosin II form a dimer that may interact with other myosin II dimers to form bipolar filaments. Under tissue culture conditions, many cells contain bundles of actin microfilaments, known as stress fibers, that exhibit a characteristic distribution of myosin II into distinct patterns that may be sarcomeric equivalents, but stress fibers are not apparent in neurons and other cells of the nervous system *in situ*. However, bipolar thick filaments assembled from myosin II dimers can be isolated from nervous tissues. Many of the cellular contractile events described in nonneuronal cells, such as the contractile ring in mitosis, are thought to include myosin II. Although brain myosin II was one of the first nonmuscle myosins to be described, relatively little is known about the function of myosin II in neurons. Myosin II has been localized in the neurites of neurons in primary culture.

Myosin I proteins have a single, smaller heavy chain that does not form filaments but possesses a homologous actinactivated ATPase domain. One exciting aspect of myosin I is its ability to interact directly with membrane

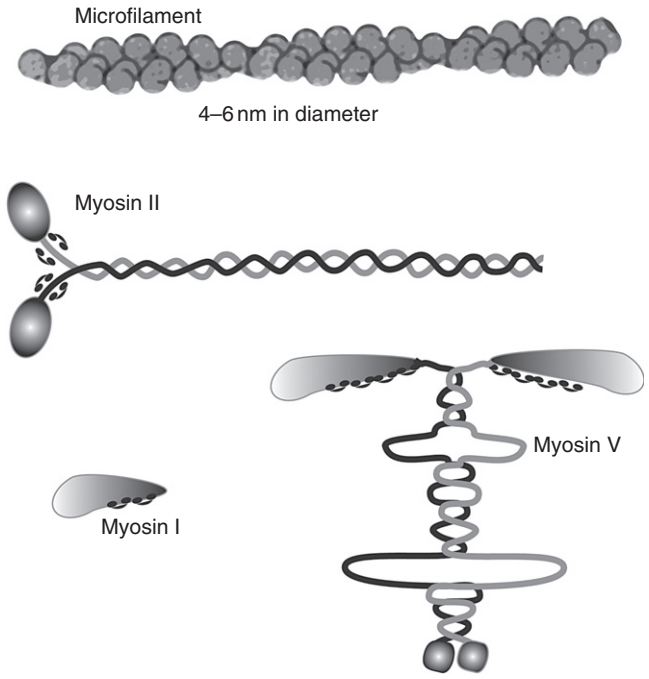

FIGURE 4.6 Examples of myosin motor proteins found in mammalian brain. Myosin heavy chains contain the motor domain, whereas light chains regulate motor function. Myosin II was the first molecular motor characterized biochemically from skeletal muscle and brain. Genetic approaches have now defined more than 15 classes of myosin, many of which are found in brain. Myosin II is a classic two-headed myosin forming thick filaments in nonmuscle cells. Myosin I motors have single motor domains, but may interact with actin microfilaments or membranes. Myosin V has multiple binding sites for calmodulin that act as light chains. Mutations in other classes of myosin have been linked to deafness. Myosins I, II, and V have been detected in growth cones as well as in mature neurons.

surfaces, which may generate movements of plasma membrane components or intracellular organelles. Myosin I has been purified from neural and neuroendocrine tissues. At least three genes in this family have been found in mammals, and multiple forms are present in brain. An interesting aspect of myosin IB is its expression in the stereocilia of hair cells in the cochlea and vestibular system, where it may play a role in mechanotransduction. Both myosin I and myosin II molecules have been proposed to have a role in the motility of lamelipodia at the leading edge of growth cones, but they are also expressed at substantial levels in adult nervous tissue in which growth cones are rare.

The mouse mutation dilute, which affects coat color, was shown to result from a mutation in a gene that encodes a novel myosin heavy chain distinct from both myosins I and II. Similar myosin molecules have been identified in other cell types and organisms and are classified as myosin V. The change in coat color seen in the dilute mouse is due to an inability of skin dendritic pigment cells to deliver the pigment to developing hairs. There are complex neurological deficits in dilute mutants, including seizures that eventually lead to death in severely altered alleles of the dilute mutation. Myosin V was also discovered independently in extracts from chicken and mammalian brain. Myosin V is thought to play a role in the delivery of membrane proteins from the microtubule-based transport system to the plasma membrane. However, neurons in dilute mice without one allele of myosin V clearly develop axons and make connections. The seizures do not begin until early adulthood.

Representatives from two more classes of myosin have been identified in nervous tissue. Genes for a myosin VI and a myosin VIIA have been identified in brain as well as in other tissues. Both have been implicated in forms of congenital deafness. Myosin VI appears to be the gene responsible for Snell's Waltzer deafness, and myosin VIIA has been identified as the gene responsible for a human disease involving both deafness and blindness, Usher syndrome type 1B. Both of these myosins are expressed in mechanosensory hair cells of the cochlea and vestibular apparatus, where they exhibit a different localization from each other and from myosin IB.

The diversity of brain myosins and their distinctive localization suggests that the various myosins may have narrowly defined functions. However, relatively little is known about specific neuronal functions for myosins despite intensive study of myosins in the nervous system. The axonal transport of myosin II-like proteins has been described, but little further progress has been made on the functions of myosin II in the mature nervous system. Even less is known about myosin I in the nervous system. However, myosins likely play roles in growth cone motility, synaptic plasticity, and even neurotransmitter release. There are few instances in our knowledge of neuronal function in which we fully understand the role played by specific molecular motors, but members of all three classes are abundant in nervous tissue. This proliferation of different motor molecules and their isoforms suggests that some physiological activities may require multiple classes of motor molecules.

Summary

The concept is now firmly in place that neurons and glial cells, like other cells, contain molecular motors responsible for moving discrete populations of molecules, particles, and organelles through intracellular compartments.

BUILDING AND MAINTAINING CELLS OF THE NERVOUS SYSTEM

The functional architecture of neurons comprises many specializations in cytoskeletal and membranous components. Each of these specializations is dynamic,

constantly changing, and being renewed at a rate determined by the local environment and cellular metabolism. The processes of axonal transport represent a key to understanding neuronal dynamics and provide a basis for exploring neuronal development, regeneration, and neuropathology. Recent advances are important sources of insight into the molecular mechanisms underlying axonal transport, although many questions remain.

Slow Axonal Transport Moves Soluble Components and Cytoskeletal Structures

Slow axonal transport has two major components, both representing the movement of cytoplasmic constituents (Fig. 4.7). The cytoplasmic and cytoskeletal elements of the axon in axonal transport move at rates at least two orders of magnitude more slowly than fast transport. Slow component a is composed largely of

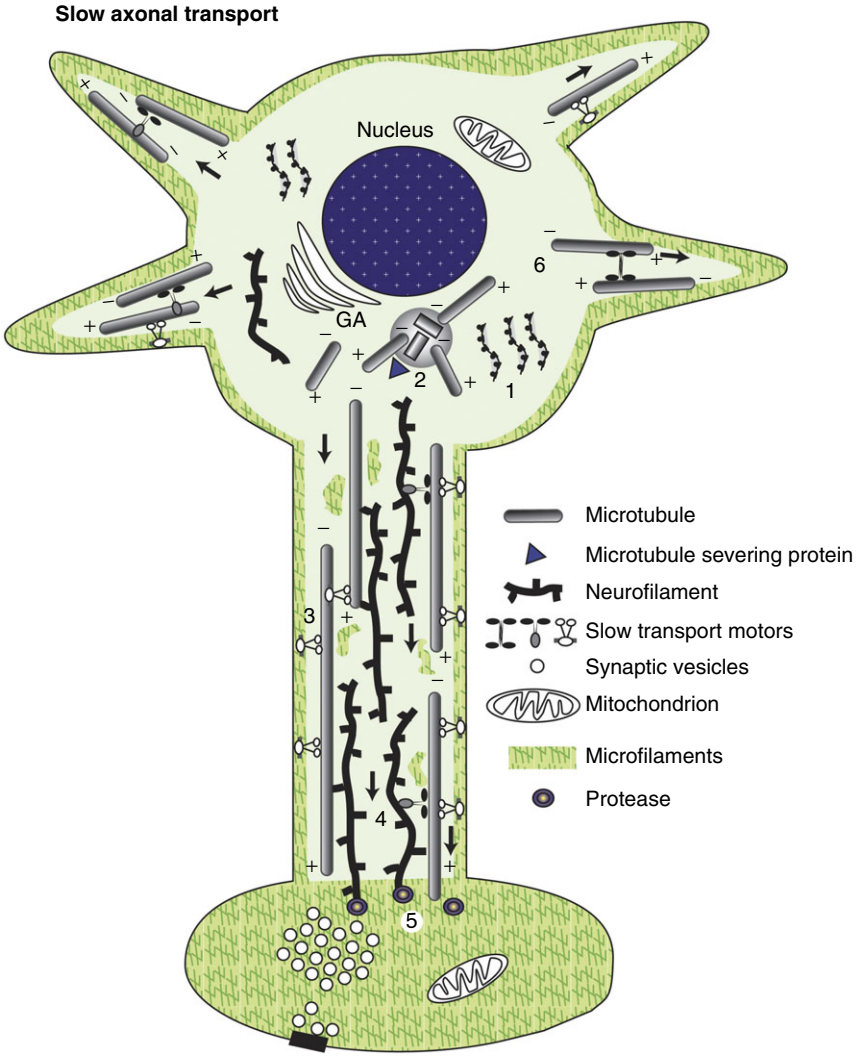

FIGURE 4.7 Slow axonal transport represents the delivery of cytoskeletal and cytoplasmic constituents to the periphery. Cytoplasmic proteins are synthesized on free polysomes and organized for transport as cytoskeletal elements or macromolecular complexes (1). Microtubules are formed by nucleation at the microtubule-organizing center near the centriolar complex (2) and then released for migration into the axon or dendrites. The molecular mechanisms are not as well understood as those for fast axonal transport, but slow transport appears to be unidirectional with no retrograde component. Studies suggest that motors like cytoplasmic dynein may interact with the axonal membrane cytoskeleton to move the microtubules with their plus ends leading (3). Neurofilaments may not be able to move on their own but may hitchhike on microtubules (4). Other cytoplasmic proteins may do the same or may be moved by other motors. Once cytoplasmic structures reach their destinations, they are degraded by local proteases (5) at a rate that allows either growth (in the case of growth cones) or maintenance of steady-state levels. The different composition and organization of the cytoplasmic elements in dendrites suggest that different pathways may be involved in the delivery of cytoskeletal and cytoplasmic materials to the dendrite (6). In addition, some mRNAs are transported into the dendrites, but not into axons.

cytoskeletal proteins, neurofilaments, and microtubule protein. Slow component b is a complex and heterogeneous rate component, including hundreds of distinct polypeptides ranging from cytoskeletal proteins such as actin (and tubulin in some nerves) to soluble enzymes of intermediary metabolism (such as glycolytic enzymes). Many characteristics of axonal transport have been described, and these characteristics provide the foundation for our understanding of mechanisms.

Neurofilaments and microtubules move as discrete cytological structures (Baas & Buster, 2004). Studies on the transport of neurofilament protein indicate that little degradation or metabolism occurs until neurofilaments reach nerve terminals, where they are degraded rapidly. Comparable results have been obtained in studies labeling microtubule protein by radioactivity or fluorescence. Under favorable conditions, movement of individual microtubules can be detected in neurites or growth cones. Both radiolabeling studies and direct observations of individual microtubules indicate that all microtubules and neurofilaments move down the axon, but the motor protein involved is uncertain. Differential metabolism appears to be a key to the targeting of cytoplasmic and cytoskeletal proteins. Proteins with slow degradative rates accumulate and reach higher steady-state concentrations. Alteration of degradation rates changes the steady-state concentration of a protein. The concentration of actin in presynaptic terminals is explained by a slower turnover in terminals relative to neurofilament proteins and tubulin, and inhibition of calpain causes neurofilament rings to appear in presynaptic terminals. Differential turnover may be accomplished by specific proteases or posttranslational modifications that affect the susceptibility to degradation.

The coherent movement of neurofilaments and microtubule proteins provides strong evidence for the "structural hypothesis." For example, pulse-labeling experiments show that radiolabeled neurofilament proteins move as a bell-shaped wave with little or no trailing of neurofilament protein. This fits with the observed stability of neurofilaments under physiological conditions. Thus, any soluble pool of neurofilament subunits is negligible. Similarly, the coherent transport of tubulin and MAPs makes sense only if microtubules are moved because MAPs do not interact with unpolymerized tubulin.

A striking demonstration of microtubule movement can be seen with fluorescent analogs of tubulin (Brown, 2003). When local segments of an axon are photoactivated, short fluorescent microtubule segments can be seen to move down the growing neurite. These microtubules move rapidly (1–2 μm/sec) with frequent pauses that produce a net anterograde transport of microtubules at 1–2 mm/day and similar rates are observed for neurofilaments. When studies of axonal transport using radiolabeled amino acids are combined with direct observations of individual microtubules or neurofilaments by video microscopy, there is little doubt that microtubules and neurofilaments can and do move in the axon as intact, individual cytoskeletal elements.

More recently, similar methods have been used to document the transport of classically soluble, cytoplasmic proteins like glycolytic enzymes and synuclein (Roy, Winton, Black, Trojanowski, & Lee, 2007). As with microtubules and neurofilaments, these movements are intermittent and rapid. The extended pauses lead to a net rate of anterograde transport of approximately 2–4 mm/day, consistent with rates obtained in pulse-chase radiolabel studies.

Fast Axonal Transport Is the Means by Which Membrane Vesicles and their Contents Are Rapidly Moved Long Distances within a Neuron

Early biochemical and morphological studies established that the material moving in fast axonal transport was associated with membrane-bound organelles (Fig. 4.8) (Brady, 1993). A variety of materials could be shown to move in fast transport. In anterograde transport, materials being moved include membrane-associated enzyme activities, neurotransmitters, and neuropeptides. Many of the materials moving down the axon in anterograde transport are returned in retrograde transport, in some cases after modification in the terminal. In addition, a number of exogenous materials taken up in the distal regions of the axon are moved back to the cell body by retrograde transport. Exogenous materials in retrograde transport include neurotrophic factors, such as nerve growth factor, and viral particles invading the nervous system. The uptake of neurotrophic factors may play a critical role in the process of regeneration.

Electron microscopic analysis of materials accumulated at a ligation or crush demonstrated that organelles moving in the anterograde direction were morphologically distinct from those moving in the retrograde direction (Tsukita & Ishikawa, 1980). Consistent with the ultrastructural differences, radiolabel and immunocytochemical studies indicate that there are both quantitative and qualitative differences between anterograde and retrograde moving material. Differences between anterograde and retrograde transport indicate that some processing or repackaging events must occur as part of turnaround in axonal transport. Turnaround processing appears to require a proteolytic event because certain protease inhibitors inhibit turnaround without affecting anterograde and retrograde transport.

Biochemical and morphological approaches resulted in considerable progress toward a description of the

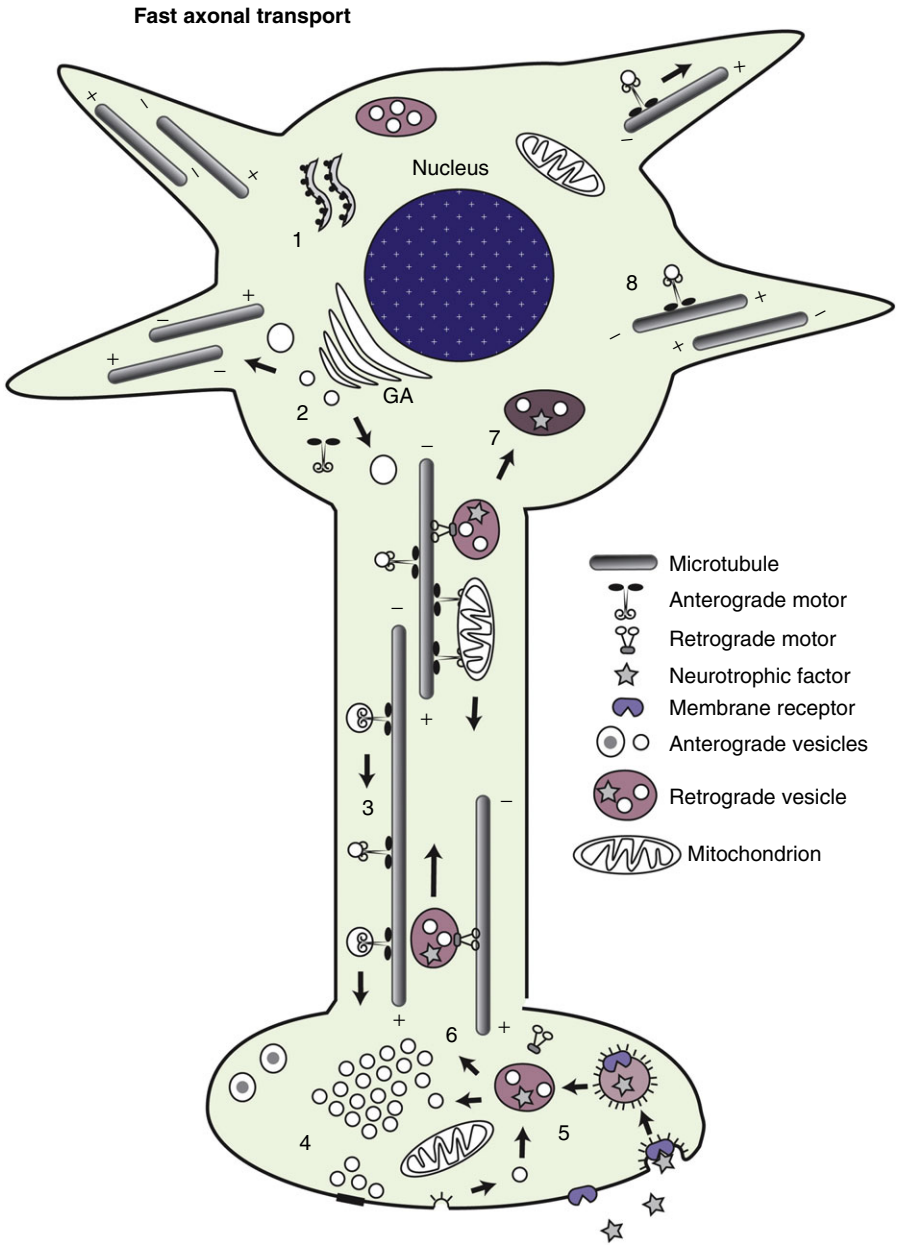

FIGURE 4.8 Fast axonal transport represents the transport of membrane-associated materials, having both anterograde and retrograde components. For anterograde transport, most polypeptides are synthesized on membrane-bound polysomes, also known as rough endoplasmic reticulum (1), and then transferred to the Golgi apparatus for processing and packaging into specific classes of membrane-bound organelles (2). Proteins following this pathway include both integral membrane proteins and secretory polypeptides in the lumen of vesicles. Cytoplasmic peripheral membrane proteins such as kinesins are synthesized on the cytoplasmic or free polysomes. Once vesicles have been assembled and the appropriate motors associate with them, they are moved down the axon at a rate of 100–400 mm per day (3). Different membrane structures are delivered to different compartments and may be regulated independently. For example, dense core vesicles and synaptic vesicles are both targeted for the presynaptic terminal (4), but the release of vesicle contents involves distinct pathways. After vesicles merge with the plasma membrane, their protein constituents are taken up by coated pits and vesicles via the receptor-mediated endocytic pathway and delivered to a sorting compartment (5). After proper sorting into appropriate compartments, membrane proteins are either committed to retrograde axonal transport or recycled (6). Retrograde moving organelles are morphologically and biochemically distinct from anterograde vesicles. These larger vesicles have an average velocity about half that of anterograde transport. The retrograde pathway is an important mechanism for the delivery of neurotrophic factors to the cell body. Material delivered by retrograde transport typically fuses with cell body compartments to form mature lysosomes (7), where most constituents are recycled. However, neurotrophic factors and neurotrophic viruses can act at the level of the cell body. Although evidence shows that vesicle transport also occurs into dendrites (8), less is known about this pocess. Dendritic vesicle transport is complicated by the fact that dendritic microtubules may have mixed polarity.

materials being transported in fast axonal transport but were not suitable for identifying the molecular motors used in translocation. A different technology that permitted direct observation of organelle movements and precise control of experimental conditions was required. Such experiments became possible with the advent of video microscopic techniques (Brady, 1991).

An early use of video-enhanced contrast (VEC) microscopy was to characterize the bidirectional movement of membrane-bound organelles in giant axons from the squid *Loligo pealeii*. Years before, studies had shown that axoplasm could be extruded from the giant axon as an intact cylinder. Properties of the isolated axoplasm had been characterized in some detail, making VEC microscopic analysis of axoplasm a natural choice. Remarkably, fast axonal transport continued unabated in isolated axoplasm for hours. Isolated axoplasm from the giant axon has no plasma membrane or other permeability barriers but can be readily maintained in an active state. Combining VEC microscopy with isolated axoplasm permitted rigorous dissection of the mechanisms for fast axonal transport with the use of biochemical and pharmacological approaches. A number of insights into axonal transport mechanisms have resulted from these studies.

How Is Axonal Transport Regulated?

The diversity of polypeptides in each axonal transport rate component and the coherent movement of proteins having many different molecular weights produce a conundrum. How can so many different polypeptides move down the axon as a group? In theory, one could propose that each protein has a motor of its own. In that case, each rate component might represent movements due to a specific class of motors or to variable affinities for a smaller number of motors. However, the relatively small numbers of motor molecules and the logistical difficulties associated with such a model effectively preclude this possibility.

The structural hypothesis mentioned earlier was formulated in response to the observation that rate components of axonal transport move as discrete waves, each with a characteristic rate and a distinctive composition (Figs. 4.7 and 4.8). The hypothesis is deceptively simple: Axonal transport represents the movement of discrete cytological structures (Brady, 1993). Proteins in axonal transport do not move as individual polypeptides. Instead, they move as part of a cytological structure or in association with a cytological structure. The only assumption made is that a limited number of elements can interact directly with transport motors, so transported material must be packaged appropriately to be moved. The different rate components result from packaging of transported material into different cytologically identifiable structures. In other words, membrane-associated proteins move as membrane-bound organelles (vesicles, mitochondria, etc.), whereas tubulin and MAPs move as microtubules, and neurofilaments move as neurofilaments.

The structural hypothesis does not require movement of a cross-linked microtubule–neurofilament complex in the form of a solid axoplasmic column. Evidence for existence of a cross-linked complex of microtubules and neurofilaments is not compelling in any case. Instead, the hypothesis specifically predicts that individual microtubules and neurofilaments move rather than tubulin dimers or neurofilament monomers. No assumptions are made about higher-order interactions between cytoskeletal structures or membranous structures. Indeed, one variant of the structural hypothesis proposes that cytoskeletal proteins move in the form of small oligomers rather than polymers, although there is no evidence for the presence of such oligomers *in vivo*. For example, to the limits of detection, neurofilaments exist only as the polymer under *in vivo* conditions. Similarly, tubulin interchanges between dimer and polymer with no known oligomeric intermediate. The movement of microtubules, neurofilaments, and complexes of soluble proteins is in fact what is observed (Baas & Buster, 2004; Roy et al., 2007).

Because synthesis of proteins takes place at some distance from many functional domains of a neuron, transport to distal regions of the neuron is necessary, but not sufficient, for proper function. Specific materials must also be delivered to their proper site of utilization and should not be left in inappropriate locations. For example, because a synaptic vesicle has no known function in axons or the cell body, it must be delivered to a presynaptic terminal along with other components necessary for regulated neurotransmitter release. The traditional picture places the presynaptic terminal at the end of an axonal process. Such images imply that a synaptic vesicle need only move along the axonal microtubules until it reaches microtubule ends in the presynaptic terminal. However, many CNS synapses are not at the end of an axon. Numerous terminals are located sequentially along a single axon, making en passant contacts with multiple target cells along the way. Targeting of synaptic vesicles then becomes a more complex problem and targeting ion channels or neurotransmitter receptors to nodes of Ranvier or other appropriate sites on the neuronal surface is equally challenging.

Although the specific details of this targeting are not well understood, a simple model for the targeting of synaptic vesicles serves to illustrate how such targeting may occur (Fig. 4.9). Synapsin I is a cytoplasmic protein enriched in presynaptic terminals that can bind reversibly to both actin microfilaments and synaptic vesicles. Both binding activities are regulated by the phosphorylation of synapsin, and this phosphorylation is increased

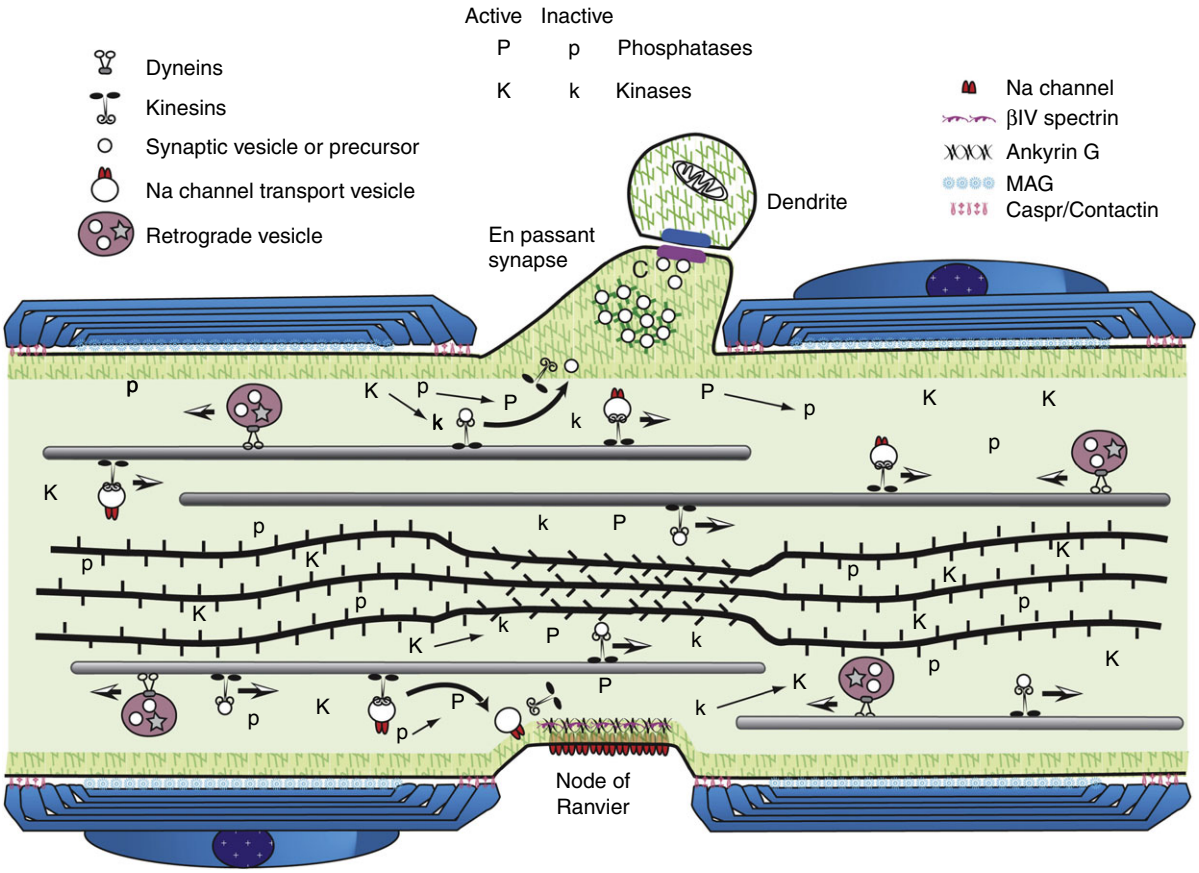

FIGURE 4.9 Axonal dynamics in a myelinated axon from the peripheral nervous system (PNS). Axons are in a constant flux with many concurrent dynamic processes. This diagram illustrates a few of the many dynamic events occurring at a node of Ranvier in a myelinated axon from the PNS. Axonal transport moves cytoskeletal structures, cytoplasmic proteins, and membrane-bound organelles from the cell body toward the periphery (from right to left). At the same time, other vesicles return to the cell body by retrograde transport (retrograde vesicle). Membrane-bound organelles are moved along microtubules by motor proteins such as the kinesins and cytoplasmic dyneins. Each class of organelles must be directed to the correct functional domain of the neuron. Synaptic vesicles must be delivered to a presynaptic terminal to maintain synaptic transmission. In contrast, organelles containing sodium channels must be targeted specifically to nodes of Ranvier for saltatory conduction to occur. Cytoskeletal transport is illustrated by microtubules (rods in the upper half of the axon) and neurofilaments (bundle of rope-like rods in the lower half of the axon) representing the cytoskeleton. They move in the anterograde direction as discrete elements and are degraded in the distal regions. Microtubules and neurofilaments interact with each other transiently during transport, but their distribution in axonal cross sections suggests that they are not stably cross-linked. In axonal segments without compact myelin, such as the node of Ranvier or following focal demyelination, a net dephosphorylation of neurofilament side arms allows the neurofilaments to pack more densely. Myelination is thought to alter the balance between kinase (K indicates an active kinase; k is an inactive kinase) and phosphatase (P indicates an active phophatase; p is an inactive phosphatase) activity in the axon. Most kinases and phosphatases have multiple substrates, suggesting a mechanism for targeting vesicle proteins to specific axonal domains. Local changes in the phosphoryation of axonal proteins may alter the binding properties of proteins. The action of synapsin I in squid axoplasm suggests that dephosphorylated synapsin cross-links synaptic vesicles to microfilaments. When a synaptic vesicle encounters the dephosphorylated synapsin and actin-rich matrix of a presynaptic terminal, the vesicle is trapped at the terminal by inhibition of further axonal transport, effectively targeting the synaptic vesicle to a presynaptic terminal. Similarly, a sodium channel-binding protein may be present at nodes of Ranvier in a high-affinity state (i.e., dephosphorylated). Transport vesicles for nodal sodium channels (Na channel vesicle) would be captured upon encountering this domain, effectively targeting sodium channels to the nodal membrane. Interactions between cells could in this manner establish the functional architecture of the neuron.

during stimulation. If nonphosphorylated synapsin were present at the border between the axon and the presynaptic terminal, then a fraction of the synaptic vesicles (or their precursors) traveling down the axon in fast axonal transport would be bound and cross-linked to the actin cytoskeleton that is enriched in the presynaptic terminal. These bound synaptic vesicles would become part of the reserve pool in the terminal at some distance from active zones. As the terminal was stimulated, local calmodulin-activated kinases would phosphorylate synapsin and allow these reserve synaptic vesicles to be mobilized. Consistent with this model, dephosphorylated synapsin has been shown to inhibit fast axonal transport when introduced directly into the axoplasm at concentrations comparable to those seen in the presynaptic terminal (McGuinness et al., 1989).

The role of kinases in this targeting appears to be a common feature in the regulation of axonal transport (Morfini, Szebenyi, Richards, & Brady, 2001). Local activation of kinases satisfies several criteria that any mechanism for targeting to specific neuronal subdomains must address. Specifically, the mechanism must be spatially restricted because distances to the cell body can be quite large. There must be some means to connect the targeting signal to an external microenvironment, such as an appropriate target cell. Finally, there must be a way of distinguishing subdomains so that synaptic vesicles are not delivered to nodes of Ranvier and voltage-gated sodium channels are not all targeted to the presynaptic terminal. The careful segregation of different organelles and polypeptides to different regions within a neuron suggests that highly efficient targeting mechanisms do exist.

Summary

A well-studied feature of the neuron is the phenomenon of axonal transport, which has been described in both anterograde and retrograde directions. The axonal transport system is responsible for the delivery of materials from the cell body to distant parts of the neuron, for membrane retrieval and circulation, and for uptake of materials from presynaptic terminals and dendrites and their delivery to the cell soma. The precise molecular mechanisms by which anterograde and retrograde transport can be targeted within an individual dendrite and/or axon are not understood at present.

Neurons and glial cells may have unusually large cell volumes enclosed within extensive plasma membrane surfaces. Nature has evolved a number of "universal" mechanisms in other systems and adapted them for the special needs of nervous tissue cells. The synthesis and delivery of components, and in particular proteins, to cytoplasmic organelles and cell surface subdomains engage general and evolutionarily conserved molecular mechanisms and pathways that are employed in single-cell yeasts as well as in cells in complex nervous tissue.

Once synthesized and sorted, most intracellular organelles (vesicles destined for axonal or dendritic domains, mitochondria, cytoskeletal components) must be distributed, and targeted, to precise intracellular locations. Because they are so extended in space, neurons and glial cells have adapted and developed to a high degree common mechanisms that operate to distribute components within all cells. In the neuron, movement of materials within the axon has been the central focus of most studies. The phenomenon of axoplasmic transport is now in some measure understood at the molecular level.

Dedication

We are very sad to report that David Colman died suddenly during the preparation of this edition. As a major contributor to our current understanding of myelination, David was a highly respected scientific colleague and, most of all, a good friend. We dedicate this chapter to his memory.

CHAPTER

5

Membrane Potential and Action Potential

The communication of information between neurons and between neurons and muscles or peripheral organs requires that signals travel over considerable distances. A number of notable scientists have contemplated the nature of this communication through the ages. In the second century A.D., the great Greek physician Claudius Galen proposed that "humors" flowed from the brain to the muscles along hollow nerves. A true electrophysiological understanding of nerve and muscle, however, depended on the discovery and understanding of electricity itself. The precise nature of nerve and muscle action became clearer with the advent of new experimental techniques by a number of European scientists, including Luigi Galvini, Emil Du Bois-Reymond, Carlo Matteucci, and Hermann von Helmholtz, to name a few (McComas, 2011). Through the application of electrical stimulation to nerves and muscles, these early electrophysiologists demonstrated that the conduction of commands from the brain to the muscle for the generation of movement was mediated by the flow of electricity along nerve fibers.

With the advancement of electrophysiological techniques, electrical activity recorded from nerves revealed that the conduction of information along the axon was mediated by the active generation of an electrical potential, called the action potential. But what precisely was the nature of these action potentials? To know this in detail required not only a preparation from which to obtain intracellular recordings but also one that could survive *in vitro*. The squid giant axon provided precisely such a preparation. Many invertebrates contain unusually large axons for the generation of escape reflexes; large axons conduct more quickly than small ones and so the response time for escape is reduced. The squid possesses an axon approximately 0.5 mm in diameter, large enough to be impaled by even a course micropipette (Fig. 5.1). By inserting a glass micropipette filled with a salt solution into the squid giant axon, Alan Hodgkin and Andrew Huxley demonstrated in 1939 that axons at rest are electrically polarized, exhibiting a resting membrane potential of approximately −60 mV inside versus outside. In the generation of an action potential, the polarization of the membrane is removed (referred to as depolarization) and exhibits a rapid swing toward, and even past, 0 mV (Fig. 5.1). This depolarization is followed by a rapid swing in the membrane potential to more negative values, a process referred to as hyperpolarization. The membrane potential following an action potential typically becomes even more negative than the original value of approximately −60 mV. This period of increased polarization is referred to as the after-hyperpolarization or the undershoot.

The development of electrophysiological techniques to the point that intracellular recordings could be obtained from the small cells of the mammalian nervous system revealed that action potentials in these neurons are generated through mechanisms similar to that of the squid giant axon.

It is now known that action potential generation in nearly all types of neurons and muscle cells is accomplished through mechanisms similar to those first detailed in the squid giant axon by Hodgkin and Huxley. This chapter considers the cellular mechanisms by which neurons and axons generate a resting membrane potential, how signals passively propagate through neuronal processes, and finally, how active propagation of electrical signals is achieved through generation of the action potential.

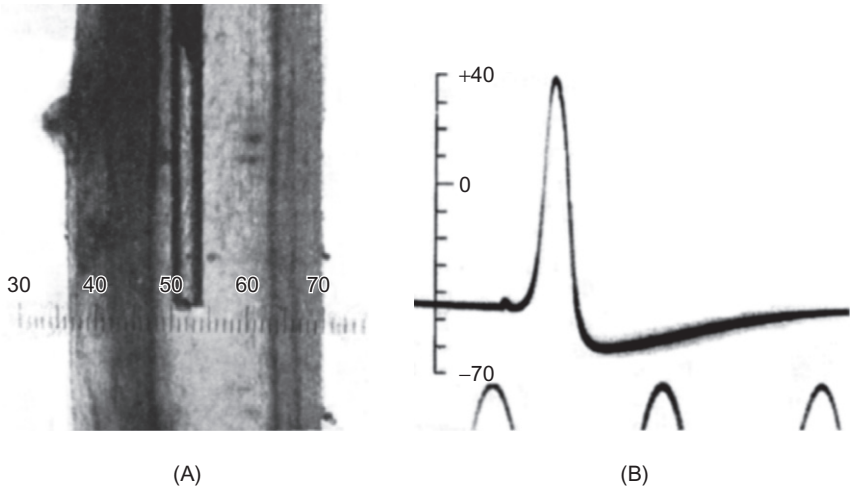

FIGURE 5.1 Intracellular recording of the membrane potential and action potential generation in the squid giant axon. (A) A glass micropipette, about 100 μm in diameter, was filled with seawater and lowered into the giant axon of the squid after it had been dissected free. The axon is about 1 mm in diameter and is transilluminated from behind. (B) One action potential recorded between the inside and the outside of the axon. Peaks of a sine wave at the bottom provided a scale for timing, with 2 ms between peaks. *From Hodgkin and Huxley (1939).*

MEMBRANE POTENTIAL

Membrane Potential Is Generated by the Differential Distribution of Ions

Through the operation of ionic pumps and special ionic buffering mechanisms, neurons actively maintain precise internal concentrations of several important ions, including Na^+, K^+, Cl^-, and Ca^{2+}. The mechanisms by which they do so are illustrated in Figures 5.2 and 5.3. The intracellular and extracellular concentrations of Na^+, K^+, Cl^-, and Ca^{2+} differ markedly (Fig. 5.2); K^+ is actively concentrated inside the cell, and Na^+, Cl^-, and Ca^{2+} are actively extruded to the extracellular space. However, this does not mean that the cell is filled only with positive charge; anions to which the plasma membrane is impermeant are also present inside the cell and almost balance the high concentration of K^+. The osmolarity inside the cell is approximately equal to that outside the cell.

Electrical and Thermodynamic Forces Determine the Passive Distribution of Ions

Ions tend to move down their concentration gradients through specialized ionic pores, known as ionic channels, in the plasma membrane. Through simple laws of thermodynamics, the high concentration of K^+ inside glial cells, neurons, and axons results in a tendency for K^+ ions to diffuse down their concentration gradient and leave the cell or cell process (Fig. 5.3). However, the movement of ions across the membrane also results in a redistribution of electrical charge. As K^+ ions move down their concentration gradient, the intracellular voltage becomes more negative, and this increased negativity results in an electrical attraction between the negative potential inside the cell and the positively charged, K^+ ions, thus offsetting the outward flow of these ions. The membrane is selectively permeable—that is, it is impermeable to the large anions inside the cell, which cannot follow the potassium ions across the membrane. At some membrane potential, the "force" of the electrostatic attraction between the negative membrane potential inside the cell and the positively charged K^+ ions will exactly balance the thermal "forces" by which K^+ ions tend to flow down their concentration gradient (Fig. 5.3). In this circumstance, it is equally likely that a K^+ ion exits the cell by movement down the concentration gradient as it is that a K^+ ion enters the cell due to the attraction between the negative membrane potential and the positive charge of this ion. At this membrane potential, there is no net flow of K^+ (the same number of K^+ ions enter the cell as leave the cell per unit time) and these ions are said to be in equilibrium. The membrane potential at which this occurs is known as the equilibrium potential. (See Box 5.1 for calculation of the equilibrium potential.)

To illustrate, let us consider the passive distribution of K^+ ions in the squid giant axon as studied by Hodgkin and Huxley. The K^+ concentration $[K^+]$ inside the squid giant axon is about 400 mM, whereas the $[K^+]$ outside the axon is about 20 mM. Because $[K^+]_i$ is greater than $[K^+]_o$, potassium ions will tend to flow down their concentration gradient, from inside to outside the axon, taking positive charge with them. The equilibrium potential (at which the tendency for K^+ ions to flow down their concentration gradient will be exactly offset by the attraction for K^+ ions to enter the cell because of

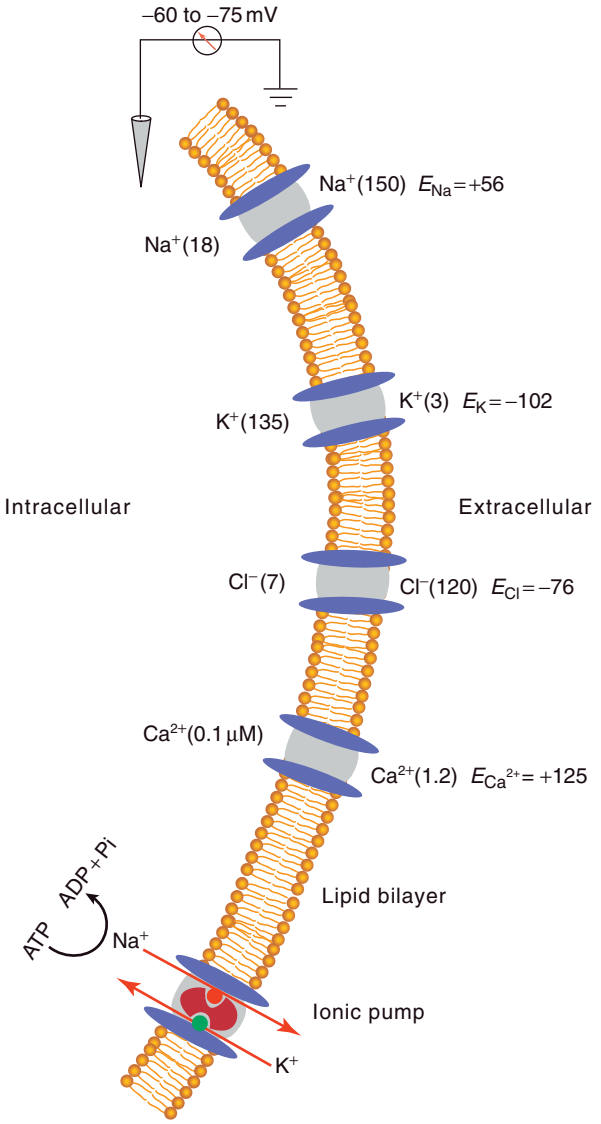

FIGURE 5.2 Differential distribution of ions inside and outside plasma membrane of neurons and neuronal processes, showing ionic channels for Na^+, K^+, Cl^-, and Ca^{2+}, as well as an electrogenic Na^+–K^+ ionic pump (also known as Na^+, K^+-ATPase). Concentrations (in millimoles except that for intracellular Ca^{2+}) of the ions are given in parentheses; their equilibrium potentials (E) for a typical mammalian neuron are indicated.

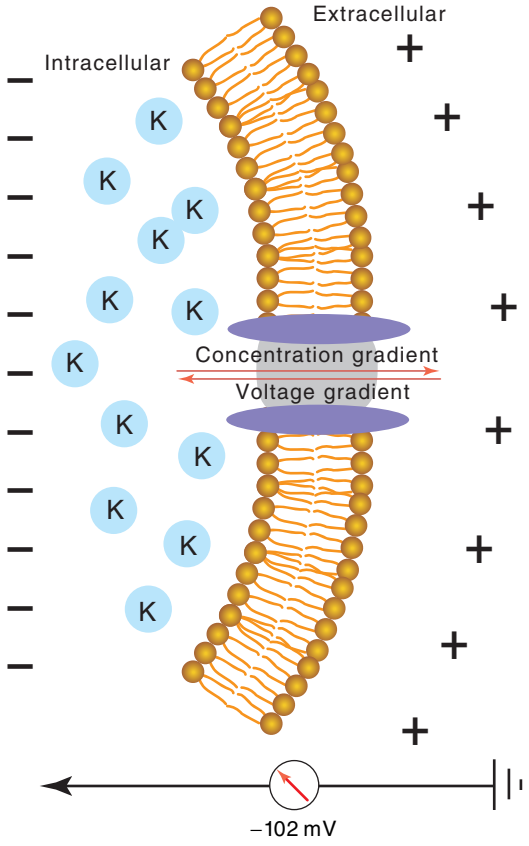

FIGURE 5.3 The equilibrium potential is influenced by the concentration gradient and the voltage difference across the membrane. Neurons actively concentrate K^+ inside the cell. These K^+ ions tend to flow down their concentration gradient from inside to outside the cell. However, the negative membrane potential inside the cell provides an attraction for K^+ ions to enter or remain within the cell. These two factors balance one another at the equilibrium potential, which in a typical mammalian neuron is –102 mV for K^+.

the negative charge inside the cell) at a room temperature of 20°C can be calculated by the Nernst equation as such:

$$E_K = 58.2 \log_{10}(20/400) = -76\ \text{mV}.$$

Therefore, at a membrane potential of –76 mV, K^+ ions have an equal tendency to flow either into or out of the axon. The concentrations of K^+ in mammalian neurons and glial cells differ considerably from that in the squid giant axon, which is adapted to live in seawater. By substituting 3.1 mM for $[K^+]_o$ and 140 mM for $[K^+]_i$ in the Nernst equation, with mammalian body temperature, T = 37°C, we obtain

$$E_K = 61.5 \log_{10}(3.1/140) = -102\ \text{mV}.$$

Movements of Ions Can Cause Either Hyperpolarization or Depolarization

In mammalian cells, at membrane potentials positive to –102 mV, K^+ ions tend to flow out of the cell. Increasing the ability of K^+ ions to flow across the membrane—that is, increasing the conductance of the membrane to K^+ (gK) causes the membrane potential to become more negative, or hyperpolarized, due to the exiting of positively charged ions from inside the cell (Fig. 5.4).

At membrane potentials negative to –102 mV, K^+ ions tend to flow into the cell; increasing the membrane conductance to K^+ causes the membrane potential to become more positive, or depolarized, due to the flow of positive charge into the cell. The membrane potential

BOX 5.1

NERNST EQUATION

The equilibrium potential is determined by (1) the concentration of the ion inside and outside the cell, (2) the temperature of the solution, (3) the valence of the ion, and (4) the amount of work required to separate a given quantity of charge. The equation that describes the equilibrium potential was formulated by a German physical chemist named Walter Nernst in 1888:

$$E_{ion} = RT/zF \cdot \ln([ion]_o/[ion]_i)$$

Here, E_{ion} is the membrane potential at which the ionic species is at equilibrium, R is the gas constant [8.315 J per Kelvin per mole (J K^{-1} mol^{-1})], T is the temperature in Kelvins ($T_{Kelvin} = 273.16 + T_{Celcius}$), F is Faraday's constant [96,485 coulombs per mole (C mol^{-1})], z is the valence of the ion, and $[ion]_o$ and $[ion]_i$ are the concentrations of the ion outside and inside the cell, respectively. For a monovalent, positively charged ion (cation) at room temperature (20°C), substituting the appropriate numbers and converting natural log (ln) into log base 10 ($\log_{10}$) result in

$$E_{ion} = 58.2 \log_{10}([ion]_o/[ion]_i)$$

at a body temperature of 37°C, the Nernst equation is

$$E_{ion} = 61.5 \log_{10}([ion]_o/[ion]_i).$$

David A. McCormick

at which the net current "flips" direction is referred to as the reversal potential. If the channels conduct only one type of ion (e.g., K^+ ions), then the reversal potential and the Nernst equilibrium potential for that ion coincide (Fig. 5.4A). Increasing the membrane conductance to K^+ ions while the membrane potential is at the equilibrium potential for K^+ (E_K) does not change the membrane potential because no net driving force causes K^+ ions to either exit or enter the cell. However, this increase in membrane conductance to K^+ decreases the ability of other species of ions to change the membrane potential because any deviation of the potential from E_K increases the drive for K^+ ions to either exit or enter the cell, thereby drawing the membrane potential back toward E_K (Fig. 5.4B). This effect is known as a "shunt" and is important for some effects of inhibitory synaptic transmission.

The exiting and entering of the cell by K^+ ions during generation of the membrane potential give rise to a curious problem. When K^+ ions leave the cell to generate a membrane potential, the concentration of K^+ changes both inside and outside the cell. Why does this change in concentration not alter the equilibrium potential, thus changing the tendency for K^+ ions to flow down their concentration gradient? The reason is that the number of K^+ ions required to leave the cell to achieve the equilibrium potential is quite small. For example, if a cell were at 0 mV and the membrane suddenly became permeable to K^+ ions, only about 10^{-12} mol of K^+ ions per square centimeter of membrane would move from inside to outside the cell in bringing the membrane potential to the equilibrium potential for K^+. In a spherical cell of 25 μm diameter, this would amount to an average decrease in intracellular K^+ of only about 4 μM (e.g., from 140 to 139.996 mM). However, there are instances when significant changes in the concentrations of K^+ may occur, particularly during the generation of pronounced activity, such as an epileptic seizure. During the occurrence of a tonic–clonic generalized (grand mal) seizure, large numbers of neurons discharge throughout the cerebral cortex in a synchronized manner. This synchronous discharge of large numbers of neurons significantly increases the extracellular K^+ concentration, by as much as a couple of millimoles, resulting in a commensurate positive shift in the equilibrium potential for K^+. This shift in the equilibrium potential can increase the excitability of affected neurons and neuronal processes and thus promote the spread of the seizure activity. Fortunately, the extracellular concentration of K^+ is tightly regulated and is kept at normal levels through uptake by glial cells, as well as by diffusion through the fluid of the extracellular space.

As is true for K^+ ions, each of the membrane-permeable species of ions possesses an equilibrium potential that depends on the concentration of that ion inside and outside the cell. Thus, equilibrium potentials may vary between different cell types, such as those found in animals adapted to live in salt water versus mammalian neurons. In mammalian neurons, the equilibrium potential is approximately 56 mV for Na^+, approximately −76 mV for Cl^-, and about 125 mV for Ca^{2+} (see Fig. 5.2). Thus, increasing the membrane conductance to Na^+ (gNa) through the opening of Na^+ channels depolarizes the membrane potential toward 56 mV; increasing the membrane conductance to Cl^- brings the membrane potential closer to −76 mV; and finally increasing the membrane conductance to Ca^{2+} depolarizes the cell toward 125 mV.

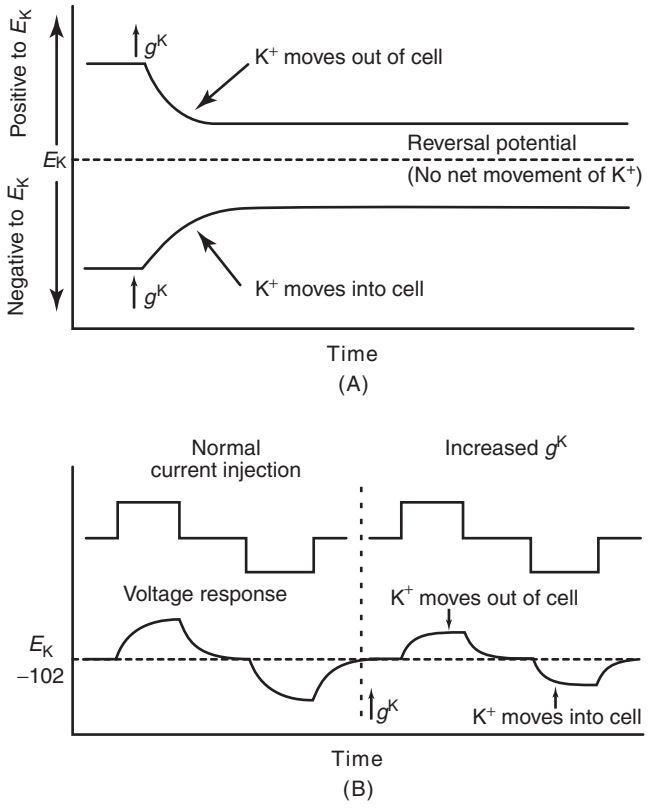

FIGURE 5.4 Increases in K^+ conductance can result in hyperpolarization, depolarization, or no change in membrane potential. (A) Opening K^+ channels increases the conductance of the membrane to K^+, denoted gK. If the membrane potential is positive to the equilibrium potential (also known as the reversal potential) for K^+, then increasing gK will cause some K^+ ions to leave the cell, and the cell will become hyperpolarized. If the membrane potential is negative to E_K when gK is increased, then K^+ ions will enter the cell, therefore making the inside more positive (more depolarized). If the membrane potential is exactly E_K when gK is increased, then there will be no net movement of K^+ ions. (B) Opening K^+ channels when the membrane potential is at E_K does not change the membrane potential; however, it reduces the ability of other ionic currents to move the membrane potential away from E_K. For example, a comparison of the ability of the injection of two pulses of current, one depolarizing and one hyperpolarizing, to change the membrane potential before and after opening K^+ channels reveals that increases in gK decrease the responses of the cell noticeably.

Na^+, K^+, and Cl^- Contribute to the Determination of the Resting Membrane Potential

If a membrane is permeable to only one ion and no electrogenic ionic pumps are operating (see next section), then the membrane potential is necessarily at the equilibrium potential for that ion. At rest, the plasma membrane of most cell types is not at the equilibrium potential for K^+ ions, indicating that the membrane is also permeable to other types of ions. For example, the resting membrane of the squid giant axon is permeable to Cl^- and Na^+, as well as K^+, due to the presence of ionic channels that not only allow these ions to pass but also are open at the resting membrane potential. Because the membrane is permeable to K^+, Cl^-, and Na^+, the resting potential of the squid giant axon is not equal to E_K, E_{Na}, or E_{Cl}, but is somewhere in between these three. A membrane permeable to more than one ion has a steady-state membrane potential whose value is between those of the equilibrium potentials for each of the permeant ions (Box 5.2).

Different Types of Neurons Have Different Resting Potentials

Intracellular recordings from neurons in the mammalian central nervous system (CNS) reveal that different types of neurons exhibit different resting membrane potentials. Indeed, some types of neurons do not even exhibit a true "resting" membrane potential; they spontaneously and continuously generate action potentials even in the total lack of synaptic input. In the visual system, intracellular recordings have shown that photoreceptor cells of the retina—the rods and cones—have a membrane potential of approximately −40 mV at rest and are hyperpolarized when activated by light. Cells in the dorsal lateral geniculate nucleus, which receive axonal input from the retina and project to the visual cortex, have a resting membrane potential of approximately −70 mV during sleep and −55 mV during waking, whereas pyramidal neurons of the visual cortex have a resting membrane potential of about −75 mV. Presumably, the resting membrane potentials of different cell types in the central and peripheral nervous system are highly regulated and are functionally important. For example, the depolarized membrane potential of photoreceptors presumably allows the membrane potential to move in both negative and positive directions in response to changes in light intensity. The hyper-polarized membrane potential of thalamic neurons during sleep (−70 mV) dramatically decreases the flow of information from the sensory periphery to the cerebral cortex, presumably to allow the cortex to be relatively undisturbed during sleep, and the 20 mV membrane potential between the resting potential and the action potential threshold in cortical pyramidal cells allows these cells to be strongly influenced by subthreshold barrages of synaptic potentials from other cortical neurons, which provide the context under which we think and behave (see Chapter 9).

Ionic Pumps Actively Maintain Ionic Gradients

Because the resting membrane potential of a neuron is not at the equilibrium potential for any particular ion, ions constantly flow down their concentration gradients. This flux becomes considerably larger with the

BOX 5.2

GOLDMAN-HODGKIN-KATZ EQUATION

An equation developed by Goldman and later used by Alan Hodgkin and Bernard Katz describes the steady-state membrane potential for a given set of ionic concentrations inside and outside the cell and the relative permeabilities of the membrane to each of those ions:

$$V_m \frac{RT}{F} \cdot \ln\left(\frac{(p_K[K^+]_o + p_{Na}[Na^+]_o + p_{Cl}[Cl^-]_i)}{(p_K[K^+]_i + p_{Na}[Na^+]_i + p_{Cl}[Cl^-]_o)}\right).$$

The relative contribution of each ion is determined by its concentration differences across the membrane and the relative permeability (p_K, p_{Na}, p_{Cl}) of the membrane to each type of ion. If a membrane is permeable to only one ion, then the Goldman–Hodgkin–Katz equation reduces to the Nernst equation. In the squid giant axon, at resting membrane potential, the permeability ratios are

$$p_K : p_{Na} : p_{Cl} = 1.00 : 0.04 : 0.45.$$

The membrane of the squid giant axon, at rest, is most permeable to K^+ ions, less so to Cl^-, and least permeable to Na^+. (Chloride appears to contribute considerably less to the determination of the resting potential of mammalian neurons.) These results indicate that the resting membrane potential is determined by the resting permeability of the membrane to K^+, Na^+, and Cl^-. In theory, this resting membrane potential may be anywhere between E_K (e.g., −76 mV) and E_{Na} (55 mV). For the three ions at 20°C, the equation is

$$V_m = \frac{58.2 \log_{10}\{(1 \cdot 20 + 0.04 \cdot 440 + 0.45 \cdot 40)}{(1 \cdot 400 + 0.04 \cdot 50 + 0.45 \cdot 560)\}}$$
$$= -62 \text{ mV}.$$

This suggests that the squid giant axon should have a resting membrane potential of −62 mV. In fact, the resting membrane potential may be a few millivolts hyperpolarized to this value through the operation of the electrogenic Na^+–K^+ pump.

David A. McCormick

generation of electrical and synaptic potentials because ionic channels are opened by these events. Although the absolute number of ions traversing the plasma membrane during each action potential or synaptic potential may be small in individual cells, the collective influence of a large neural network of cells, such as in the brain, and the presence of ion fluxes even at rest can substantially change the distribution of ions inside and outside neurons. Cells have solved this problem with the use of active transport of ions against their concentration gradients. The proteins that actively transport ions are referred to as ionic pumps, of which the Na^+–K^+ pump is perhaps the most thoroughly understood (Lauger, 1991). The Na^+–K^+ pump is stimulated by increases in the intracellular concentration of Na^+ and moves Na^+ out of the cell while moving K^+ into it, achieving this task through the hydrolysis of ATP (Fig. 5.2). Three Na^+ ions are extruded for every two K^+ ions transported into the cell. Because of the unequal transport of ions, the operation of this pump generates a hyper-polarizing electrical potential and is said to be electrogenic. The Na^+–K^+ pump typically results in the membrane potential of the cell being a few millivolts more negative than it would be otherwise.

The Na^+–K^+ pump consists of two subunits, α and β, arranged in a tetramer $(\alpha\beta)_2$. The Na^+–K^+ pump is believed to operate through conformational changes that alternatively bind Na^+ ions from the inside of the cell and release them to the extracellular space, while binding K^+ ions from outside the cell and releasing them into the intracellular mileau (Fig. 5.2). Such a conformation change is due to the phosphorylation and dephosphorylation of the protein.

The membranes of neurons and glia contain multiple types of ionic pumps, used to maintain the proper distribution of each ionic species important for cellular signaling (Reithmeier, 1994). Many of these pumps are operated by the Na^+ gradient across the cell, whereas others operate through a mechanism similar to that of the Na^+–K^+ pump (i.e., the hydrolysis of ATP). For example, the calcium concentration inside neurons is kept to very low levels (typically 50–100 nM) through the operation of both types of ionic pumps, as well as special intracellular Ca^{2+} buffering mechanisms. Ca^{2+} is extruded from neurons through both a Ca^{2+}, Mg^{2+}-ATPase and a Na^+–Ca^{2+} exchanger. The Na^+–Ca^{2+} exchanger is driven by the Na^+ gradient across the membrane and extrudes one Ca^{2+} ion for each Na^+ ion allowed to enter the cell.

The Cl^- concentration in neurons is actively maintained at a low level through operation of a chloride-bicarbonate exchanger, which brings in one ion of Na^+ and one ion of HCO_3^- for each ion of Cl^- extruded. Intracellular pH can also markedly affect neuronal excitability and is therefore tightly regulated, in part by a Na^+–H^+ exchanger that extrudes one proton for each Na^+ allowed to enter the cell.

Summary

The membrane potential is generated by the unequal distribution of ions, particularly K^+, Na^+, and Cl^-, across the plasma membrane. This unequal distribution of ions is maintained by ionic pumps and exchangers. K^+ ions are concentrated inside the neuron and tend to flow down their concentration gradient, leading to a hyperpolarization of the cell. At the equilibrium potential, the tendency of K^+ ions to flow out of the cell will be exactly offset by the tendency of K^+ ions to enter the cell due to the attraction of the negative potential inside the cell. The resting membrane is also permeable to Na^+ and Cl^- and therefore the resting membrane potential is approximately −75 to −40 mV, in other words, substantially positive to E_K.

PASSIVE ELECTRICAL PROPERTIES OF THE NEURON

Electrical activity in the nervous system not only conducts actively along neuronal processes, owing to the opening and closing of ion channels, but also moves passively, with electrical charges pushing or pulling other charges both inside and outside thin neuronal elements. How electrical charge moves passively through neurons shapes how these cells process synaptic inputs and generate action potential outputs, and thus interact with other neurons. Three properties that strongly influence the passive response properties of neuronal elements are: membrane resistance, axial resistance, and membrane capacitance (Fig. 5.5A). These three properties not only determine the amplitude of the neuron's passive response to a synaptic input, but also the amplitude and speed of spread of this input to other parts of the neuron and the properties of the action potential response.

The outer membrane of the neuron, being composed of phosholipids and ion channels, offers resistance to the flow of charged ions and thus exhibits a specific membrane resistance, R_m. Conversely, the cell membrane can be considered to exhibit a specific level of conductivity (G_m; conductance) to electrical currents, which is mathematically described as $1/R_m$. The amount of current that flows across a given conductance is proportional to the voltage applied, in what is known as Ohm's law:

$$I = VG \quad \text{or} \quad I = V/R \quad \text{or} \quad V = IR$$

This is a linear relationship that states that the larger the voltage that is applied to a fixed conductance, the greater the current that will flow. Likewise, increasing membrane conductance (e.g., opening ion channels) increases the current that flows across the membrane in the presence of a fixed voltage. Imagine measuring the flow of water through a pipe. The rate of flow of the water (current) is proportional to the pressure applied (voltage) as well as the size of the pipe (conductance or resistance). Increasing the diameter of the pipe increases the rate at which water flows as long as the pressure doesn't change. The change in voltage (pressure) that occurs with a fixed current flow against a resistance can also be determined (V = IR). In a neuron, for example, the opening of enough ion channels to produce 100 pA of current in a cell that is 100 Megohms in resistance will result in a change in membrane potential of 10 mV at the point of entry of the ionic current and at steady state. The qualifiers "at the point of entry" and "at steady state" are given because neurons have two properties that strongly shape the response to ionic currents: Current flows down processes and not just across membranes, and membranes not only have resistance but also capacitance (Fig. 5.5A).

Capacitance is the ability to store electrical charge and occurs whenever two electrical conductors (e.g., cytoplasm and extracellular fluid) are separated by a nonconductor (e.g., lipid membrane). The gathering of ions near one side of the membrane will push like charges away, and attract opposite charges toward, the other side of the membrane. For example, the entry of positive charge into a neuron will result in an increase in positive ions under the membrane. These positive ions on the inside of the cell membrane will repel positive ions away from the outside of the membrane, resulting in a capacitative current (I_c). In a way, capacitors conduct electricity, just as conductors do. However, there are marked differences. While a resistor conducts a constant flow of current (e.g., charges/second) with a constant voltage (I = V/R), a capacitor requires an ever increasing voltage (e.g., volts/second) in order to deliver a constant flow of current. In other words, the ability of a capacitor to provide a conduit for current flow is dependent upon the rate of change of membrane potential; it is frequency dependent. In fact, one way of thinking of a capacitor is that it is a variable resistor in which the resistance depends on frequency: at high frequencies (i.e., volts/sec is high), the resistance is low and current flows readily, while at low frequencies, the resistance is high and current flow is limited. Let's consider why this is so and how this affects the manner in which neurons behave.

A capacitor is defined by the amount of charge (measured in coulombs; Q = 6.24×10^{18} electrons or protons) that are stored on the opposing plates per volt (C = Q/V). The current flowing through a capacitor (I_c), measured in amperes, is dQ/dt (coulombs/sec), which is equal to CdV/dt (i.e., the time differential of Q = CV). Thus, the greater the rate of change of membrane potential, the greater the flow of current through the membrane capacitance. Likewise, when the membrane potential is steady,

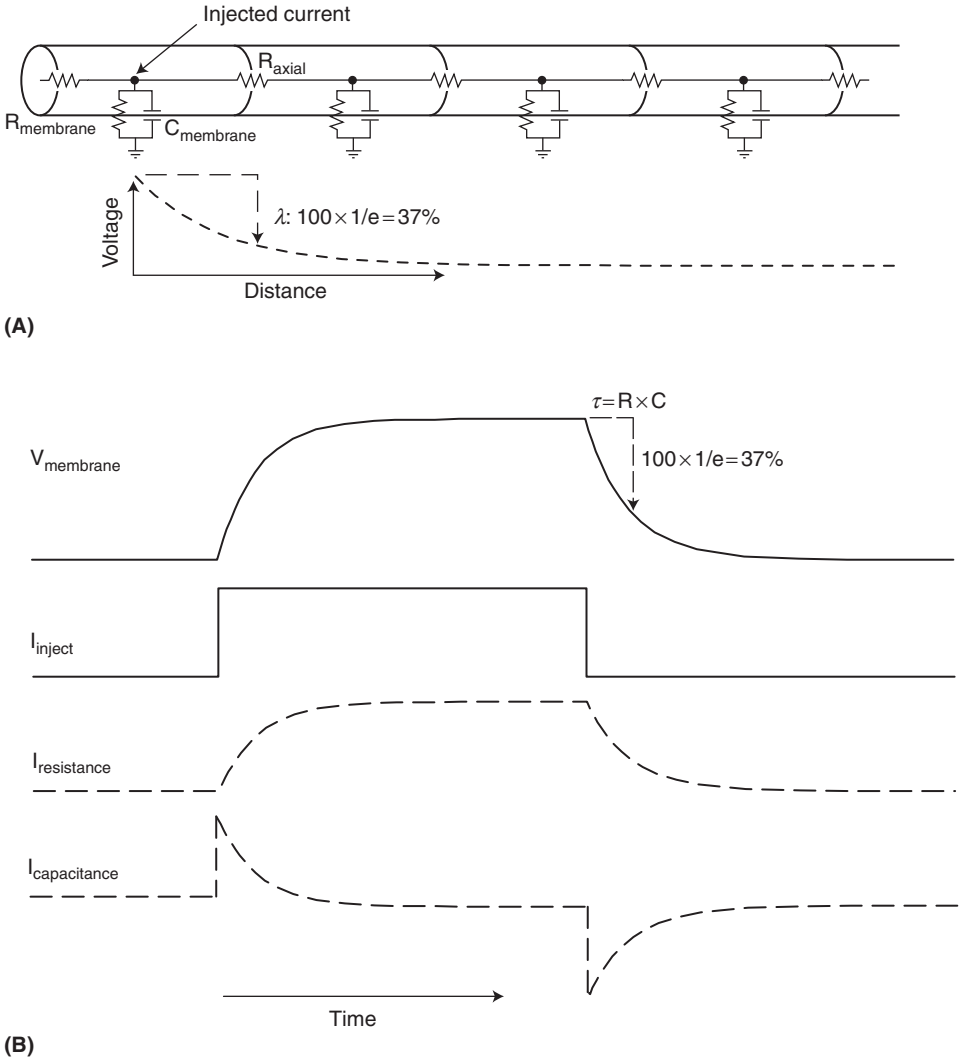

FIGURE 5.5 Passive response properties of neuronal element. (A) Idealized cylindrical neuronal process. The injection of current into a particular point in the process will result in the flow of ions across three paths: down the process through the axial resistance (R_{axial}) and across the membrane through the membrane resistance ($R_{membrane}$) and capacitance ($C_{membrane}$). The leak of current out of the process as it flows down the process and across the membrane will result in an exponential decrease in voltage. The point at which the voltage has reduced to 1/e (37%) of its original value is known as the length constant (λ). (B) Response of the membrane to the injection of a constant current pulse. Initially the injected current flows readily through the membrane capacitance (bottom trace). As this capacitative current ($I_{capacitance}$) decreases (bottom trace), there is a rise in charge inside the membrane and thus the voltage rises ($V_{membrane}$; top trace). This increase in voltage inside the cell results in an increase in current flow across the membrane resistance ($I_{resistance}$). Turning off the current pulse will result in the opposite flow of current through the capacitance, and the membrane potential will return to it's previous level with an exponential time course. The time it takes to move to 1/e (37%) of the steady state change in membrane potential is known as the membrane time constant (τ).

there is no current flow through the capacitance. A second big difference between current flow through capacitance versus resistance is that the capacitative current is made up of the movement of different ions on each side of the membrane; the gathering of ions on one side influences the distribution of ions on the other. In contrast, the movement of ions through the membrane resistance, which is made up largely of ionic pores, consists of the actual movement of ions across the membrane and therefore can result in changes in ion concentrations inside and outside the cell.

Membranes are characterized by a capacitance and resistance in parallel (Fig. 5.5). If we apply a steady current to the inside of the membrane, at first the capacitance acts as a low-resistance pathway and there is a large flow of current (initially equal to that of the applied current) through the membrane capacitance (Fig. 5.5B; $I_{capacitance}$). The change in distribution of charge across the membrane will alter the membrane potential, and this will provide a new driving force for ions to move through the ionic pores that make up the membrane resistance/conductance (Fig. 5.5B; $I_{resistance}$). As ions move through

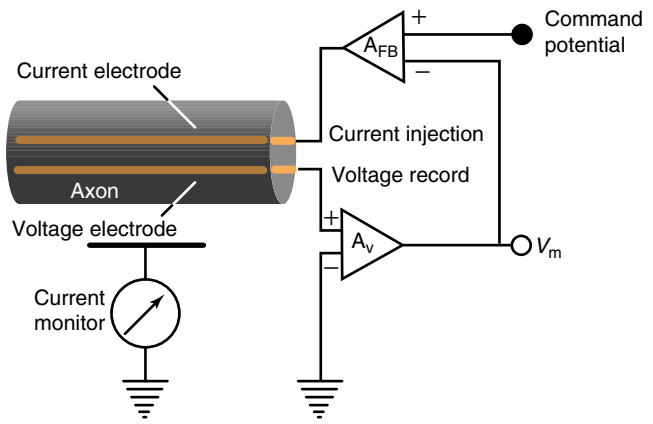

FIGURE 5.6 The voltage-clamp technique keeps the voltage across the membrane constant so that the amplitude and time course of ionic currents can be measured. In the two-electrode voltage-clamp technique, one electrode measures the voltage across the membrane while the other injects current into the cell to keep the voltage constant. The experimenter sets a voltage to which the axon or neuron is to be stepped (the command potential). Current is then injected into the cell in proportion to the difference between the present membrane potential and the command potential. This feedback cycle occurs continuously, thereby clamping the membrane potential to the command potential. By measuring the amount of current injected, the experimenter can determine the amplitude and time course of the ionic currents flowing across the membrane.

the membrane resistance/conductance, the rate at which they accumulate under the membrane will slow down, resulting in a decreased rate of change of membrane potential (dV/dt) and consequently a decrease in current flow through the membrane capacitance. Eventually, the membrane potential will settle at a value dictated by the magnitude of the current injected and the membrane resistance, according to Ohm's law.

The time course over which the change in membrane potential occurs in response to a step change in current is described by an exponential function in which the time constant τ_m, is determined by the product of the specific membrane resistance and membrane capacitance per unit area (τ_m = RC) and is equal to the time it takes for the membrane potential to reach 37% (100 * 1/e) of its steady-state value (Fig. 5.5B). Once the current step is turned off, current will then flow across the capacitor in the opposite direction. In the example of Figure 5.5B, the removal of the positive current step leaves the inner membrane with a buildup of positive charge (and the outer membrane with an excess of negative charge). As the inner positive and outer negative charges move away from the membrane, the membrane potential will decrease exponentially, and thus the current through the membrane resistance (conductance) will also decrease exponentially (Fig. 5.5B).

Let's consider the hydraulic analogy again. Imagine two parallel pipes connected together on both ends. One pipe contains a chamber with a diaphragm inside (a capacitor), and the other contains a constriction (a resistor). Applying a steady flow of water to one end of the two parallel connected pipes will at first cause an equal movement of water at the other end by distending the diaphragm (capacitor). However, as the diaphragm stretches, it will start to resist further movement, and thus the water pressure inside the pipes will begin to rise. This rise in pressure will force water through the parallel (resistor) pipe at a rate determined by the pressure/resistance. Since water is now flowing through the "resistor" pipe, there is less further accumulation of water against the diaphragm, resulting in a decreased rate of water flow through the "capacitor" path. Eventually, all of the water flow will be through the "resistive" pipe and none will be through further distension of the diaphragm. Once the steady flow of water is removed, however, the diaphragm will provide a temporary source for water to flow once again, resulting in the slow dissipation of the "capacitive current" and a slow return to the precurrent water pressure (e.g., Fig. 5.5B).

An important consideration in passive properties of membrane responses, owing in part to the parallel capacitance/resistance properties of the membrane, is their frequency filtering properties. In the example in Figure 5.5B, a square pulse of current was applied, yet the membrane responded with a gradual increase (at the onset of current) and then decrease (at the offset of current) in membrane potential; the high-frequency components of the current step were filtered out by the capacitive/resistive properties of the membrane. Neuronal membranes naturally respond to some frequencies (e.g., low frequencies) better than others (e.g., high frequencies). Since conductance through the membrane capacitance is frequency dependent, being highest with rapid changes in current, the membrane capacitor, in parallel with membrane resistance, acts as a low-pass filter for changes in membrane potential (voltage across the membrane). Higher frequencies are decreased in amplitude, while low frequencies are preserved (in other words, the high-frequency currents escape from the neuron passing easily through the capacitance of the membrane, thereby reducing the ability of high-frequency current entry into the neuron to build up voltage ["pressure"] inside the cell). For a neuron with a membrane time constant of 20 msec, the "cutoff" frequency (defined as $f_c = 1/(2\pi RC)$) of the filtering properties of the membrane will be 8 Hz, meaning that increasing frequency above 8 Hz will result in a larger and larger decrease in the membrane voltage response. One often overlooked property of filters is that they not only change the amplitude but also the phase (timing) of an input in a frequency-dependent manner.

Next let's consider how current flows along a neuronal process. The entry of ions into the cell at one point will result not only in the flow of current across the membrane

resistance and capacitance but also the movement of current away from the entry point along the neuronal process. This movement of charge along the inner part of the neuron is known as "axial current." The resistance to the movement of axial current, owing to the properties of cytoplasm and organelles within the neuron, is referred to as axial resistance (Fig. 5.5A). Axial resistance in neurons is usually small in comparison to membrane resistance, allowing current to flow readily down neuronal processes. However, as the current flows, some of it escapes through the local membrane resistance and capacitance of each neuronal compartment that it enters. Imagine a garden hose that not only is elastic (can bulge, representing capacitance) but also has small holes in it all along its length. The application of a given value of water pressure at the end of the hose will result in a gradient of pressure along the hose, owing to the local reduction in water pressure through the leaking and bulging of the hose. Likewise, in a neuronal process, the voltage (e.g., "pressure") decreases exponentially as the current spreads across the axial resistance and leaks out through the resistance and capacitance of the membrane (Fig. 5.5A). The point at which the membrane potential has fallen to 1/e (or 37%) of its original value is known as the length constant (λ) of the process (Fig. 5.5A). Neuronal processes such as dendrites and axons have characteristic length constants in the range of 0.1 to 1 mm at steady state, depending on their diameter. Larger-diameter processes, such as the squid giant axon, have lower axial resistance (higher axial conductance) and therefore a longer length constant, allowing electrical current to have a broader influence and to flow quickly. The length constant also depends upon the frequency of the input, since the outer membrane acts as a frequency dependent filter. This filtering property not only affects the amplitude of electrical events as they propagate, but also their phase. Since the dendritic processes of many neurons are within the 0.1–1 mm length constant, voltage changes at one part of a dendrite can passively spread to a significant portion of the local dendritic arbor. For the vast majority of axons, a length constant of 0.1–1 mm is insufficient to spread information to synaptic boutons, resulting in the need of action potentials to propagate information over long distances. It is interesting to note, however, that a length constant of 0.2–0.4 mm, even in the fine axons of the brain, suggests that local changes in membrane potential at the soma can actually propagate to nearby synaptic terminals and potentially influence synaptic transmission (Shu, Hasenstaub, Duque, Yu, & McCormick, 2006).

The flow of current in actual neurons is complex, owing to both the complicated geometries of dendritic and axonal arbors and the presence of ionic channels that actively open and close in response to changes in membrane voltage. These active properties of neurons result not only in the ability of the cell to communicate over long distances, but they also allow each cell type to exhibit its own unique electrophysiological properties that are useful for achieving its specific task in brain function.

ACTION POTENTIAL

An Increase in Na^+ and K^+ Conductance Generates Action Potentials

Hodgkin and Huxley not only recorded the action potential with an intracellular microelectrode (Fig. 5.1), but they also went on to perform a remarkable series of experiments that explained qualitatively and quantitatively the ionic mechanisms by which the action potential is generated (Hodgkin & Huxley, 1952a, 1952b). As mentioned earlier, these investigators found that during the action potential, the membrane potential of the cell rapidly overshoots 0 mV and approaches the equilibrium potential for Na^+. After generation of the action potential, the membrane potential repolarizes and becomes more negative than before, generating an after-hyperpolarization. These changes in membrane potential during generation of the action potential were associated with a large increase in conductance of the plasma membrane, but to what does the membrane become conductive in order to generate the action potential? The prevailing hypothesis was that there was a nonselective increase in conductance causing the negative resting potential to increase toward 0 mV. Since publication of the experiments of E. Overton in 1902, the action potential had been known to depend on the presence of extracellular Na^+. Reducing the concentration of Na^+ in the artificial seawater bathing the axon resulted in a marked reduction in the amplitude of the action potential. On the basis of these and other data, Hodgkin and Katz proposed that the action potential is generated through a rapid increase in the conductance of the membrane to Na^+ ions. A quantitative proof of this theory was lacking, however, because ionic currents could not be observed directly. Development of the voltage-clamp technique by Kenneth Cole at the Marine Biological Laboratory in Massachusetts resolved this problem and allowed quantitative measurement of the Na^+ and K^+ currents underlying the action potential (Cole, 1949; Box 5.3).

Hodgkin and Huxley used the voltage-clamp technique to investigate the mechanisms of generation of the action potential in the squid giant axon. Axons and neurons have a threshold for the initialization of an action potential of about −45 to −55 mV. Increasing the voltage from −60 to 0 mV produces a large, but transient, flow of positive charge into the cell (known as inward current). This transient inward current is followed by a sustained flow of positive charge out of the cell (the outward current). By

BOX 5.3

VOLTAGE-CLAMP TECHNIQUE

In the voltage-clamp technique, two independent electrodes are inserted into the squid giant axon: one for recording the voltage difference across the membrane and the other for intracellularly injecting the current (Fig. 5.6). These electrodes are then connected to a feedback circuit that compares the measured voltage across the membrane with the voltage desired by the experimenter. If these two values differ, then current is injected into the axon to compensate for this difference. This continuous feedback cycle, in which the voltage is measured and current is injected, effectively "clamps" the membrane at a particular voltage. If ionic channels were to open, then the resultant flow of ions into or out of the axon would be compensated for by the injection of positive or negative current into the axon through the current-injection electrode. The current injected through this electrode is necessarily equal to the current flowing through the ionic channels. It is this injected current that is measured by the experimenter. The benefits of the voltage-clamp technique are twofold. First, the current injected into the axon to keep the membrane potential "clamped" is necessarily equal to the current flowing through the ionic channels in the membrane, thereby giving a direct measurement of this current. Second, ionic currents are both voltage and time dependent; they become active at certain membrane potentials and do so at a particular rate. Keeping the voltage constant in the voltage clamp allows these two variables to be separated; the voltage dependence and the kinetics of the ionic currents flowing through the plasma membrane can be measured directly.

David A. McCormick

voltage clamping the cell and substituting different ions inside or outside the axon or both, Hodgkin, Huxley, and colleagues demonstrated that the transient inward current is carried by Na^+ ions flowing into the cell, and the sustained outward current is mediated by a sustained flux of K^+ ions moving out of the cell (Fig. 5.7) (Hille, 1977; Hodgkin & Huxley, 1952a, 1952b).

Na^+ and K^+ currents (I_{Na} and I_K, respectively) can be blocked, allowing each current to be examined in isolation (Fig. 5.7B). Tetrodotoxin (TTX), a powerful poison found in the puffer fish *Spheroides rubripes*, selectively blocks voltage-dependent Na^+ currents (the puffer fish remains a delicacy in Japan and must be prepared with the utmost care by the chef). Using TTX, one can selectively isolate I_K and examine its voltage dependence and time course (Fig. 5.7B).

Another compound, tetraethylammonium (TEA), is a useful pharmacological tool for selectively blocking I_K (Fig. 5.7B). The use of TEA to examine the voltage dependence and time course of the Na^+ current underlying action-potential generation (Fig. 5.7B) reveals some fundamental differences between Na^+ and K^+ currents. First, the inward Na^+ current activates, or "turns on," much more rapidly than the K^+ current (giving rise to the name "delayed rectifier" for this K^+ current). Second, the Na^+ current is transient; it inactivates, even if the membrane potential is maintained at 0 mV (Fig. 5.7A). In contrast, the outward K^+ current, once activated, remains "on" as long as the membrane potential is clamped to positive levels; that is, the K^+ current does not inactivate but is sustained. Remarkably, from one experiment, we see that the Na^+ current both activates and inactivates rapidly, whereas the K^+ current only activates slowly. These fundamental properties of the underlying Na^+ and K^+ channels allow the generation of action potentials.

Hodgkin and Huxley proposed that K^+ channels possess a voltage-sensitive "gate" that opens by depolarization and closes by the subsequent repolarization of the membrane potential. This process of "turning on" and "turning off" the K^+ current came to be known as activation and deactivation. The Na^+ current also exhibits voltage-dependent activation and deactivation (Fig. 5.7), but the Na^+ channels also become inactive despite maintained depolarization. Thus, the Na^+ current not only activates and deactivates, but it also exhibits a separate process known as inactivation, whereby the channels become blocked even though they are activated. Removal of this inactivation is achieved by removal of depolarization and is a process known as deinactivation. Thus, Na^+ channels possess two voltage-sensitive processes: activation–deactivation and inactivation–deinactivation.

The kinetics of these two properties of Na^+ channels are different; inactivation takes place at a slower rate than activation. The functional consequence of the two mechanisms is that Na^+ ions are allowed to flow across the membrane only when the current is activated but not inactivated. Accordingly, Na^+ ions do not flow at resting membrane potentials because the activation gate is closed (even though the inactivation gate is not). Upon depolarization, the activation gate opens, allowing Na^+ ions to flow into the cell. However, this depolarization also results in closure (at a slower rate) of the inactivation gate, which then blocks the flow of

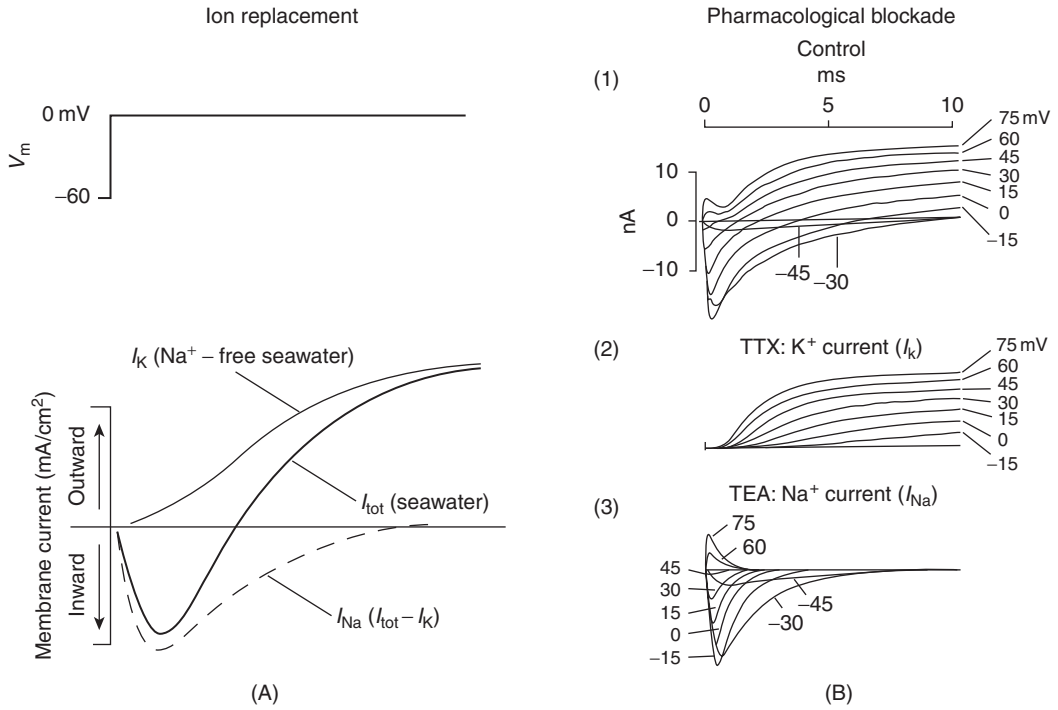

FIGURE 5.7 Voltage-clamp analysis reveals ionic currents underlying action potential generation. (A) Increasing the potential from −60 to 0 mV across the membrane of the squid giant axon activates an inward current followed by an outward current. If the Na^+ in seawater is replaced by choline (which does not pass through Na^+ channels), then increasing the membrane potential from −60 to 0 mV results in only the outward current, which corresponds to I_K. Subtracting I_K from the recording in normal seawater illustrates the amplitude–time course of the inward Na^+ current, I_{Na}. Note that I_K activates more slowly than I_{Na} and that I_{Na} inactivates with time. *From Hodgkin and Huxley (1952).* (B) These two ionic currents can also be isolated from one another through the use of pharmacological blockers. (1) Increasing the membrane potential from −45 to 75 mV in 15-mV steps reveals the amplitude–time course of inward Na^+ and outward K^+ currents. (2) After the block of I_{Na} with the poison tetrodotoxin (TTX), increasing the membrane potential to positive levels activates I_K only. (3) After the block of I_K with tetraethylammonium (TEA), increasing the membrane potential to positive levels activates I_{Na} only. *From Hille (1977).*

Na^+ ions. Upon repolarization of the membrane potential, the activation gate once again closes and the inactivation gate once again opens, preparing the axon for generation of the next action potential (Fig. 5.8)

Depolarization allows ionic current to flow by virtue of activation of the channel. The rush of Na^+ ions into the cell further depolarizes the membrane potential and more Na^+ channels become activated, forming a positive feedback loop that rapidly (within 100 μs or so) brings the membrane potential toward E_{Na}. However, the depolarization associated with generation of the action potential also inactivates Na^+ channels, and, as a larger and larger percentage of Na^+ channels become inactivated, the rush of Na^+ into the cell diminishes. This inactivation of Na^+ channels and the activation of K^+ channels result in the repolarization of the action potential. This repolarization deactivates the Na^+ channels. Then, the inactivation of the channel is slowly removed, and the channels are ready, once again, for the generation of another action potential (Fig. 5.8).

By measuring the voltage sensitivity and kinetics of these two processes, activation–deactivation and inactivation–deinactivation of the Na^+ current, as well as the activation–deactivation of the delayed rectifier K^+ current, Hodgkin and Huxley generated a series of mathematical equations that quantitatively described the generation of the action potential (calculation of the propagation of a single action potential required an entire week of cranking a mechanical calculator). According to these early experimental and computational neuroscientists, the action potential is generated as follows. Depolarization of the membrane potential increases the probability of Na^+ channels being in the activated but not yet inactivated, state. At a particular membrane potential, the resulting inflow of Na^+ ions tips the balance of the net ionic current from outward to inward (remember that depolarization will also increase K^+ and Cl^- currents by moving the membrane potential away from E_K and E_{Cl}). At this membrane potential, known as the action potential threshold (typically about −55 mV), the movement of Na^+ ions into the cell depolarizes the axon and opens more Na^+ channels, causing yet more depolarization of the membrane; repetition of this process yields a rapid, positive feedback loop that brings the axon close to E_{Na}. However, even as more and more Na^+ channels are becoming activated, some of these channels are also

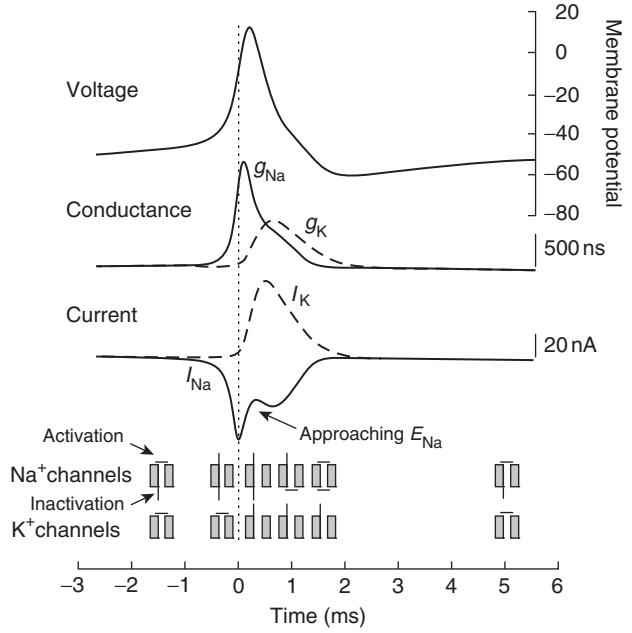

FIGURE 5.8 Generation of the action potential is associated with an increase in membrane Na^+ conductance and Na^+ current followed by an increase in K^+ conductance and K^+ current. Before action potential generation, Na^+ channels are neither activated nor inactivated (illustrated at the bottom of the figure). Activation of Na^+ channels allows Na^+ ions to enter the cell, depolarizing the membrane potential. This depolarization also activates K^+ channels. After activation and depolarization, the inactivation particle on the Na^+ channels closes and the membrane potential repolarizes. The persistence of the activation of K^+ channels (and other membrane properties) generates an after-hyperpolarization. During this period, the inactivation particle of the Na^+ channel is removed and the K^+ channels close.

inactivating and therefore no longer conducting Na^+ ions. In addition, the delayed rectifier K^+ channels are also opening, due to the depolarization of the membrane potential, and allowing positive charge to exit the cell. At some point, close to the peak of the action potential, the inward movement of Na^+ ions into the cell is exactly offset by the outward movement of K^+ ions out of the cell. After this point, the outward movement of K^+ ions dominates, and the membrane potential is repolarized, corresponding to the fall of the action potential. The persistence of the K^+ current for a few milliseconds following the action potential generates the after-hyperpolarization. During this after-hyperpolarization, which is lengthened by the membrane time constant, inactivation of the Na^+ channels is removed, preparing the axon for generation of the next action potential (Fig. 5.8).

The occurrence of an action potential is not associated with substantial changes in the intracellular or extracellular concentrations of Na^+ or K^+, as shown earlier for the generation of the resting membrane potential. For example, generation of a single action potential in a 25-μm-diameter hypothetical spherical cell should increase the intracellular concentration of Na^+ by only approximately 6 μM (from about 18 to 18.006 mM). Thus, the action potential is an electrical event generated by a change in the distribution of charge across the membrane and not by a marked change in the intracellular or extracellular concentration of Na^+ or K^+.

Action Potentials Typically Initiate in the Axon Initial Segment and Propagate Down the Axon and Backwards Through the Dendrites

Neurons have complex morphologies, including dendritic arbors, a cell body, and typically one axonal output that branches extensively. In many cells, all of these parts of the neuron are capable of independently generating action potentials. The activity of most neurons is dictated by barrages of synaptic potentials generated at each moment by a variable subset of the thousands of synapses impinging upon the cell's dendrites and soma. Where, then, is the action potential initiated? In most cells, each action potential is initiated in the initial portion of the axon, known as the axon initial segment (Coombs, Curtis, & Eccles, 1957; Popovic, Foust, McCormick, & Zecevic, 2011; Stuart, Spruston, Sakmann, & Hausser, 1997). The initial segment of the axon has the lowest threshold for action potential generation because it typically contains a moderately high density of Na^+ channels that have a more negative activation threshold and it is a small compartment that is easily depolarized by the in-rush of Na^+ ions. Once a spike is initiated (e.g., about 30–50 μm down the axon from the cell body in cortical pyramidal cells), this action potential then propagates orthodromically down the axon to the synaptic terminals, where it causes release of transmitter, as well as antidromically back through the cell body and into the cell dendrites, where it can modulate intracellular processes.

Refractory Periods Prevent "Reverberation"

The ability of depolarization to activate an action potential varies as a function of the time since the last generation of an action potential, due to the inactivation of Na^+ channels and the activation of K^+ channels. Immediately after the generation of an action potential, another action potential usually cannot be generated regardless of the amount of current injected into the axon. This period corresponds to the absolute refractory period and is largely mediated by the inactivation of Na^+ channels. The relative refractory period occurs during the action potential after-hyperpolarization and follows the absolute refractory period. The relative refractory period is characterized by a requirement for

the increased injection of ionic current into the cell to generate another action potential and results from persistence of the outward K^+ current. The practical implication of refractory periods is that action potentials are not allowed to "reverberate" between the soma and the axon terminals.

The Speed of Action Potential Propagation Is Affected by Myelination

Axons may be either myelinated or unmyelinated. Invertebrate axons or small vertebrate axons are typically unmyelinated, whereas larger vertebrate axons are often myelinated. As described in Chapter 3, sensory and motor axons of the peripheral nervous system are myelinated by specialized cells (Schwann cells) that form a spiral wrapping of multiple layers of myelin around the axon (Fig. 5.9). Several Schwann cells wrap around an axon along its length; between the ends of successive Schwann cells are small gaps (nodes of Ranvier). In the central nervous system, a single oligodendrocyte, a special type of glial cell, typically ensheaths several axonal processes.

In unmyelinated axons, the Na^+ and K^+ channels taking part in action potential generation are distributed along the axon, and the action potential propagates along the length of the axon through local depolarization of each neighboring patch of membrane, causing that patch of membrane to also generate an action potential (Fig. 5.9). Myelination of the axon reduces its membrane capacitance by moving the electrical charge differences between the inside and outside of the axon further apart and thus reducing their influence on each other. This has the effect of significantly increasing the passive length constant (λ) of the axon. In myelinated axons, however, the Na^+ channels are concentrated at the nodes of Ranvier. The generation of an action potential at each node results in depolarization of several adjacent nodes (owing to the long length constant of the myelinated axon) and subsequently generation of an action potential with an internode delay of only about 20 μs, referred to as saltatory conduction (from the Latin *saltare*, "to leap"). Interestingly, since action potentials are typically 1 msec or longer in duration, many adjacent nodes of Ranvier are in the process of generating action potentials at the same time (Popovic et al., 2011). Growing evidence indicates that, near the nodes of Ranvier and underneath the myelin covering, K^+ channels may play a role in determining the resting membrane potential and repolarization of the action potential. A cause of some neurological disorders, such as multiple sclerosis and Guillain-Barre syndrome, is the demyelination of axons, resulting in a block of conduction of the action potentials.

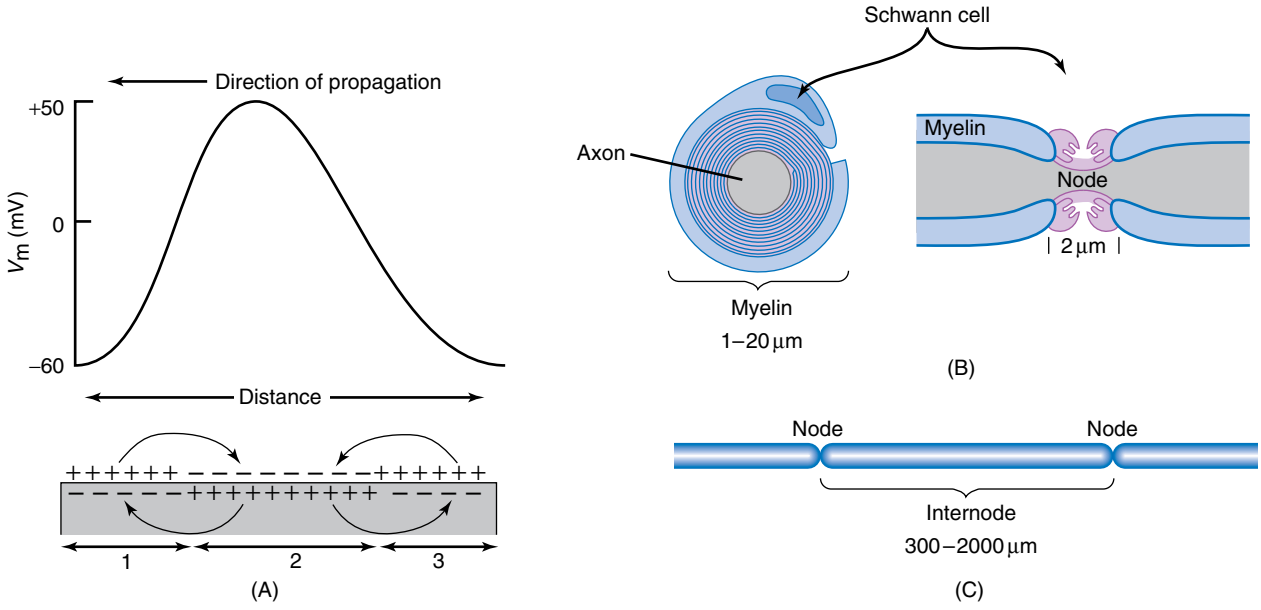

FIGURE 5.9 Propagation of the action potential in unmyelinated and myelinated axons. (A) Action potentials propagate in unmyelinated axons through the depolarization of adjacent regions of membrane. In the illustrated axon, region 2 is undergoing depolarization during the generation of the action potential, whereas region 3 has already generated the action potential and is now hyperpolarized. The action potential will propagate further by depolarizing region 1. (B) Vertebrate myelinated axons have a specialized Schwann cell that wraps around them in many spiral turns. The axon is exposed to the external medium at the nodes of Ranvier (Node). (C) Action potentials in myelinated fibers are regenerated at the nodes of Ranvier, where there is a high density of Na^+ channels. Action potentials are induced at each node through the depolarizing influence of the generation of an action potential at adjacent nodes, thereby increasing conduction velocity.

Ion Channels are Membrane-Spanning Proteins with Water-Filled Pores

The generation of ionic currents useful for the propagation of action potentials requires the movement of significant numbers of ions across the membrane in a relatively short time. The rate of ionic flow during the generation of an action potential is far too high to be achieved by an active transport mechanism and results instead from the opening of ion channels. Although the existence of ionic channels in the membrane has been postulated for decades, their properties and structure have only recently become known in detail. The powerful combination of electrophysiological and molecular techniques has enhanced our knowledge of the structure–function relations of ionic channels greatly (Box 5.4).

Various neural toxins were particularly useful in the initial isolation of ionic channels. For example, three subunits (α, $\beta 1$, $\beta 2$) of the voltage-dependent Na^+ channel were isolated with the use of a derivative of a scorpion toxin. The α subunit of the Na^+ channel is a large glycoprotein with a molecular mass of 270 kDa, whereas the $\beta 1$ and $\beta 2$ subunits are smaller polypeptides of molecular masses 39 and 37 kDa, respectively (Fig. 5.10). The α subunit, of which there are at least nine different isoforms, is the building block of the water-filled pore of the ionic channel, whereas the β subunits have some other role, such as in the regulation or structure of the native channel (Catterall, 2000a).

The α subunit of the Na^+ channel contains four internal repetitions (Fig. 5.10B). Hydrophobicity analysis of these four components reveals that each contains six

BOX 5.4

ION CHANNELS AND DISEASE

Cells cannot survive without functional ion channels. It is therefore not surprising that an ever-increasing number of diseases have been found to be associated with defective ion channel function. There are a number of different mechanisms by which this may occur.

1. Mutations in the coding region of ion channel genes may lead to gain or loss of channel function, either of which may have deleterious consequences. For example, mutations producing enhanced activity of the epithelial Na^+ channel are responsible for Liddle's syndrome, an inherited form of hypertension, whereas other mutations in the same protein that cause reduced channel activity give rise to hypotension. The most common inherited disease in Caucasians is also an ion channel mutation. This disease is cystic fibrosis (CF), which results from mutations in the epithelial chloride channel, known as CFTR. The most common mutation, deletion of a phenylalanine at position 508, results in defective processing of the protein and prevents it from reaching the surface membrane. CFTR regulates chloride fluxes across epithelial cell membranes, and this loss of CFTR activity leads to reduced fluid secretion in the lung, resulting in potentially fatal lung infections.
2. Mutations in the promoter region of the gene may cause under- or overexpression of a given ion channel.
3. Other diseases result from defective regulation of channel activity by cellular constituents or extracellular ligands. This defective regulation may be caused by mutations in the genes encoding the regulatory molecules themselves or defects in the pathways leading to their production. Some forms of maturity-onset diabetes of the young (MODY) may be attributed to such a mechanism. ATP-sensitive potassium (K-ATP) channels play a key role in the glucose-induced insulin secretion from pancreatic β cells, and their defective regulation is responsible for one form of MODY.
4. Autoantibodies to channel proteins may cause disease by downregulating channel function—often by causing internalization of the channel protein itself. Well-known examples are myasthenia gravis, which results from antibodies to skeletal muscle acetylcholine channels, and Lambert–Eaton myasthenic syndrome, in which patients produce antibodies against presynaptic Ca^{2+} channels.
5. Finally, a number of ion channels are secreted by cells as toxic agents. They insert into the membrane of the target cell and form large nonselective pores, leading to cell lysis and death. The hemolytic toxin produced by the bacterium *Staphylococcus aureus* and the toxin secreted by the protozoan *Entamoeba histolytica*, which causes amebic dysentery, are examples.

Natural mutations in ion channels have been invaluable for studying the relationship between channel structure and function. In many cases, genetic analysis of a disease has led to the cloning of the relevant ion channel. The first K^+ channel to be identified (Shaker), for example, came from the cloning of the gene that caused *Drosophila* to shake when exposed to ether. Likewise, the gene encoding the primary subunit of a cardiac potassium channel (KCNQ1) was identified by positional cloning in families carrying mutations that caused a cardiac disorder known

BOX 5.4 (*cont'd*)

as long QT syndrome (see later). Conversely, the large number of studies on the relationship between Na^+ channel structure and function has greatly assisted our understanding of how mutations in Na^+ channels produce their clinical phenotypes.

Many diseases are genetically heterogeneous, and the same clinical phenotype may be caused by mutations in different genes. Long QT syndrome is a relatively rare inherited cardiac disorder that causes abrupt loss of consciousness, seizures, and sudden death from ventricular arrhythmia in young people. Mutations in five different genes, two types of cardiac muscle K^+ channels (HERG, KCNQ1, KCNE1, KCNE2) and the cardiac muscle sodium channel (SCN1A), give rise to long QT syndrome. The disorder is characterized by a long QT interval in the electrocardiogram, which reflects the delayed repolarization of the cardiac action potential. As might therefore be expected, mutations in the cardiac Na^+ channel gene that cause long QT syndrome enhance the Na^+ current (by reducing Na^+ channel inactivation), whereas those in potassium channel genes cause loss of function and reduce the K^+ current.

Mutations in many different types of ion channels have been shown to cause human diseases. In addition to the examples listed earlier, mutations in water channels cause nephrogenic diabetes insipidus; mutations in gap junction channels cause Charcot–Marie–Tooth disease (a form of peripheral neuropathy) and hereditary deafness; mutations in the skeletal muscle Na^+ channel cause a range of disorders known as periodic paralyses; mutations in intracellular Ca^{2+}-release channels cause malignant hyperthermia (a disease in which inhalation anesthetics trigger a potentially fatal rise in body temperature); and mutations in neuronal voltage-gated Ca^{2+} channels cause migraine and episodic ataxia. The list increases daily. As is the case with all single gene disorders, the frequency of these diseases in the general population is very low. However, the insight they have provided into the relationship between ion channel structure and function, and into the physiological role of the different ion channels, has been invaluable. As William Harvey said in 1657, "Nor is there any better way to advance the proper practice of medicine than to give our minds to the discovery of the usual form of nature, by careful investigation of the rarer forms of disease."

Frances M. Ashcroft

hydrophobic domains that may span the membrane as an α-helix. Of these six membrane-spanning components, the fourth (S4) has been proposed to be critical to the voltage sensitivity of the Na^+ channels. Voltage-sensitive gating of Na^+ channels is accomplished by the redistribution of ionic charge ("gating charge") in the channel. Positive charges in the S4 region may act as voltage sensors such that an increase in the positivity of the inside of the cell results in a conformational change of the ionic channel. In support of this hypothesis, site-directed mutagenesis of the S4 region of the Na^+ channel to reduce the positive charge of this portion of the pore also reduces the voltage sensitivity of activation of the ionic channel.

The mechanisms of inactivation of ionic channels have been analyzed with a combination of molecular and electrophysiological techniques. The most convincing hypothesis is that inactivation is achieved by a block of the inner mouth of the aqueous pore. Ionic channels are inactivated without detectable movement of ionic current through the membrane; thus inactivation is probably not directly gated by changes in the membrane potential alone. Rather, inactivation is triggered or facilitated as a secondary consequence of activation. Site-directed mutagenesis or the use of antibodies has shown that the part of the molecule between regions III and IV may be allowed to move to block the cytoplasmic side of the ionic pore after the conformational change associated with activation.

Neurons of the Central Nervous System Exhibit a Wide Variety of Electrophysiological Properties

The first intracellular recordings of action potentials in mammalian neurons by Sir John Eccles and colleagues revealed a remarkable similarity to those of the squid giant axon and gave rise to the assumption that the electrophysiology of neurons in the CNS was really rather simple: when synaptic potentials brought the membrane potential positive to action potential threshold, action potentials were produced through an increase in Na^+ conductance followed by an increase in K^+ conductance, as in the squid giant axon. The assumption, therefore, was that the complicated patterns of activity generated by the brain during the resting, sleeping, or active states were brought about as an interaction of the very large numbers of neurons present in the mammalian CNS. However, intracellular recordings of invertebrate neurons revealed that different cell types exhibit a wide variety of different electrophysiological behaviors, indicating that neurons may be significantly more complicated than the squid giant axon.

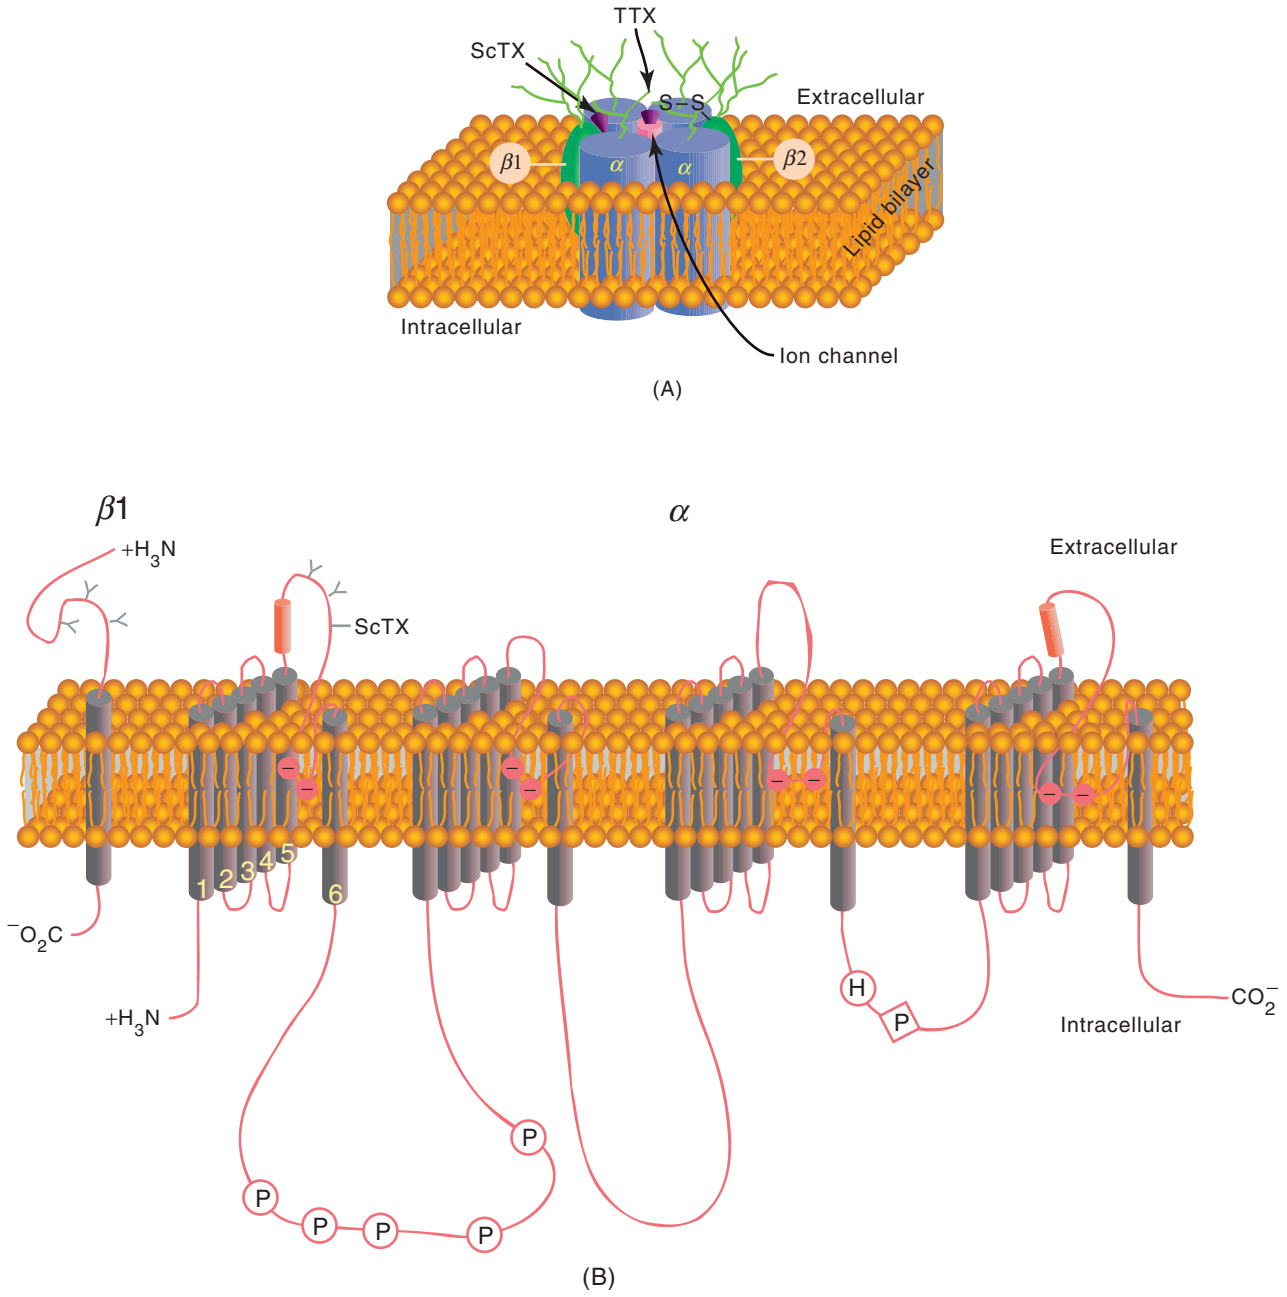

FIGURE 5.10 Structure of the sodium channel. (A) Cross section of a hypothetical sodium channel consisting of a single transmembrane α subunit in association with a $\beta 1$ subunit and a $\beta 2$ subunit. The α subunit has receptor sites for α-scorpion toxins (ScTX) and tetrodotoxin (TTX). (B) Primary structures of α and $\beta 1$ subunits of sodium channel illustrated as transmembrane-folding diagrams. Cylinders represent probable transmembrane α-helices.

Elucidation of the basic electrophysiology and synaptic physiology of different types of neurons and neuronal pathways within the mammalian CNS was facilitated by the *in vitro* slice technique, in which thin (~0.5 mm) slices of brain can be maintained for several hours. Intracellular recordings from identified cells revealed that neurons of the mammalian nervous system, such as those of invertebrate networks, can generate complex patterns of action potentials entirely through intrinsic ionic mechanisms and without synaptic interaction with other cell types. For example, Rodolfo Llinás and colleagues discovered that Purkinje cells of the cerebellum can generate high-frequency trains (>200 Hz) of Na^+- and K^+-mediated action potentials interrupted by Ca^{2+} spikes in the dendrites, whereas a major afferent to these neurons, the inferior olivary cell, can generate rhythmic sequences of

broad action potentials only at low frequencies (<15 Hz) through an interaction between various Ca^{2+}, Na^{+}, and K^{+} conductances (Fig. 5.11). These *in vitro* recordings confirmed a major finding obtained with earlier intracellular recordings *in vivo*: each morphologically distinct class of neuron in the brain exhibits distinct electrophysiological features. Just as cortical pyramidal cells are morphologically distinct from cerebellar

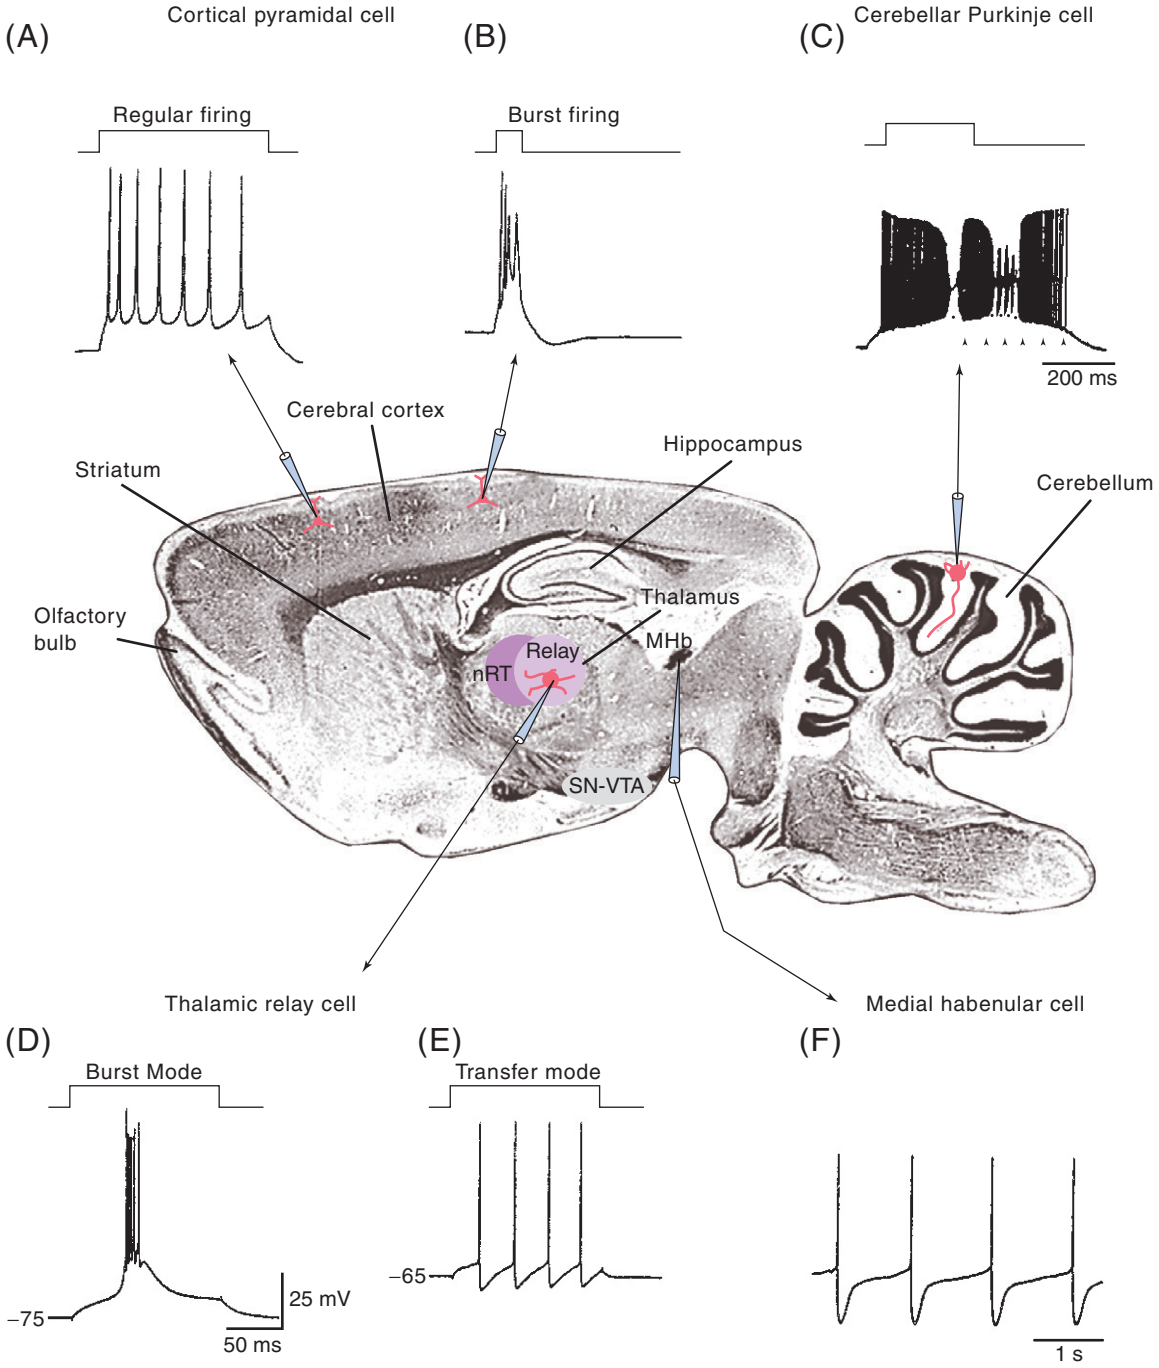

FIGURE 5.11 Neurons in the mammalian brain exhibit widely varying electrophysiological properties. (A) Intracellular injection of a depolarizing current pulse in a cortical pyramidal cell results in a train of action potentials that slow down in frequency. This pattern of activity is known as "regular firing." (B) Some cortical cells generated bursts of three or more action potentials, even when depolarized only for a short period of time. (C) Cerebellar Purkinje cells generate high-frequency trains of action potentials in their cell bodies that are disrupted by the generation of Ca^{2+} spikes in their dendrites. These cells can also generate "plateau potentials" from the persistent activation of Na^{+} conductances (arrowheads). Thalamic relay cells may generate action potentials either as bursts (D) or as tonic trains of action potentials (E) due to the presence of a large low-threshold Ca^{2+} current. (F) Medial habenular cells generate action potentials at a steady and slow rate in a "pacemaker" fashion.

Purkinje cells, which are distinct from thalamic relay cells, the electrophysiological properties of each of these different cell types are also markedly distinct (Llinás, 1988).

Although no uniform classification scheme has been formulated in which all the different types of neurons of the brain can be classified, a few characteristic patterns of activity seem to recur. The first general class of action potential generation is characterized by those cells that generate trains of action potentials one spike at a time. The more prolonged the depolarization of these cells, the more prolonged their discharge. The more intensely these cells are depolarized, the higher the frequency of action potential generation. This type of relatively linear behavior is typical for brainstem and spinal cord motor neurons functioning in muscle contraction. A modification of this basic pattern of "regular firing" is characterized by the generation of trains of action potentials that exhibit a marked tendency to slow down in frequency with time, a process known as spike frequency adaptation. Examples of cells that discharge in this manner are cortical and hippocampal pyramidal cells.

In addition to these regular firing cells, many neurons in the central nervous system exhibit the intrinsic propensity to generate rhythmic bursts of action potentials (Fig. 5.11). Examples of such neurons are thalamic relay neurons, inferior olivary neurons, and some types of cortical and hippocampal pyramidal cells. In these cells, clusters of action potentials can occur together when the membrane is brought above the firing threshold. These clusters of action potentials are typically generated through the activation of specialized Ca^{2+} currents that, through their slower kinetics, allow the membrane potential to be depolarized for a sufficient period to result in the generation of a burst of regular, Na^+- and K^+-dependent action potentials (discussed in the next section).

Yet another general category of neurons in the brain comprises cells that generate relatively short duration (<1 ms) action potentials and can discharge at relatively high frequencies (>300 Hz). Such electrophysiological properties are often found in neurons that release the inhibitory amino acid γ-aminobutyric acid (Fig. 5.11), including Purkinje cells of the cerebellum and some types of interneurons in the cerebral cortex, thalamus, and hippocampus. Finally, the last general category of neurons consists of those that spontaneously generate action potentials at relatively slow frequencies (e.g., 1–10 Hz). This type of electrophysiological behavior is often associated with neurons that release neuromodulatory transmitters, such as acetylcholine, norepinephrine, serotonin, and histamine. Neurons that release these neuromodulatory substances often innervate wide regions of the brain and appear to set the "state" of the different neural networks of the CNS in a manner similar to the modulation of the different organs of the body by the sympathetic and parasympathetic nervous systems.

Each of these unique intrinsic patterns of activity in the nervous system is due to the presence of a distinct mixture and distribution of different ionic currents in the cells. As in classical studies of the squid giant axon, these different ionic currents have been characterized, at least in part, with voltage-clamp and pharmacological techniques, and the basic electrophysiological properties have been replicated with computational simulations (Figs. 5.8 and 5.13).

Neurons Have Multiple Active Conductances

The search for the electrophysiological basis of the varying intrinsic properties of different types of neurons of vertebrates and invertebrates revealed a wide variety of ionic currents. Each type of ionic current is characterized by several features: (1) the type of ions conducted by the underlying ionic channels (e.g., Na^+, K^+, Ca^{2+}, Cl^-, or mixed cations), (2) their voltage and time dependence, and (3) their sensitivity to second messengers. In vertebrate neurons, two distinct Na^+ currents have been identified and six distinct Ca^{2+} currents and more than seven distinct K^+ currents are known (Fig. 5.12). This is a minimal number, since these currents are formed from a much greater pool of channel subunits. The following sections briefly review these classes of ionic currents and their ionic channels, relating them to the different patterns of behavior mentioned earlier for neurons in the mammalian CNS.

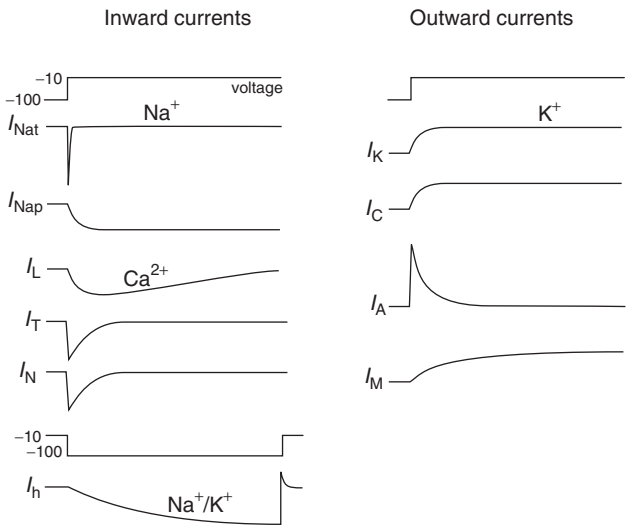

FIGURE 5.12 Voltage dependence and kinetics of different ionic currents in the mammalian brain. Depolarization of the membrane potential from –100 to –10 mV results in the activation of currents entering or leaving neurons.

Na^+ Currents are Both Transient and Persistent

Depolarization of many different types of vertebrate neurons results not only in the activation of the rapidly activating and inactivating Na^+ current (I_{Nat}) underlying action potential generation, but also in the rapid activation of a Na^+ current that does not inactivate and is therefore known as the "persistent" Na^+ current (I_{Nap}). The threshold for activation of the persistent Na^+ current is typically about −65 mV—that is, below the threshold for the generation of action potentials. This property gives this current the interesting ability to enhance or facilitate the response of the neuron to depolarizing, yet subthreshold, inputs. For example, synaptic events that depolarize the cell will activate I_{Nap}, resulting in an extra influx of positive charge and therefore a larger depolarization than otherwise would occur. Likewise, hyper-polarizations may result in deactivation of I_{Nap}, again resulting in larger hyperpolarizations than would otherwise occur. In this manner, the persistent Na^+ current may play an important regulatory function in the control of the functional responsiveness of the neuron to synaptic inputs and may contribute to the dynamic coupling of the dendrites to the soma.

Persistent activation of I_{Nap} may also contribute to another electrophysiological feature of neurons: the generation of plateau potentials. A plateau potential refers to the ability of many different types of neurons to generate, through intrinsic ionic mechanisms, a prolonged (from tens of milliseconds to seconds) depolarization and action potential discharge in response to a short-lasting depolarization (Fig. 5.11C). One can wonder whether such plateau potentials contribute to persistent firing in neurons during the performance of working memory tasks, where groups of neurons have to retain information for brief (seconds) periods of time.

K^+ Currents Vary in Their Voltage Sensitivity and Kinetics

Potassium currents that contribute to the electrophysiological properties of neurons are numerous and exhibit a wide range of voltage-dependent and kinetic properties (reviewed in Coetzee et al., 1999). Perhaps the simplest K^+ current is that characterized by Hodgkin and Huxley: this K^+ current, I_K, activates rapidly on depolarization and does not inactivate (Fig. 5.12). Other K^+ currents activate with depolarization but also inactivate with time. For example, the rapid activation and inactivation of I_A give this current a transient appearance (Fig. 5.12), and I_A is believed to be important in controlling the rate of action potential generation, particularly at low frequencies (Fig. 5.13). Like the Na^+ channel, I_A channels are inactivated by the plugging of the inner mouth of the pore through movement of an inactivation particle.

Another broad class of K^+ channels consists of those that are sensitive to changes in the intracellular concentration of Ca^{2+}. These K^+ currents are collectively referred to as I_{KCa} (Fig. 5.12). Still other K^+ channels are not only activated by voltage but are also modulated by the activation of various modulatory neurotransmitter receptors (e.g., I_M; Fig. 5.12). Between these classic examples of K^+ currents are a variety of other types that have not been fully characterized, including K^+ currents that vary from one another in their voltage sensitivity, kinetics, and response to various second messengers.

Molecular biological studies of voltage-sensitive K^+ channels, first done in Drosophila and later in mammals, have revealed the presence of a large number of genes that generate K^+ channels. The voltage-gated K^+ channel subunits are contained within nine distinct subfamilies: Kv1-9 (reviewed in Coetzee et al., 1999). These genes generate a wide variety of different K^+ channels, not only due to the large number of genes involved, but also due to alternative RNA splicing, gene duplication, and other mechanisms. Functional expression of different K^+ channels reveals remarkable variation in the rate of inactivation, such that some are rapidly inactivating (A-current like), whereas others inactivate more slowly and, finally, some K^+ channels do not inactivate, such as I_K. One of the largest subfamilies of K^+ channels are those that give rise to the resting membrane potential, so-called "leak channels." Interestingly, these channels appear to be opened by gaseous anesthetics, indicating that hyperpolarization of central neurons is a major component of general anesthesia. It is now clear that each type of neuron in the nervous system contains a unique set of functional voltage-sensitive K^+ channels, selected, modified, and placed in particular spatial locations in the cell in a manner that facilitates the unique role of that cell type in neuronal processing.

An additional current that also regulates the responsiveness of neurons to depolarizing inputs is the voltage-sensitive K^+ current known as the M current (Figs. 5.12 and 5.13D) (Brown & Passmore, 2009). By investigating the ionic mechanisms by which the release of acetylcholine from preganglionic neurons in the brain results in prolonged changes in the excitability of neurons of the sympathetic ganglia, Brown and Adams (1980) discovered a unique K^+ current that slowly (over tens of milliseconds) turns on with depolarization of the neuron (Fig. 5.13D). The slow activation of this K^+ current results in a decrease in the responsiveness of the cell to depolarization and therefore regulates how the cell responds to excitation. This K^+ current, like I_{AHP}, is reduced by the activation of a wide variety of receptors, including muscarinic receptors, for which it is named. Reduction of I_M results in a marked increase in responsiveness of the affected cell to depolarizing inputs and

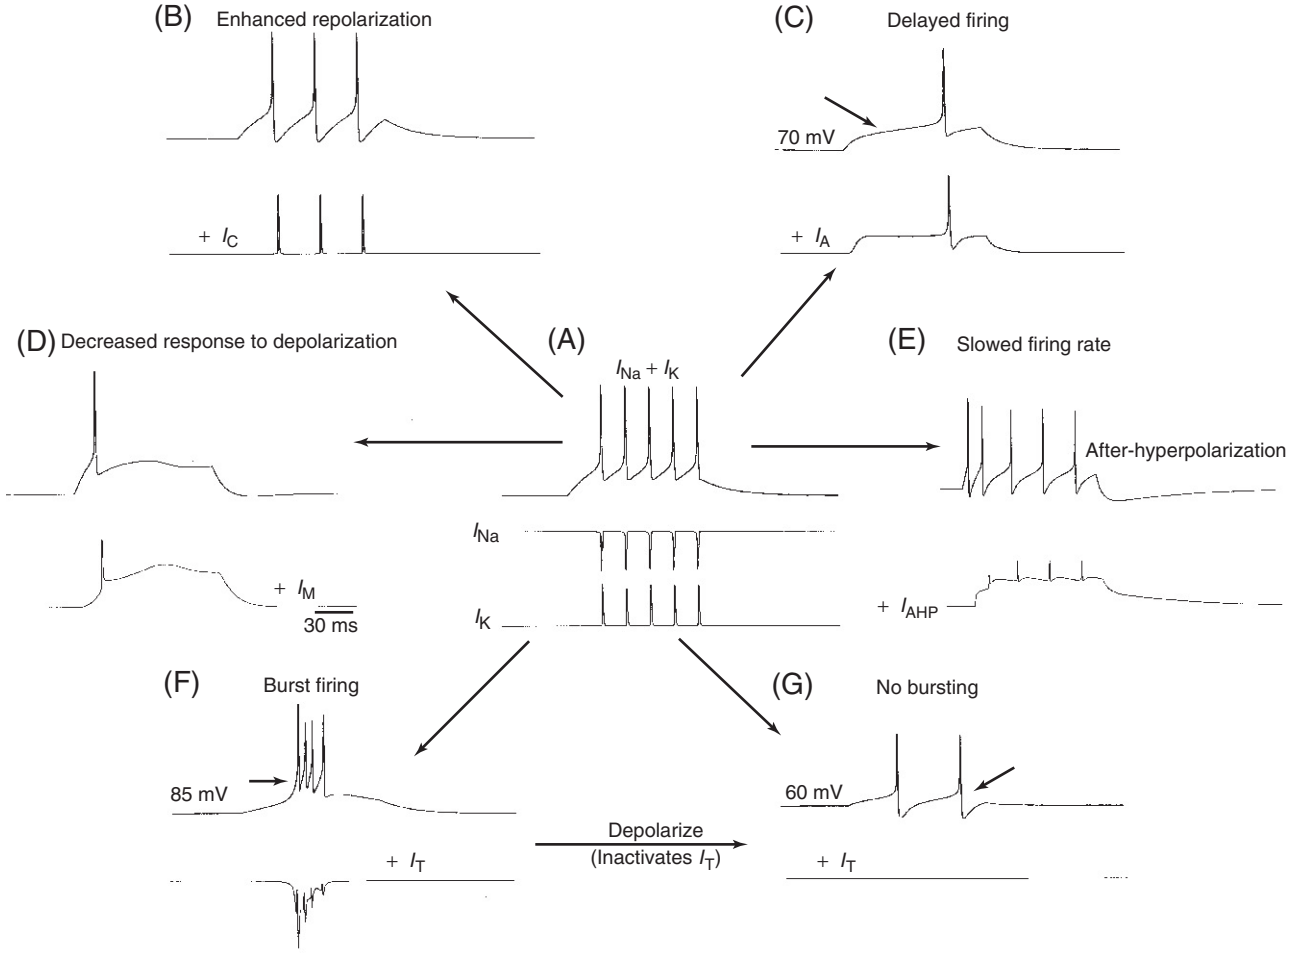

FIGURE 5.13 Simulation of the effects of the addition of various ionic currents to the pattern of activity generated by neurons in the mammalian CNS. (A) The repetitive impulse response of the classical Hodgkin–Huxley model (voltage recordings above, current traces below). With only I_{Na} and I_K, the neuron generates a train of five action potentials in response to depolarization. Addition of I_C (B) enhances action potential repolarization. Addition of I_A (C) delays the onset of action potential generation. Addition of I_M (D) decreases the ability of the cell to generate a train of action potentials. Addition of I_{AHP} (E) slows the firing rate and generates a slow after-hyperpolarization. Finally, addition of the transient Ca^{2+} current I_T results in two states of action potential firing: (F) burst firing at −85 mV and (G) tonic firing at −60 mV. *From Huguenard and McCormick (1994).*

again may contribute to the mechanisms by which neuromodulatory systems control the state of activity in cortical and hippocampal networks (reviewed in McCormick, 1992; Nicoll, 1988).

Ca^{2+} Currents Control Electrophysiological Properties and Ca^{2+}-Dependent Second-Messenger Systems

Ionic channels that conduct Ca^{2+} are present in all neurons. These channels are special in that they serve two important functions. First, Ca^{2+} channels are present throughout the different parts of the neuron (dendrites, soma, synaptic terminals) and contribute greatly to the electrophysiological properties of these processes. Second, Ca^{2+} channels are unique in that Ca^{2+} is an important second messenger in neurons, and entry of Ca^{2+} into the cell can affect numerous physiological functions, including neurotransmitter release, synaptic plasticity, neurite outgrowth during development, and even gene expression. On the bases of their voltage sensitivity, their kinetics of activation and inactivation, and their ability to be blocked by various pharmacological agents, Ca^{2+} currents can be separated into at least six separate categories, three of which are I_T ("transient"), I_L ("long lasting"), and I_N ("neither"), illustrated in Figure 5.12A. A fourth, I_P, is found in Purkinje cells of the cerebellum, as well as in many different cell types of the CNS. These Ca^{2+} channels are formed from at least 10 different α subunits as well as a variety of β and γ subunits, indicating that an even greater number of Ca^{2+} currents are yet to be characterized.

Neurons Possess Multiple Subtypes of High-Threshold Ca^{2+} Currents

High-voltage-activated Ca^{2+} channels are activated at membrane potentials positive to approximately −40 mV and include the currents I_L, I_N, and I_P. L-type calcium currents exhibit a high threshold for activation (about −10 mV) and give rise to rather persistent, or long-lasting, ionic currents (Fig. 5.12A). Dihydropyridines, Ca^{2+} channel antagonists, are clinically useful for their effects on the heart and vascular smooth muscle (e.g., for the treatment of arrhythmias, angina, and migraine headaches) and selectively block L-type Ca^{2+} channels. In contrast with I_L, I_N is not blocked by dihydropyridines: it is blocked selectively by a toxin found in Pacific cone shells (ω-conotoxin-GVIA). N-type Ca^{2+} channels have a threshold for activation of about −20 mV, inactivate with maintained depolarization, and are modulated by a variety of neurotransmitters. In some cell types, I_N has a role in the Ca^{2+}-dependent release of neurotransmitters at presynaptic terminals. The P-type calcium channel is distinct from N and L types in that it is not blocked by either dihydropyridines or ω-conotoxin-GVIA but is blocked by a toxin (ω-agatoxin-IVA) present in the venom of the Funnel web spider. This type of calcium channel activates at relatively high thresholds and does not inactivate. Prevalent in Purkinje cells, as well as other cell types, as mentioned earlier, the P-type Ca^{2+} channel participates in the generation of dendritic Ca^{2+} spikes, which can strongly modulate the firing pattern of the neuron in which it resides (Fig. 5.11C; Llinás, 1988).

Collectively, high-threshold-activated Ca^{2+} channels contribute to the generation of action potentials in mammalian neurons. The activation of Ca^{2+} currents adds somewhat to the depolarizing part of the action potential, but, more importantly, these channels allow Ca^{2+} to enter the cell, which has the secondary consequence of activation of various Ca^{2+}-activated K^+ currents and protein kinases (see Chapter 8). As mentioned earlier, activation of these K^+ currents modifies the pattern of action potentials generated in the cell (Figs. 5.11 and 5.13).

High-threshold Ca^{2+} channels are similar to the Na^+ channel in that they are composed of a central α1 subunit that forms the aqueous pore and several regulatory or auxiliary subunits. As in the Na^+ channel, the primary structure of the α1 subunit of the Ca^{2+} channel consists of four homologous domains (I–IV), each containing six regions (S1–S6) that may generate transmembrane α-helices. Genes for at least 10 different Ca^{2+} channel α subunits have been cloned and are separated into three subfamilies (Cav1, Cav2, and Cav3). The properties of the products of these genes indicate that I_L is likely to correspond to the Cav1 subfamily, whereas I_N corresponds to Cav2.2 and I_T is formed from the Cav3 subfamily (see Catterall, 2000b).

Low-Threshold Ca^{2+} Currents Generate Bursts of Action Potentials

Low-threshold Ca^{2+} currents (Fig. 5.12A) often take part in the generation of rhythmic bursts of action potentials (Figs. 5.11 and 5.13). The low-threshold Ca^{2+} current is characterized by a threshold for activation of about −65 mV, which is below the threshold for generation of typical Na^+–K^+-dependent action potentials (−55 mV). This current inactivates with maintained depolarization. Because of these properties, the role of low-threshold Ca^{2+} currents differs markedly from that of the high-threshold Ca^{2+} currents. Through activation and inactivation of the low-threshold Ca^{2+} current, neurons can generate slow (about 100 ms) Ca^{2+} spikes, which can result, due to their prolonged duration, in generation of a high-frequency "burst" of short-duration Na^+–K^+ action potentials (Fig. 5.11).

In the mammalian brain, this pattern is especially well exemplified by the activity of thalamic relay neurons; in the visual system, these neurons receive direct input from the retina and transmit this information to the visual cortex. During periods of slow wave sleep, the membrane potential of these relay neurons is relatively hyperpolarized, resulting in the removal of inactivation (deinactivation) of the low-threshold Ca^{2+} current. This deinactivation allows these cells to spontaneously generate low-threshold Ca^{2+} spikes and bursts of from two to five action potentials (Fig. 5.14). The large number of thalamic relay cells bursting during sleep in part gives rise to the spontaneous synchronized activity that early investigators were so surprised to find during recordings from the brains of sleeping animals. It has even proved possible to maintain one of the sleep-related brain rhythms (spindle waves) intact in slices of thalamic tissue maintained *in vitro*, due to the generation of this rhythm by the interaction of a local network of thalamic cells and their electrophysiological properties.

The transition to waking or the period of sleep when dreams are prevalent (rapid eye movement sleep) is associated with a maintained depolarization of thalamic relay cells to membrane potentials ranging from about −60 to −55 mV. The low-threshold Ca^{2+} current is inactivated and therefore the burst discharges are abolished. In this way, the properties of a single ionic current (I_T) help explain in part the remarkable changes in brain activity taking place in the transition from sleep to waking (Fig. 5.14).

Hyperpolarization-Activated Ionic Currents Are Involved in Rhythmic Activity

In most types of neurons, hyperpolarization negative to approximately −60 mV activates an ionic current, known as I_h, that conducts both Na^+ and K^+ ions (Fig. 5.12). This

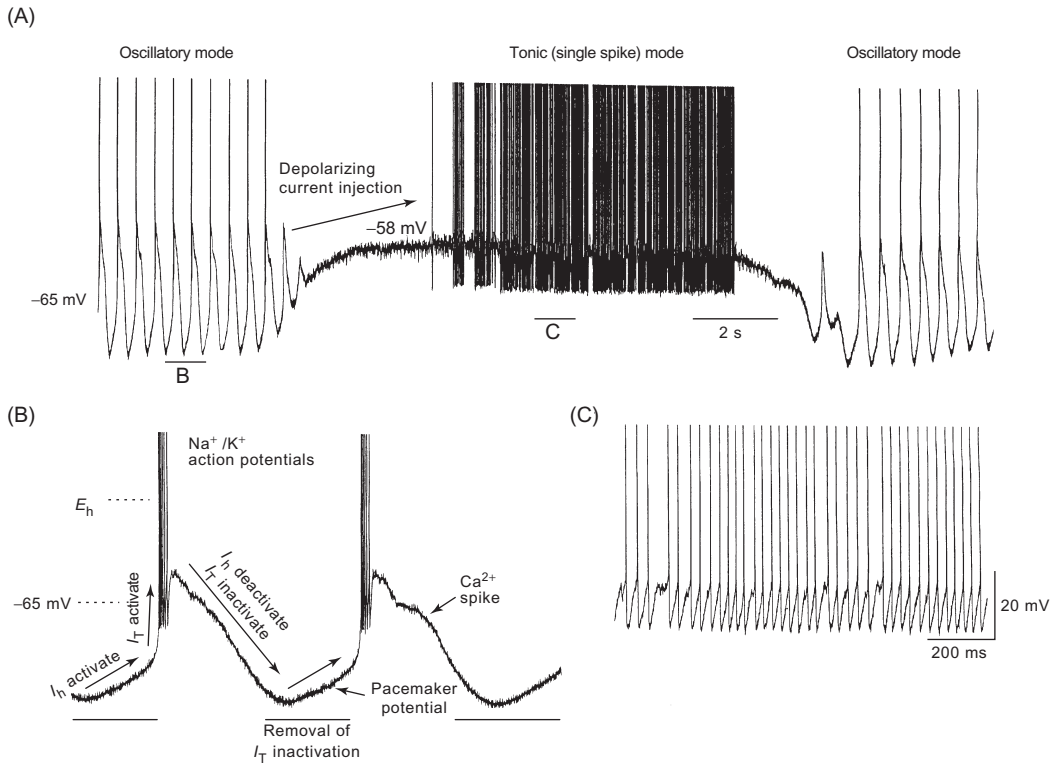

FIGURE 5.14 Two different patterns of activity generated in the same neuron, depending on membrane potential. (A) The thalamic neuron spontaneously generates rhythmic bursts of action potentials due to the interaction of the Ca^{2+} current I_T and the inward "pacemaker" current I_h. Depolarization of the neuron changes the firing mode from rhythmic burst firing to tonic action potential generation in which spikes are generated one at a time. Removal of this depolarization reinstates rhythmic burst firing. This transition from rhythmic burst firing to tonic activity is similar to that which occurs in the transition from sleep to waking. (B) Expansion of detail of rhythmic burst firing. (C) Expansion of detail of tonic firing. *From McCormick and Pape (1990).*

current typically has very slow kinetics, turning on with a time constant on the order of tens of milliseconds to seconds. Because the channels underlying this current allow the passage of both Na^+ and K^+ ions, the reversal potential of I_h is typically about −35 mV—between E_{Na} and E_K. Because this current is activated by hyperpolarization below approximately −60 mV, it is typically dominated by the inward movement of Na^+ ions and is therefore depolarizing. For what purpose could neurons use a depolarizing current that activates when the cell is hyperpolarized? A clue comes from cardiac cells in which this current, known as I_f for "funny," is important for determining heart rate. Activation of I_f results in a slow depolarization of the membrane potential between adjacent cardiac action potentials. The more that I_f is activated, the faster the membrane depolarizes between beats, and therefore the sooner the threshold for the next action potential is reached and the next beat is generated. In this manner, the amplitude, or sensitivity to voltage, of I_f can modify the heart rate. Interestingly, the sensitivity of I_f to voltage is adjusted by the release of noradrenaline and acetylcholine; the activation of adrenoceptors by noradrenaline increases I_f and therefore increases the heart rate, whereas the activation of muscarinic receptors decreases I_f, thereby decreasing the heart rate (see DiFrancesco, 2005). This continual adjustment of I_f results from a "push–pull" arrangement between β-adrenergic and muscarinic cholinergic receptors and is mediated by the adjustment of intracellular levels of cyclic AMP. Indeed, the recent cloning of H channels reveals that their structure is similar to that of cyclic nucleotide-gated channels.

Could I_h play a role in neurons similar to that of I_f in the heart? Possibly. Synchronized rhythmic oscillations in the membrane potential of large numbers of neurons, in some respects similar to those of the heart, are characteristic of the mammalian brain. Oscillations of this type are particularly prevalent in thalamic relay neurons during some periods of sleep, as mentioned earlier. Intracellular recordings from these thalamic neurons reveal that they often generate rhythmic "bursts" of action potentials mediated by the activation of a slow spike that is generated through the activation of the low-threshold, or transient, Ca^{2+} current, I_T (Fig. 5.14). Between the occurrence of each low-threshold Ca^{2+} spike is a slowly depolarizing membrane potential generated by activation of the mixed Na^+–K^+ current I_h, as with I_f in the heart. The amplitude, or

voltage sensitivity, of I_h adjusts the rate at which the thalamic cells oscillate, and, as with the heart, this sensitivity is adjusted by the release of modulatory neurotransmitters. In a sense, the thalamic neurons are "beating" in a manner similar to that of the heart.

Summary

An action potential is generated by the rapid influx of Na^+ ions followed by a slightly slower efflux of K^+ ions. Although the generation of an action potential does not disrupt the concentration gradients of these ions across the membrane, the movement of charge is sufficient to generate a large and brief deviation in the membrane potential. Action potentials are typically initiated in the axon initial segment and the propagation of the action potential along the axon allows communication of the output of the cell to its distant synapses. Neurons possess many different types of ionic channels in their membranes, allowing complex patterns of action potentials to be generated and complex synaptic computations to occur within single neurons.

CHAPTER

6

Neurotransmitters

The pioneering studies of Santiago Ramon y Cajal revealed that each cell (neuron) of the brain is an independent structure in close proximity but not physical contact with another neuron (see Shepherd, 1991). Although a half century elapsed before the introduction of the electron microscope led to the final confirmation of this hypothesis, a general acceptance of neurons as the independent building blocks of the brain emerged much more quickly. In turn, this resulted in a new debate: How do these neurons communicate? The answer to this question has evolved continuously over the past century and has become increasingly complex, but the major mode of communication is by chemical messengers.

Neurons share certain structural characteristics (see Chapter 3). They have a cell body (soma) from which processes emerge. One of these types of processes, the axon, is often long but can also be short and thus exert local effects or distant ones. Moreover, axons can branch extensively or have a very confined arbor. In contrast, dendrites are exclusively local structures. The identification of long (axon) and short (dendrite) processes led to the idea that the long axonal projections served to transmit information between neurons over (relatively) long distances, and dendrites were the receptive elements of neurons, responding to the information conveyed by long axons. The gap over which information between neurons must be relayed was termed the *synapse* by Charles Sherrington and came to identify pre- and postsynaptic cells. This general conceptual framework remains in place today, although there are many exceptions, including dendrites that release neuroactive substances and axons that receive inputs from other neurons. One other characteristic proposed by Sherrington that is central to the concept of chemical communication between neurons is that synaptic transmission does not follow all-or-none rules, but is graded in strength and is flexible.

SEVERAL MODES OF NEURONAL COMMUNICATION EXIST

Over the first half of the twentieth century, there was a vigorous debate on the nature of neuronal communication: as one overview of this debate described, it was a war of sparks (electrical communication) and soups (chemical messengers) (see Valenstein, 2005). The debate raged despite the fact that some evidence was marshaled in support of chemical transmission in the mid-nineteenth century. In 1849, Claude Bernard noted that curare, the active constituent of a poison that was applied to arrows in South America, blocked nerve-to-muscle signaling. This effect subsequently was shown to be due to the binding of curare to postsynaptic (muscle) receptors for acetylcholine (ACh), thus blocking neuro-muscular transmission. About 50 years later, Thomas Elliott found that epinephrine caused the contraction of smooth muscle that had been deprived of its nerve inputs, suggesting that muscle contraction depended on the action of chemical molecules liberated from nerves. In a key series of studies using isolated frog hearts, Otto Loewi provided firm evidence in support of chemical neurotransmission by showing that ACh was released upon nerve stimulation and activated a target muscle.

These and other data suggested that the major means of interneuronal communication is chemical in nature, but that neurons also use other processes for intercellular communication. Among these are electrical synaptic transmission, ephaptic interactions, and autocrine, paracrine, and long-range signaling, to which molecules produced by both neural and nonneural cells contribute. The nonsynaptic mode of intercellular communication with the longest range (distance) is hormonal signaling. For example, some hormones made outside of the brain can enter the central nervous system (CNS) to exert effects

© 2013 Elsevier Inc. All rights reserved.

on neurons that express receptors for the hormones. These hormone actions may occur over the short term (changes in neuronal activity) or, more often, over a longer period (long-lasting changes in gene expression).

Molecules released from neurons can also be used in intercellular signaling that does not require synaptic specializations. A variety of molecules are secreted by neurons or diffuse passively from cells, ranging from conventional neurotransmitters to gases such as nitric oxide. These factors may act through autocrine mechanisms (activating receptors on the same cell that releases them) or paracrine pathways to influence nearby cells. Some of these compounds can be retrograde signaling molecules, providing chemically coded feedback to the presynaptic neuron and reversing the more common forward (anterograde) direction of information flow. The role of such molecules is thought to be primarily in modulating neural activity, although they may also provide guidance cues for neurons that are growing toward their final targets in the brain, as well as for the establishment and maintenance of synaptic connections (see Chapters 16 and 18).

CHEMICAL TRANSMISSION

Chemically mediated transmission is the major mode of neuronal communication. The general acceptance of chemical neurotransmission as the means of conveying information between neurons resulted in specific criteria being required for designation of a compound as a neurotransmitter. Based on these "classical" criteria, a relatively small number of compounds have been designated as neurotransmitters. However, over the past generation it has become apparent that a large number of chemical messengers broadly qualify as intercellular transmitters, although these compounds often do not meet—and even seem to sharply differ from—the classical criteria.

Criteria for Designation as a Neurotransmitter

Neurotransmitters are usually considered to be endogenous substances that are released from neurons, act on receptor sites that are typically present on membranes of postsynaptic cells, and produce a functional change in the properties of the target cell. Over the years general agreement evolved that several criteria should be met for a substance to be designated a neurotransmitter:

1. A neurotransmitter must be synthesized by and released from neurons. Thus, the presynaptic neuron should contain both the transmitter and the appropriate enzymes needed to synthesize that neurotransmitter.
2. The substance should be released from nerve terminals in a chemically or pharmacologically identifiable form. It should therefore be possible to isolate the transmitter and characterize its structure.
3. A neurotransmitter should reproduce at the postsynaptic cell the specific events (such as changes in membrane properties) that are seen after stimulation of the presynaptic neuron.
4. The effects of a putative neurotransmitter should be blocked by competitive antagonists of the receptor for that transmitter in a dose-dependent manner. In addition, treatments that inhibit synthesis of the transmitter should block the effects of presynaptic stimulation.
5. There should be active mechanisms to terminate the action of the neurotransmitter. Among such mechanisms are uptake of the transmitter by the presynaptic neurons or glial cells through specific transporter molecules and enzymatic inactivation of the chemical messenger.

The Five Steps of Chemical Neurotransmission

Synaptic transmission consists of a number of steps. The general mechanisms of chemical synaptic transmission are depicted in Figure 6.1.

1. *Synthesis of the neurotransmitter in the presynaptic neuron.* In order for the transmitter to be synthesized, precursors should be present in appropriate places within neurons. Enzymes that convert the precursor(s) into the transmitter should be present in an active form and localized to the appropriate compartment in the neuron. For example, one would not expect synthetic enzymes for the transmitter to be found in the nucleus or the mitochondrion, but these enzymes should be found in the cytosol or in intracellular structures that store the transmitter. In addition, any cofactors that are required for enzyme activity should be present. Drugs that affect the synthesis of neurotransmitters have long been of value in medicine. An example is "α-methyl-*p*-tyrosine, a drug used to treat an adrenal gland tumor that sharply increases blood pressure by releasing very large amounts of norepinephrine (NE); α-methyl-*p*-tyrosine prevents the synthesis of NE and thereby lowers blood pressure.
2. *Storage of the neurotransmitter and/or its precursor in the presynaptic nerve terminal.* Classical and peptide transmitters are stored in synaptic vesicles, where they are sequestered and protected from enzymatic degradation and are ready for quick release. In the case of classical neurotransmitters such as acetylcholine, the synaptic vesicles are small (~50 nm in diameter), in contrast to the large dense-core

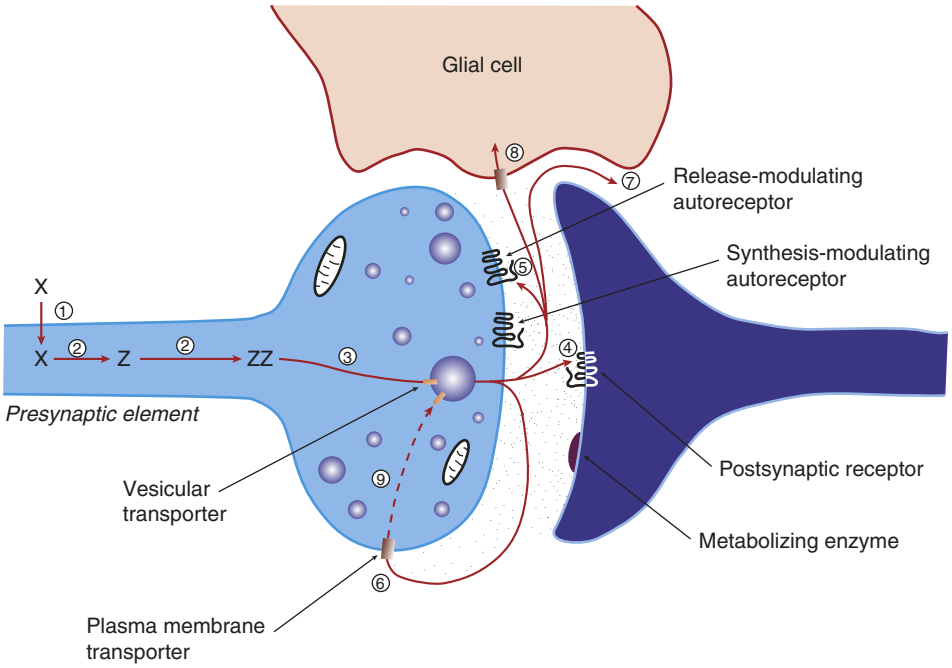

FIGURE 6.1 Schematic representation of the life cycle of a classical neurotransmitter. After accumulation of a precursor amino acid into the neuron (1), the amino acid precursor is metabolized sequentially (2) to yield the mature transmitter. The transmitter is then accumulated into vesicles by the vesicular transporter (3), where it is poised for release and protected from degradation. Once released, the transmitter can interact with postsynaptic receptors (4) or autoreceptors (5) that regulate transmitter release, synthesis, or firing rate. Transmitter actions are terminated by means of a high-affinity membrane transporter (6) that usually is associated with the neuron that released the transmitter. Alternatively, transmitter actions may be terminated by diffusion from the active sites (7) or accumulation into glia through a membrane transporter (8). When the transmitter is taken up by the neuron, it is subject to metabolic inactivation (9).

vesicles (~100 nm in diameter) in which neuropeptide transmitters are stored. Vesicles are often found adjacent to the presynaptic membrane, where they are poised to be released in response to stimulation of the neuron. Because most neurotransmitters are synthesized in the cytosol of neurons, there must be some mechanism through which the transmitter enters the vesicle. This occurs through a vesicular transporter protein that accumulates the transmitter through an energy-dependent process.

3. *Release of the neurotransmitter into the synaptic cleft.* The vesicle in which the transmitter is stored fuses with the cell membrane and releases the transmitter. Neurons use two pathways to secrete proteins. The release of most neurotransmitters occurs by a regulated pathway that is controlled by extracellular signals. The neurotransmitter release process is discussed more fully in Chapter 7. A second (constitutive) pathway of release is not triggered by extracellular stimulation and is used to continuously secrete membrane components, viral proteins, and extracellular matrix molecules. Some unconventional transmitters (such as growth factors) may be synthesized and released by both constitutive and regulated pathways.
4. *Binding and recognition of the neurotransmitter by target receptors.* Once released, neurotransmitters interact with receptors located on the target cell. Most transmitter receptors fall into two broad classes. The first are membrane proteins called metabotropic receptors, which are coupled to intracellular G proteins as effectors (see Chapter 8). Ionotropic receptors form channels through which ions such as Na^+ and Ca^{2+} can enter the neuron. Receptors are also found on the neuron that releases the transmitter. This presynapatic receptor can respond to the transmitter released from the same cell as part of a feedback process to the presynaptic neuron. Such receptors are called autoreceptors, and regulate transmitter release, synthesis, or impulse flow. Alternatively, presynaptic receptors can respond to a chemical signal elaborated from the postsynaptic neuron, another type of feedback mechanism. Finally, receptors on axon terminals can respond to transmitter released from the axon of a different cell, in which case the receptor is called a heteroceptor.
5. *Termination of the action of the released transmitter.* If a cell cannot stop the continued actions of a neurotransmitter, chaotic information flow and sometimes overt cell damage results. Sustained activation of postsynaptic targets can result in tetanus (sustained muscle contraction) or seizures. If one thinks of chemical transmission as being the flow of information, continuous unregulated transmitter release is not conveying to the target cell temporally specific data, such as the rate of firing of the presynaptic neuron or the pattern of firing of the neuron. Neurotransmitter actions may be terminated actively or passively. Among the active termination processes is reuptake of the neurotransmitter through specific transporter proteins on the presynaptic neuron or on glial cells. Another common means of terminating the action of a transmitter is by

enzymatic degradation to an inactive substance. Finally, inactivation can happen by simple diffusion of the transmitter from the synaptic region. All three processes often work cooperatively to terminate the action of a neurotransmitter.

These five steps form a logical scaffold for understanding classical and peptide chemical neurotransmission. There are, however, differences across the various transmitters. We discuss in detail one class of neurotransmitters, the catecholamines, to illustrate the process of chemical neurotransmission, and then examine more briefly other classical neurotransmitters. We also discuss differences between classical and nonclassical transmitters or chemical messengers, including peptide transmitters and unconventional transmitters (such as nitric oxide, growth factors, and endocannabinoids).

CLASSICAL NEUROTRANSMITTERS

The term *classical* is used to differentiate acetylcholine, the biogenic amines, and the amino acid transmitters from other transmitters. The designation is somewhat arbitrary, although these compounds were all accepted as neurotransmitters by the late 1950s. Several factors differentiate classical and other transmitters. First, storage vesicles for classical transmitters are smaller. Second, an energy-dependent reuptake process accumulates classical transmitters that have been released by the presynaptic neuron, allowing subsequent reuse of the transmitter. In contrast, there is no energy-dependent, high-affinity reuptake process for nonclassical transmitters. Third, most classical transmitters are synthesized in the nerve terminal by the actions of one or more enzymes, while peptides are synthesized in the soma from a precursor protein and are then transported to the nerve terminal. The remainder of this chapter deals with the biochemistry of several different transmitter groups, discussing their synthesis, storage, and release, and concludes with new developments that have recently been discovered and expand significantly our understanding of neuronal communication. Other aspects of chemical transmission, including detailed discussions of transmitter release and the receptors for various transmitters is presented in Chapters 7 and 8.

Catecholamine Neurotransmitters

Catecholamines are organic compounds that contain a catechol nucleus (a benzene ring with two adjacent hydroxyl substitutions) and an amine group. The term *catecholamine* is normally used to refer to the three transmitters dopamine (DA), norepinephrine (NE), and epinephrine (Epi). These three neurotransmitters derived from a common precursor are formed by successive enzymatic steps requiring separate enzymes (Fig. 6.2). The presence of these specific synthesizing enzymes in different cells results in different groups of neurons in the brain that synthesize and use as a transmitter either DA, NE, or Epi.

Catecholamines also have transmitter roles in the peripheral (autonomic) nervous system or have certain hormonal functions. For example, catecholamine-containing cells are present in the lining of the intestines where they regulate gut motility. NE is the transmitter of the sympathetic nervous system in mammals, whereas Epi is the sympathetic transmitter in frogs. Despite this species difference, biochemical aspects of neurotransmission are remarkably constant across different vertebrate species and even invertebrates.

Biosynthesis of Catecholamines

The amino acids phenylalanine and tyrosine are precursors for catecholamines. Both amino acids are found in high concentrations in the plasma and brain. In mammals, tyrosine can be formed from dietary phenylalanine by the enzyme phenylalanine hydroxylase, which is found in large amounts in the liver. Insufficient amounts of phenylalanine hydroxylase result in phenylketonuria, a metabolic disorder that leads to intellectual deficits unless treated by dietary manipulation.

Catecholamine synthesis in the brain is usually considered to begin with tyrosine. The enzyme tyrosine hydroxylase (TH) converts the amino acid L-tyrosine into 3,4-dihydroxyphenylalanine (L-DOPA). In turn, L-DOPA is metabolized by L-aromatic amino acid decarboxylase (AADC; see Iversen, Iversen, Bloom, & Roth, 2008) to the transmitter dopamine. This latter step occurs so rapidly that it is almost impossible to measure L-DOPA in the brain without first inhibiting AADC. In neurons that use DA as a transmitter, the decarboxylation of L-DOPA to DA is the final step in transmitter synthesis. However, in neurons that use norepinephrine (also known as noradrenaline) or epinephrine (adrenaline) as transmitters, the enzyme dopamine-β-hydroxylase (DBH), which converts DA to yield NE, is also present. In still other neurons in which epinephrine is the transmitter, a third enzyme (phenylethanolamine *N*-methyltransferase, PNMT) converts NE into Epi. Thus, a cell that uses Epi as its transmitter contains four key enzymes (TH, AADC, DBH, and PNMT), whereas NE neurons contain three enzymes (lacking PNMT), while DA cells have but two transmitter biosynthetic enzymes (TH and AADC).

Tyrosine Hydroxylase

In human beings, a single TH gene is alternatively spliced to yield four TH mRNAs, leading to four TH protein isoforms. In most other primates, only two TH

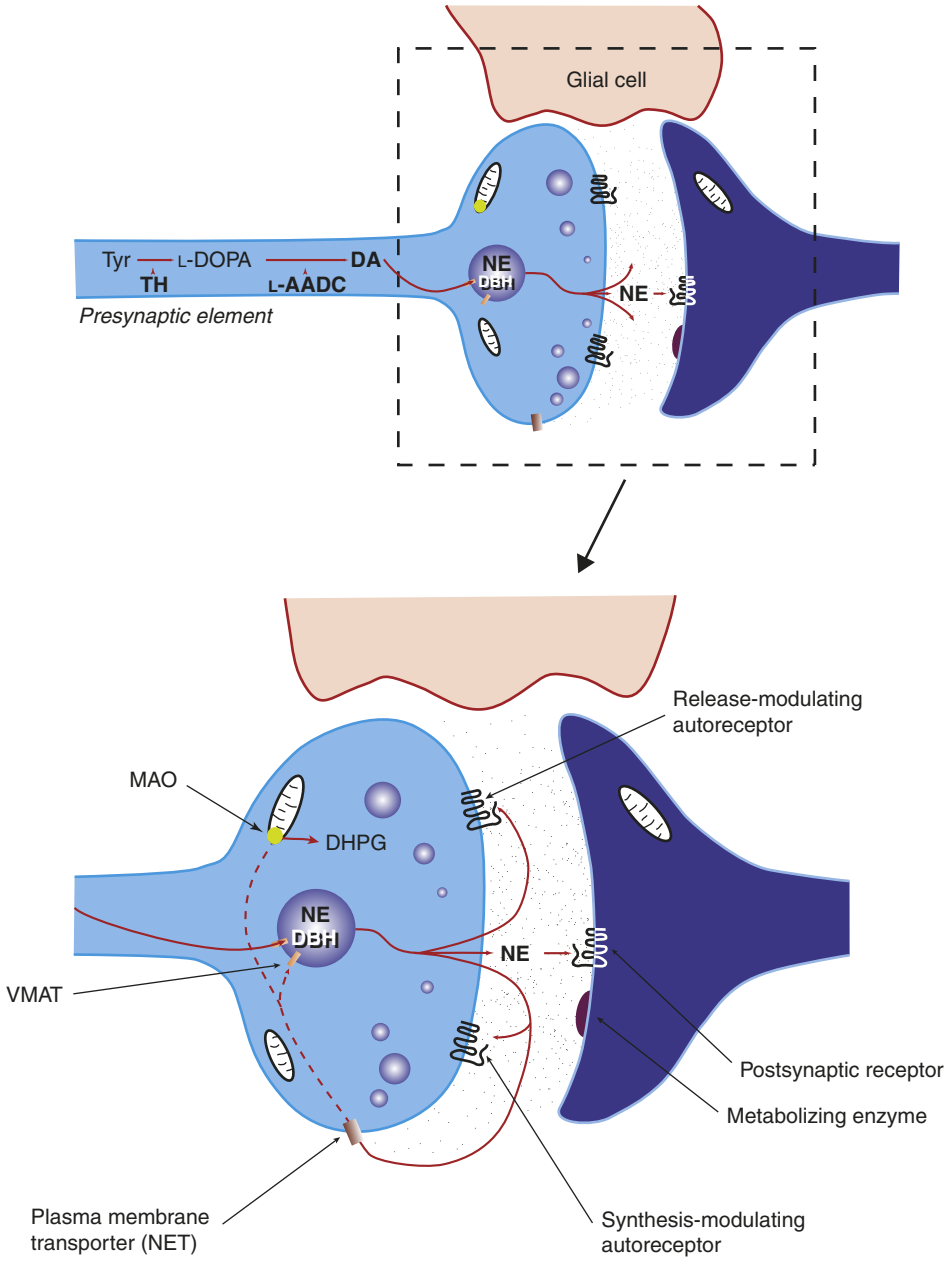

FIGURE 6.2 Characteristics of a norepinephrine (NE)-containing catecholamine neuron. Tyrosine (Tyr) is accumulated by the neuron and then is metabolized sequentially by tyrosine hydroxylase (TH) and L-aromatic amino acid decarboxylase (L-AADC) to dopamine (DA). The DA is then taken up through the vesicular monoamine transporter into vesicles. In DA neurons, this is the final step. However, in this NE-containing cell, DA is metabolized to NE by dopamine-b-hydroxylase (DBH), which is found in the vesicle. Once NE is released, it can interact with postsynaptic noradrenergic receptors or presynaptic noradrenergic autoreceptors. The accumulation of NE by the high-affinity membrane NE transporter (NET) terminates the actions of NE. Once taken back up by the neuron, NE can be metabolized to inactive compounds (DHPG) by degradative enzymes such as monoamine oxidase (MAO) or taken back up by the vesicle.

isoforms are present, and rodents have but a single form of TH. It has been suggested that the human TH isoforms are differentially regulated and have different activities.

TH is a mixed-function oxidase with moderate substrate specificity, hydroxylating phenylalanine, as well as tyrosine. The actions of TH require the cofactor tetrahydrobiopterin (BH4) and iron (Fe^{2+}). BH4 is also an essential cofactor for tryptophan hydroxylase, an enzyme that synthesizes another transmitter, serotonin. Because BH4 is not present in saturating concentrations under basal conditions, it is crucial in regulating TH activity. Intracellular levels of BH4 are determined by its own synthesizing enzyme, GTP cyclohydrolase. Mutations in the gene encoding GTP cyclohydrolase cause DOPA-responsive dystonia, a movement disorder in which DA synthesis is markedly decreased; treatment consists of bypassing the disruption of TH synthesis by administering L-DOPA, the immediate precursor of dopamine.

The two major processes that determine the function of enzymes are mechanisms that control enzyme activity (the rate at which the enzyme converts a precursor into its product) and the amount of newly synthesized enzyme protein. The major factor that determines the activity of TH is phosphorylation of the enzyme at four key serine residues. A second means of regulating enzyme activity is through end-product inhibition: catecholamines can

inhibit the activity of TH by competing for a required cofactor for the enzyme (Iversen et al., 2008).

When neurons require additional catecholamine transmitter to keep demand with release, this can be accomplished by synthesizing new TH protein or increasing the activity of the TH activity. The degree to which increases in catecholamine synthesis depend on *de novo* synthesis of new enzyme protein or changes in the activity of existing enzymes differs across brain regions. For example, chronic increases in the activity of most norepinephrine neurons are accompanied by increases in TH gene expression and subsequent translation of the enzyme. But midbrain dopamine neurons do not appear to meet increased neurotransmitter demand by making more of the enzyme, instead primarily relying on increasing activity of the enzyme through phosphorylation.

The synthesis of catecholamines starts with the entry of tyrosine into the brain. This process is an energy-dependent one in which tyrosine competes with large neutral amino acids as a substrate for a transporter. Because brain tyrosine levels are high enough to saturate TH, catecholamine synthesis cannot usually be increased by administration of tyrosine. Exceptions to this rule are catecholamine synthesis in cells that have a very high activity and thus release the catecholamine transmitter at rapid rates, or in disease states in which entry of tyrosine into the brain is retarded.

L-Aromatic Amino Acid Decarboxylase

As noted above, the hydroxylation of tyrosine by TH generates L-DOPA, which is then decarboxylated to dopamine by the enzyme L-aromatic amino acid decarboxylase (AADC; also sometimes referred to as DOPA decarboxylase). AADC has low substrate specificity and decarboxylates tryptophan as well as tyrosine. Because AADC is found in serotonin as well as catecholamine neurons, it plays an important role in the synthesis of both serotonin and catecholamines. In dopaminergic neurons, AADC is the final enzyme of the synthetic pathway.

Administration of L-DOPA is the primary treatment for Parkinson's disease, which is due to loss of dopamine. Dopamine itself cannot readily enter the brain, but the dopamine precursor L-DOPA freely enters the brain and, after being accumulated by dopamine neurons, is metabolized to dopamine. Although L-DOPA crosses the blood–brain barrier to enter the brain, systemically administered L-DOPA is so rapidly metabolized in the blood that little of the precursor actually reaches the brain. To circumvent this problem L-DOPA is administered together with a second drug that does not enter the brain but inhibits decarboxylases in the bloodstream.

Dopamine-β-Hydroxylase

Noradrenergic and adrenergic neurons contain the enzyme dopamine-β-hydroxylase (DBH), which converts DA into NE. In noradrenergic neurons, this is the final step in catecholamine synthesis. Humans have two different DBH mRNAs that are generated from a single gene. DBH has poor substrate specificity and *in vitro* oxidizes almost any phenylethylamine to its corresponding phenylethanolamine. For example, in addition to forming NE from DA, DBH converts tyramine into octopamine. Receptors that have a high affinity for the trace amines tyramine and octopamine have recently been discovered (see Zucchi, Chiellini, Scanlan, & Grandy, 2006) and may be involved in certain psychiatric disorders and in the side effects of certain drugs used to treat major depression.

Phenylethanolamine-N-Methyltransferase

Phenylethanolamine-N-methyltransferase is present at high levels in a small number of brainstem neurons that use epinephrine as a transmitter. PNMT is also found in the inner portion (medulla) of the adrenal gland, where it methylates NE to form Epi, the major adrenal catecholamine. There is a single PNMT gene. Brain PNMT regulation has not been extensively studied, but expression of the mRNA encoding PNMT is regulated by adrenal glucocorticoids and nerve growth factor.

Storage of Catecholamines and Their Enzymes

Catecholamines are stored in specialized subcellular organelles called vesicles. Accordingly, a specialized vesicular transporter protein is required in order for dopamine and other transmitters that are formed in the cytosol to enter the vesicle (El Mestikawy, Wallén-Mackenzie, Fortin, Descarries, & Trudeau, 2011).

Vesicular Storage

The vesicle serves as a depot for the transmitter until it is released by appropriate physiological stimuli (see Chapters 5 and 7). In addition, by storing transmitters in an organelle, vesicles protect the transmitter from metabolic inactivation by cytosolic enzymes.

The norepinephrine-synthesizing enzyme DBH differs from the other enzymes in catecholamine synthesis by being found in the vesicle rather than the cytosol. This means that only *after* DA is taken up by vesicles through a vesicular monoamine transporter (VMAT) is it metabolized to NE. This vesicular storage of DBH has an interesting consequence: DBH and dopamine can both be released into the synapse along with NE.

Vesicular Monoamine Transporters

The ability of vesicles to accumulate DA and other compounds depends on VMAT. The vesicular transporter differs from the neuronal membrane transporter that terminates the action of catecholamines in terms of substrate affinity and localization. Two VMAT genes have

been cloned: VMAT1 is found in adrenal gland cells that synthesize and release catecholamines, and VMAT2 is found in the catecholamine and serotonin-containing neurons of the brain. VMAT2 is not very specific and accumulates catecholamines, indoleamines such as serotonin, and histamine into vesicles.

The VMATs are inhibited by reserpine. This drug has been used for centuries in India as a folk medicine to treat high blood pressure and psychoses. These uses of reserpine were reported in international journals in the early 1930s, but these therapeutic actions were not appreciated in Western medicine until a generation later; the unpleasant side effects of reserpine initially garnered more attention. In the 1950s Bernard Brodie and coworkers discovered that reserpine depleted brain serotonin. The contemporaneous discovery that the hallucinogen LSD is structurally similar to serotonin led to the proposal that the antipsychotic actions of reserpine were due to its ability to deplete serotonin in the brain. However, it was soon realized that reserpine depletes both serotonin and catecholamines in the brain; thus, antipsychotic effects of reserpine might be due to serotonin or catecholamine depletion, or both.

To determine if serotonin or catecholamines were more important for the antipsychotic effect of reserpine, Arvid Carlsson and colleagues administered catecholamine and serotonin precursors to rats treated with reserpine in an attempt to replenish the levels of the transmitters. At the time of these studies dopamine was not thought to be a transmitter, but was considered to be present solely as a precursor of norepinephrine. Carlsson and collaborators examined locomotor activity, which is severely depressed by reserpine. Motor function was restored by the DA precursor L-DOPA but not by the serotonin precursor 5-hydroxytryptophan. This work led to the characterization of DA as a neurotransmitter. The demonstration that L-DOPA increases brain DA concentrations in animals treated with reserpine to deplete vesicular stores of DA also suggested that the primary mechanism through which reserpine exerts antipsychotic effects was through its ability to disrupt DA transmission. This idea led directly to the hypothesis that the dysfunction of central DA systems underlies schizophrenia.

VMATs have significant homology with bacterial antibiotic drug resistance transporters, suggesting a role of VMAT in detoxification. This is indeed the case: VMAT can sequester toxins (as it sequesters transmitters) in vesicles. This is perhaps best illustrated by studies of genetically modified mice with low VMAT2 expression. In these mice, the toxin MPTP (which disrupts mitochondrial function and elicits dopamine neuron degeneration) results in a greater loss of dopamine than seen in control mice. This is because less MPTP is sequestered in vesicles, with more MPTP in the cytosol where it may disrupt mitochondria.

Release of Catecholamines

Catecholamine release usually occurs through a calcium-dependent exocytotic process involving brief fusion of the transmitter-containing vesicle with the plasma membrane (see Chapter 8). However, catecholamine release can also occur through at least two other mechanisms. First, catecholamines can be released by a reversal of the dopamine and NE transporters to extrude the catecholamines; this mode of release is seen after administration of amphetamine. Second, dopamine can be released from dendrites through a process that does not appear to involve calcium.

Regulation of Catecholamine Synthesis and Release by Autoreceptors

Enzymes that control catecholamine synthesis can be regulated at both the transcriptional level and by post-translational modifications (such as phosphorylation) that alter enzymatic activity. In addition, DA and NE synthetic enzymes can be regulated by autoreceptors on the nerve terminal.

Autoreceptors are found on most parts of the neuron and are defined functionally by the events that they regulate. Thus, synthesis-, release-, and impulse-modulating DA autoreceptors have been described (see Iversen et al., 2008). All three types of DA autoreceptors belong to the D2 family of DA receptors, which includes three different receptors (D_2, D_3, and D_4). It is clear that D_2 autoreceptors exist, but the presence of D_3 DA autoreceptors remains controversial; there are no D_4 autoreceptors. Because all three types of autoreceptors are D_2 receptors, there must be different coupling to distinct intracellular signaling cascades to acount for the functional differences between release-, synthesis, and impulse-modulating autoreceptors.

The autoreceptor can be thought of as a key part of a feedback mechanism. Thus, DA that is released from a neuron stimulates an autoreceptor to inhibit further DA release. *Release-modulating* autoreceptors are a common regulatory feature of all neurons that use classical transmitters. Because *intra*cellular DA levels regulate tyrosine hydroxylase activity by interfering with the binding of TH to its cofactor, changes in the release of DA may also alter transmitter synthesis. *Synthesis-modulating* autoreceptors directly regulate DA synthesis: DA release and subsequent binding to the D_2 autoreceptor decreases DA synthesis, while DA antagonists that block the autoreceptor increase catecholamine synthesis. Interestingly, synthesis-modulating autoreceptors are not found on all DA neurons: some midbrain and hypothalamic DA neurons lack synthesis-modulating autoreceptors. Finally, *impulse-modulating* autoreceptors are found on the soma and dendrites of DA neurons and regulate the firing rates of these cells. Because the release of DA can alter synthesis

of the transmitter by changing feedback inhibition on TH, it follows that impulse-modulating autoreceptors also change DA synthesis. Thus, all three types of DA autoreceptors may ultimately regulate synthesis. The interdependence of regulatory processes governing DA cells is characteristic of monoaminergic neurons.

Inactivation of Catecholamine Transmission

Constant levels of a neurotransmitter in the synapse will not accurately convey information about the dynamic state of the presynaptic neuron to its follower cell. In addition, continuous stimulation of certain receptors is pathological and can damage postsynaptic cells. For example, when certain receptors for the transmitter glutamate are activated continuously, the result is "excitotoxic" cell death. In order to prevent continuous presynaptic signaling, different mechanisms have evolved for terminating the actions of a transmitter. The simplest is diffusion of the transmitter and its subsequent dilution in extracellular fluid to subthreshold concentrations. More important, however, are active modes of halting transmitter action, including uptake of the transmitter by membrane-associated transporter proteins and enzymatic inactivation of the transmitter.

Enzymatic Inactivation of Catecholamines

Enzymatic inactivation originally was thought to be the major means of terminating catecholamine actions in the CNS. Two enzymes contribute to catecholamine catabolism: monoamine oxidase (MAO) and catechol-*O*-methyltransferase (COMT). These enzymes can act independently or can act on the products generated by the other enzyme, leading to catecholamine metabolites that are deaminated, *O*-methylated, or both. COMT is a relatively nonspecific enzyme that transfers methyl groups from the donor *S*-adenosylmethionine to the *m*-hydroxy group of catechols. COMT is found both in peripheral tissues and the central nervous system and is the major means of inactivating catecholamines that are released from the adrenal gland.

MAOs oxidatively deaminate catecholamines and their *O*-methylated derivatives to form inactive and unstable derivatives that can be further degraded by other enzymes. Two forms of MAO have been identified. MAO_A has high affinities for NE and serotonin and is selectively inhibited by drugs such as clorgyline. In contrast, MAO_B has a higher affinity for *o*-phenylethylamines and is selectively inhibited by different compounds, such as deprenyl. The MAOs are important targets of drugs used to treat several neuropsychiatric disorders (Box 6.1).

Neuronal Catecholamine Transporters

The reuptake of a transmitter released by a neuron is the major mode of inactivation of classical neurotransmitters in the brain. Accumulation of the transmitter also allows intracellular enzymes that degrade the transmitter to act, thus bolstering the actions of extracellular enzymes.

Several characteristics define the high-affinity reuptake process for transmitters. The process is energy dependent and saturable, depends on Na^+ cotransport, and requires extracellular Cl^-. Because reuptake depends on coupling to the Na^+ gradient across the neuronal membrane, toxins that inhibit Na^+,K^+-ATPase inhibit reuptake. Under certain conditions, the coupling of transporter function to Na^+ flow may cause local changes in membrane Na^+ gradients and thereby paradoxically cause the transporter to operate in "reverse" to "release" the transmitter from the cell to the extracellular space.

Membrane catecholamine transporters are not Mg^{2+} dependent and are not inhibited by reserpine, which distinguishes neuronal and vesicular membrane transporters. Catecholamine transporters are localized to neurons. Although a reuptake process accumulates catecholamines into astrocytes, a type of glial cell, this is not a high affinity process and its functional significance is unclear.

Two distinct mammalian catecholamine transporters, one for dopamine (dopamine transporter, DAT) and one for norepinephrine (NET), have been identified. The two are closely related members of a class of transporter proteins (including serotonin and amino acid transmitter transporters) with 12 transmembrane domains. Neither transporter is specific, with each accumulating both DA and NE. In fact, NET has a higher affinity for dopamine than for NE.

The regional distribution of DAT and NET largely follows the expected localization to DA and NE neurons, respectively. However, DAT does not appear to be expressed in all DA cells. Certain hypothalamic cells that release DA into the blood system of the pituitary lack detectable DAT mRNA and protein. Because DA released from these neurons is carried away in the blood, there is no need for a transporter protein on these DA cells.

Immunohistochemical studies of the subcellular localization of DAT found that the transporter is not present at the synaptic junction, but is located just outside of this region. Thus, the transporter may be used to accumulate DA that has escaped from the synaptic cleft. This suggests that diffusion is the initial process by which DA is removed from the synapse. The extrasynaptic localization of the catecholamine transporters, coupled with a similar extrasynaptic localization of dopamine receptors, suggests that extrasynaptic ("volume") neurotransmission may be of major importance in transmitter actions (see Agnati, Guidolin, Guescini, Genedani, & Fuxe, 2010).

Mice in which the gene encoding DAT has been deleted have been particularly useful in clarifying the function of transporters. Transgenic mice that lack DAT have a remarkable number of changes in DA function, ranging from increased extracellular DA levels and

BOX 6.1

MAO AND COMT INHIBITORS IN THE TREATMENT OF NEUROPSYCHIATRIC DISORDERS

One hypothesis of the pathophysiology of depression posits a decrease in noradrenergic levels in the brain. MAO_A inhibitors, such as tranylcypromine, effectively increase NE levels (as well as DA and 5-HT concentrations) and were once a mainstay in the treatment of depression. However, the use of MAO inhibitors in depression is less common today, with the major pharmacological treatments being drugs that increase extracellular NE levels by blocking the NE transporter (tricyclic antidepressants) and other drugs that increase 5-HT or DA levels by blocking SERT or DAT (such as Prozac and Welbutrin). The treatment of depression with MAO_A inhibitors, although still useful for certain patients who do not respond to other antidepressants, is marred by a large number of side effects. Among the most serious is hypertensive crisis. Patients treated with MAO_A inhibitors cannot metabolize tyramine efficiently, which is present in large amounts in foods such as aged cheeses and red wines. Because tyramine releases catecholamines peripherally, small amounts of tyramine increase blood pressure significantly and increase the risk for a stroke.

Deprenyl, a specific inhibitor of MAO_B, has been used as an initial treatment for Parkinson's disease (PD; see Chapter 31). The use of deprenyl in the treatment of PD and the rationale for its use were based on data from studies of a neurotoxin, 1-methyl-4-pheny 1-1,2,3,6-tetrahydropyridine (MPTP). MPTP causes degeneration of midbrain DA neurons and a parkinsonian syndrome. MPTP-induced parkinsonism was first noted in a group of opiate addicts: in an attempt to synthesize a designer drug, the structurally related MPTP was inadvertently produced. Addicts who injected this drug developed a severe parkinsonian syndrome. Subsequent animal studies showed that MPTP itself is not toxic, but that its active metabolite, MPP^+, is highly toxic. The formation of MPP^+ from MPTP is catalyzed by MAO_B, and thus treatment with MAO inhibitors such as deprenyl can prevent MPTP toxicity. The realization that MPTP administration reproduces the motor deficits on PD reawakened interest in environmental toxins as a cause of PD. The MPTP saga also led to the idea that deprenyl treatment might slow the progression of PD by preventing metabolism of some environmental compound to an active toxin. Although clinical studies initially were interpreted to suggest that deprenyl treatment slowed progression of Parkinson's disease, later studies showed that deprenyl increases DA levels slightly and thus gives some symptomatic relief.

Catechol O-methyl transferase, which together with MAO degrades catecholamines, also plays a role in the treatment of PD. Two COMT inhibitors are used to prevent the enzymatic inactivation of DOPA. By inhibiting COMT, these drugs prolong the therapeutic action of DOPA and may smooth out fluctuations in the therapeutic response to DOPA.

Changes in catecholamine function also have been the object of intense scrutiny in schizophrenia, with recent attention focusing on possible changes in dopamine. One allelic variant of the COMT gene results in a much reduced activity of the enzyme. Data have examined COMT alleles for full vs. low COMT activity in normal subjects and schizophrenics. Individuals bearing the allele that confers lower COMT activity display improved performance on cognitive tasks that involve DA actions in the prefrontal cortex; the performance of schizophrenic persons on these tasks is impaired. It therefore has been proposed that high COMT activity may confer an increased risk to schizophrenia.

Ariel Y. Deutch and Robert H. Roth

delayed clearance of released DA to a striking decrease in tissue concentrations of DA in the face of increased DA synthesis (Gainetdinov, Jones, Fumagalli, Wightman, & Caron, 1998). Some of the deficits in DAT knockout mice have been suggested to reflect a disinhibition of tyrosine hydroxylase due to a lack of intraneuronal DA (removing feedback inhibition of the enzyme), resulting in a marked increased in DA synthesis and release.

The catecholamine transporters are important targets of many drugs. Cocaine and amphetamine both increase extracellular levels of catecholamines by blocking transporters. In particular, cocaine shows a very high affinity for DAT; amphetamine is a less potent inhibitor but also "releases" catecholamine by reversing the normal direction of transporter function, extruding the transmitter from neurons. The tricyclic antidepressant drugs work by blocking the norepinephrine transporter, as do newer norepinephrine-selective uptake blockers.

Serotonin

Well over a century ago, scientists were aware of a substance in the blood that induced powerful contractions of smooth muscle organs. In the mid-twentieth

century, Page and collaborators succeeded in isolating the compound, which they suggested to be a possible cause of high blood pressure, from platelets. At the same time, Italian researchers were studying a substance in intestinal mucosa that caused contractions of intestinal smooth muscle. The material isolated from platelets was called "serotonin," and the substance isolated from the intestinal tract was named "enteramine." Studies soon revealed that the two substances were the same compound, 5-hydroxytryptamine (5-HT), which now is commonly referred to as serotonin.

Serotonin is found in neurons and in several other types of cells in the body. In fact, the brain accounts for only about 1% of total body stores of serotonin. Although the isolation and identification of serotonin were made from peripheral tissues, much of the subsequent interest in serotonin was based on its potential involvement in psychiatric disorders. The finding that serotonin's chemical structure is similar to that of LSD led to theories that associated abnormalities in serotonin function to schizophrenia and depression.

The basic process of serotonin synthesis is very similar to that of catecholamine transmitters: a peripheral amino acid (tryptophan) gains entry into the brain and is metabolized in serotonergic neurons via a series of enzymatic steps. Once tryptophan enters the serotonergic neuron, it is hydroxylated by tryptophan hydroxylase, the rate-limiting step in serotonin synthesis, giving rise to 5-hydroxytryptophan (5-HTP). In turn, 5-HTP is decarboxylated by L-aromatic amino acid decarboxylase to the transmitter serotonin. Thus, only two critical enzymes (tryptophan hydroxylase and AADC) are involved in the synthesis of 5-HT (Iversen et al., 2008).

Alternative Tryptophan Metabolic Pathways

Although serotonin is usually the endpoint of tryptophan metabolism in brain, serotonin can be metabolized further to yield active products. In the pineal gland, 5-HT is metabolized to form 5-methoxy-N-acetyltryptamine (melatonin), a hormone thought to play an important role in sleep.

In peripheral tissues, most tryptophan is not used to synthesize 5-HT but instead is metabolized by the kynurenine pathway. This kynurenine "shunt" is also present in the brain and leads to the accumulation of several interesting active substances (see Schwarcz, 2004). The two major tryptophan metabolites generated by the kynurenine shunt are quinolinic and kynurenic acids. Quinolinic acid is a potent activator of certain glutamate receptors and upon administration to animals causes cell loss and convulsions. In contrast, kynurenic acid is an agonist that activates one type of acetylcholine receptor in brain and decreases extracellular levels of the transmitter glutamate; levels of kynurenic acid have been reported to be increased in schizophrenia.

Inactivation of Released Serotonin

Serotonin is inactivated primarily by reuptake through SERT, the serotonin transporter that belongs to the same family of transporters as the catecholamine transporters. Selective serotonin reuptake blockers (SSRIs), which block SERT, are widely used as antidepressants; the prototypic SSRI is fluoxetine (Prozac). Because different antidepressant drugs increase levels of serotonin or NE, or both, current theories of depression posit critical modulatory roles for NE and 5-HT.

The enzymatic degradation of 5-HT is catalyzed by monoamine oxidase (MAO). The product of this reaction, 5-hydroxyindole acid aldehyde, is oxidized further to 5-hydroxyindoleacetic acid. MAO inhibitors prevent the metabolism of serotonin and thus increase 5-HT levels, and have been widely used as antidepressants (Box 6.1).

Acetylcholine

Our basic ideas about chemical synaptic transmission are based on early studies of acetylcholine (ACh). Pharmacological and electrophysiological studies at the neuromuscular junction led to an understanding that ACh is a chemical messenger between excitable cells. These ideas about cholinergic signaling between cells are the cornerstone of today's understanding of chemical neurotransmission. For example, electrophysiological studies revealed fast excitatory responses of muscle fibers to the stimulation of nerves innervating the muscle. The presence of miniature end plate potentials (mEPPs) in muscle fiber was noted, and in the early 1950s, Fatt and Katz demonstrated that these mEPPs resulted from the slow "leakage" of ACh, with each mEPP representing the release of transmitter in one vesicle (termed a quantum). Overt depolarization generated an increase in the number of quanta released over a given period of time (see Chapter 7). Over the past half century many of the rules that govern ACh neurotransmission have been found to be general principles that apply to many transmitters.

The synthesis of ACh has a single step: the acetyl group from acetyl coenzyme A is transferred to choline by the enzyme choline acetyltransferase (ChAT), forming Ach. The acetyl-CoA that serves as the donor is derived from pyruvate generated by glucose metabolism. There is one interesting twist on ACh synthesis: acetyl-CoA is found in mitochondria, but the synthetic enzyme ChAT is cytoplasmic. This means that acetyl-CoA must exit the mitochondria to gain access to ChAT. Despite the fact that ChAT is the only enzyme involved in ACh synthesis, it is not the rate-limiting step in synthesis of the transmitter. The full enzymatic activity of ChAT is not expressed *in vivo*: ChAT activity measured

in vitro is much greater than would be expected on the basis of measurements of ACh synthesis *in vivo*. The reason for this discrepancy has been suggested to be related to the requirement that acetyl-CoA be transported from the mitochondria to the cytoplasm. Alternatively, intracellular choline concentrations may determine the rate of ACh synthesis. This latter idea led to the use of choline precursors in attempts to increase ACh synthesis in Alzheimer's disease, in which there is a marked decrease of cortical ACh levels. Unfortunately, these attempts have not proven successful.

ACh is taken up into storage vesicles by the vesicular cholinergic transporter (VAChT). Cloning of the human VAChT revealed that the gene is localized to chromosome 10, near the gene encoding ChAT. Subsequent studies demonstrated that the entire VAChT coding region is contained in the first intron of the ChAT gene. These observations suggested that both genes are coordinately regulated, a suspicion that subsequently was confirmed.

A major way of inactivating ACh is enzymatic, in which ACh is hydrolyzed to choline. There are two types of cholinesterases that accomplish this step: acetylcholinesterases (AChEs) and butyrylcholinesterases (Taylor & Brown, 2006). The former are relatively specific for ACh and are found in high concentration in the brain, whereas butyrylcholinesterases are enriched in the liver.

Acetylcholinesterase is present in high concentrations in cholinergic neurons. However, AChE is also found in moderately high concentrations in some noncholinergic neurons that receive cholinergic inputs. This observation is consistent with the fact that AChE is a secreted enzyme that is associated with the cell membrane. Thus, ACh hydrolysis takes place extracellularly, and the choline generated is conserved by the high-affinity reuptake process. In addition to its role in inactivating acetylcholine, AChE has been proposed to be a chemical messenger in the CNS (Greenfield, Zimmermann, & Bond, 2008).

γ-Aminobutyric Acid: The Major Inhibitory Neurotransmitter

Several amino acids fulfill most of the criteria for consideration as neurotransmitters. The best studied of these are γ-aminobutyric acid (GABA), the major inhibitory transmitter in brain, and glutamate, which is the brain's major excitatory transmitter. Many of the principles concerning transmitter synthesis and inactivation that we have previously discussed also apply to amino acid transmitters. However, there are also some key differences. The most obvious difference is that GABA is derived from glucose metabolism (Fig. 6.3). Thus, mechanisms must exist to segregate the transmitter and general metabolic pools of the amino acid transmitters (Olsen & Betz, 2006). A second difference between amino acid and catecholamine transmitters is that inactivation of the former involves several types of transporters that are found on glial cells as well as neurons.

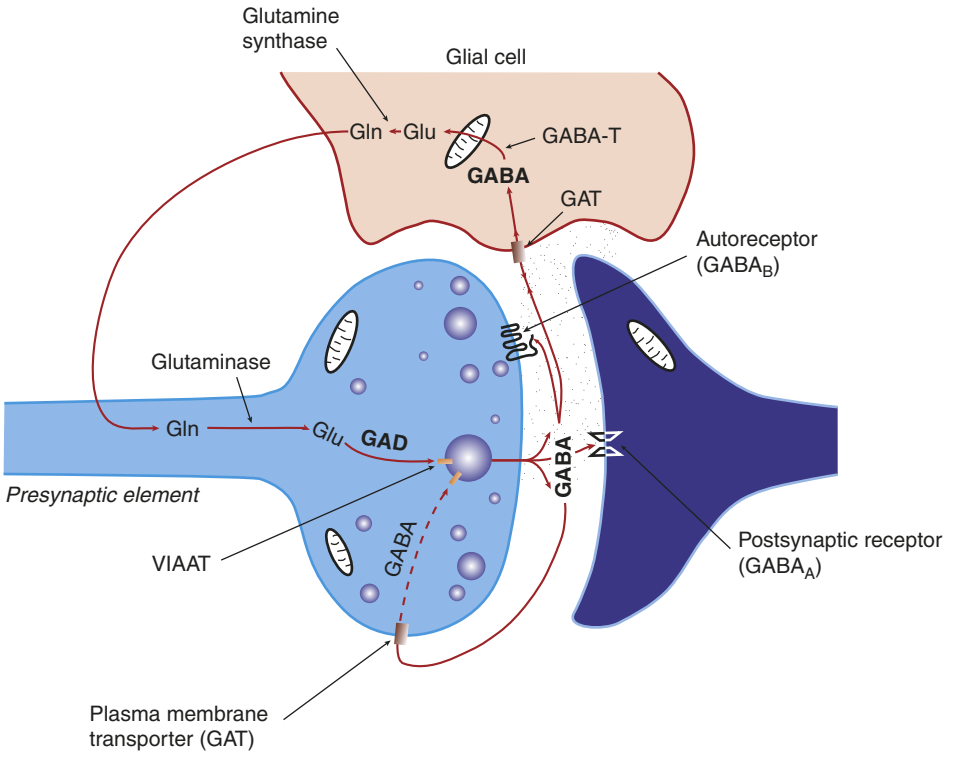

FIGURE 6.3 Schematic depiction of the life cycle of the transmitter pool of GABA. a-Ketoglutarate formed in the Krebs cycle is transaminated to glutamate (Glu) by GABA transaminase (GABA-T). The transmitter GABA is formed from the Glu by glutamic acid decarboxylase (GAD). GABA that is released is taken by high-affinity GABA transporters (GAT) present on neurons and glia.

GABA Synthesis

The GABA Shunt and GABA Transaminase

GABA ultimately is derived from glucose metabolism. α-Ketoglutarate formed by the Krebs cycle is transaminated to the amino acid glutamate by GABA-transaminase (GABA-T). In those cells in which GABA is used as a transmitter, the presence of another enzyme, glutamic acid decarboxylase (GAD), generates GABA from glutamate (Fig. 6.3). The presence of GAD is therefore an unambiguous marker of neurons that use GABA as a transmitter.

An unusual feature of GABA synthesis is that intraneuronal GABA is inactivated by the actions of GABA-T, which appears to be associated with mitochondria. Thus, GABA-T is both a synthetic and a degradative enzyme! GABA-T metabolizes GABA to succinic semialdehyde but only if α-ketoglutarate is present to receive the amino group that is removed from GABA. This unusual GABA shunt serves to maintain supplies of GABA.

How Are Transmitter and Metabolic Pools Separate?

A major question concerning amino acid transmitters is how the transmitter pool is separately maintained from the general metabolic roles of amino acids. The GABA synthetic enzyme GAD is a cytosolic enzyme, but GABA-T, which converts α-ketoglutarate into the GAD substrate glutamate, is present in mitochondria. Thus, the metabolic pool is present in mitochondria, and glutamate destined for the transmitter pool must be exported from mitochondria to the cytosol.

Glutamate is not only a precursor to GABA, but it is also the major excitatory neurotransmitter found in the brains of mammals. Why GABA neurons fail to use the precursor glutamate as a transmitter probably involves different vesicular transporters that accumulate glutamate and GABA into vesicles, as well as different biosynthetic enzymes for the transmitter and metabolic pools of glutamate. In the case of glutamate, three different vesicular glutamate transporters are responsible for determining if glutamate is used as a transmitter.

Storage and Release of GABA

Vesicular Inhibitory Amino Acid Transporter

A vesicular GABA transporter was cloned on the basis of homology to a protein found in the worm *Caenorhabditis elegans*. The strategy of moving from invertebrate to mammalian species has been very useful in identifying a variety of mammalian transmitter-related genes. The vesicular GABA transporter shares with the vesicular monoamine transporters a lack of substrate specificity, and will transport the inhibitory transmitter glycine as well as GABA.

Autoreceptor Regulation of GABA Release

There are two major classes of GABA receptors. One type of GABA receptor (the $GABA_A$ receptor) forms ion channels and is mainly on cells postsynaptic to GABA terminals (see Chapter 8). A second type of receptor, the $GABA_B$ receptor, is coupled to intracellular G proteins. Pharmacological studies indicate that the autoreceptor-mediated regulation of GABA neurons involves $GABA_B$ receptors located on GABAergic axon terminals. Anatomical studies have revealed that $GABA_B$ receptors also are found on postsynaptic non-GABAergic neurons. It is possible that these postsynaptic $GABA_B$ sites respond to GABA released from a neuron that is presynaptic to another GABA neuron. Interestingly, when one GABA neuron terminates on another GABA cell, the inhibition of the second (postsynaptic cell) will have the same functional consequence as an autoreceptor (decreasing subsequent transmitter release) on the third cell in the chain.

Inactivation of GABA

Reuptake is the primary mode of inactivation of the transmitter GABA. There are four GABA transporters (GATs), providing a diverse means of regulating GABA neurons. Early studies defined the different GABA transporters as neuronal or glial based on pharmacological criteria. However, anatomical studies found that one GAT that was defined on pharmacological grounds as a glial transporter is present in both neurons and glia. The reason for multiple GABA transporters is not clear. GATs are expressed in both GABAergic and non-GABAergic cells (presumably cells that receive a GABA innervation). Consistent with the promiscuous uptake of transmitters by other transporters, amino acids other than GABA are also substrates for GATs.

Glutamate and Aspartate: Excitatory Amino Acid Transmitters

Excitatory amino acid transmitters account for most of the fast synaptic transmission that occurs in the mammalian brain. Glutamate and aspartate are the major excitatory amino acid neurotransmitters, and several related amino acids, such as N-acetylaspartylglutamate, are also thought to have neurotransmitter roles.

Neither glutamate nor aspartate crosses the blood–brain barrier, and in the brain these transmitters are derived by local synthesis from glucose. Two processes lead to glutamate synthesis in the nerve terminal. As discussed earlier, glutamate is formed from glucose through the Krebs cycle and transamination of α-ketoglutarate. Glutamate can also be formed directly from glutamine. Because glutamine is synthesized in glial cells, both

neurons and glia are important in determining the transmitter pool of glutamate. Glutamine is exported from glia and incorporated by nerve terminals before being converted into glutamate by a glutaminase enzyme (Hassel & Dingledine, 2006).

Because of the intermingling of glial and neuronal contributions to glutamate synthesis, and the lack of specific enzymes or other proteins to distinguish the metabolic pool of glutamate from the transmitter glutamate, the identification of glutamatergic neurons was initially made on the basis of physiological studies. More recently the identification of three vesicular glutamate transporters, VGluT1-3, has provided a relatively simple means for identifying glutamatergic neurons. However, in neuroscience facts are rarely unambiguous, and anatomical studies over the past several decades have revealed that many glutamate neurons also contain one or more other transmitters (Fremeau, Voglmaier, Seal, & Edwards, 2004), with some even containing GABA. Because GABA hyperpolarizes cells in adult neurons, while glutamate depolarizes neurons, one would not expect to find transmitter pools of GABA and glutamate in the same neuron. The functional significance of such an arrangement is not clear.

Just as there are several vesicular glutamate receptors, there are several glutamate transporters that terminate the action of glutamate. An unusual aspect is that the major cell type taking up glutamate is the astrocyte, which expresses very high levels of one glutamate transporter. This is one of several findings that point to glia as releasing glutamate in a signaling capacity (Halassa & Haydon, 2010). These findings have led to an increasing awareness of glia as being far more than structural support cells and argue for a much broader contribution of glia to neuronal communication.

NONCLASSICAL NEUROTRANSMITTERS

Classical transmitters account for relatively few of all neurotransmitters. For example, many more transmitters are peptides, which share many but not all key attributes of classical transmitters. Both classical and peptide transmitters usually are well conserved across species, and indeed many of the peptide transmitters were initially isolated from amphibians. In addition, both classical and peptide transmitters are synthesized in neurons, where they are stored in vesicles and released in a Ca^{2+}-dependent manner. However, the synthetic mechanisms and the modes of inactivation of the two types of transmitters are quite different. We will first consider the question of the significance of multiple neurotransmitters, and then turn to general principles of peptide transmitter life cycle.

Why Do Neurons Have So Many Transmitters?

About a dozen molecules are generally accepted as "classical" transmitters. Many more neuropeptides serve as transmitters. And there are "unconventional" transmitters that fail to meet most of the criteria for classical transmitters yet have clearly been shown to function as chemical messengers over restricted spatial and temporal domains. If transmitters simply serve as a chemical bridge that conveys information between two spatially distinct cells, why have so many chemical messengers?

Convergence of Different Transmitter-containing Axons on a Common Neuron

Perhaps the simplest explanation for multiple transmitters is that many nerve terminals synapse onto a single neuron. How can a neuron distinguish between multiple inputs that carry different information? One way is to segregate the place on the neuron at which an input arrives, such as the soma, axon, or dendrite. However, because many afferents terminate in close proximity, another means of distinguishing inputs and their information is necessary. Chemical coding of inputs from various neurons can provide a high degree of both spatial and temporal resolution.

Colocalization of Neurotransmitters

The idea that a neuron is limited to one transmitter can be traced to Henry Dale, or more accurately, to an informal restatement of what is termed Dale's principle. In the 1940s, Dale posited that a metabolic process that takes place in the cell body can reach or influence events in all processes of the neuron. Sir John Eccles restated Dale's view to suggest that a neuron releases the same transmitter from all of its processes. Illustrating the dangers of scientific sound bites, this "principle" was soon misinterpreted to indicate that only a single transmitter can be present in a given neuron, a view that held sway for about 40 years. We now know that neurons can contain multiple transmitters, including both a classical transmitter (such as DA) and a peptide transmitter (such as neurotensin). Indeed, it appears that few, if any, neurons contain only one transmitter, and in many if not most cases three or more transmitters are found in a single neuron.

The presence of multiple transmitters in single neurons suggests that different transmitters are used by a neuron to signal different functional states to its target cell. The firing rates of the neurons differ considerably, and it may be useful to encode fast firing by one transmitter and slower firing by a different transmitter. The firing *pattern* of neurons also conveys information. For example, a neuron may discharge five times every second on average; this may mean that the cell regularly

discharges every 200 ms, but can also represent a cell that has a burst of five discharges during an initial 100-ms period followed by 900 ms of silence. Peptide transmitters often are released at higher firing rates and particularly under burst-firing patterns.

The different synthetic steps in peptides and classical transmitters lead to differential release. Classical transmitters can be replaced rapidly because their synthesis occurs in nerve terminals, with rapid uptake of the released transmitter and energy-efficient recycling of the transmitter. In contrast, peptide transmitters must be synthesized in the cell body and transported to the terminal. Thus, it is useful to conserve peptide transmitters for situations of high demand because they would otherwise be depleted rapidly.

Transmitter Release from Different Processes

The restatement of Dale's principle by Eccles held that a transmitter is found in all processes of a neuron. In invertebrate species a transmitter can be localized to different parts of a neuron, and it is now clear that most proteins in mammalian neurons are not randomly distributed but present in distinct "compartments" of a neuron, often being reversibly tethered there by anchoring proteins. For example, if a transmitter were restricted to a particular part of a neuron, the neuron would need multiple transmitters to account for different release sites. Receptors are very specific in their locations on neurons, and certain receptors are recruited to "hot spots" on neuronal processes by the activity patterns of presynaptic inputs.

Synaptic Specializations versus Nonjunctional Appositions between Neurons

The anatomical relations between one cell and its follower may contribute to the need for different transmitters. We usually think of synaptic specializations as the physical substrate of communication between two neurons. However, nonsynaptic communication between two neurons can also take place, including over longer distances than that of conventional synapses. In such a situation the requirements for transmitter action would differ from those discussed previously because the distance traversed by the transmitter molecule would be farther than at a synaptic apposition. Thus, transmitters that lack an efficient reuptake system, such as peptide transmitters, might be favored at nonsynaptic sites. Because a single neuron can form both synaptic and nonsynaptic specializations, a single neuron may require more than one neurotransmitter.

Fast versus Slow Responses of Target Neurons to Neurotransmitters

Different firing rates or patterns of firing may be accompanied by changes in the type or relative amounts of a transmitter being released from a neuron. For example, stimulation of receptors that form ion channels leads to very rapid changes, whereas actions at metabotropic receptors that are coupled to intracellular events through specific transduction molecules have slower response characteristics. Differences in temporal response characteristics allow the receptive neuron to respond differently to a stimulus depending on the antecedent activity in the cell. A transmitter can change the response characteristics of a particular cell to subsequent stimuli by seconds or even minutes, and thus short-term changes can occur independent of changes in gene expression.

PEPTIDE TRANSMITTERS

Synthesis and Storage of Peptide Transmitters

Classical transmitters are synthesized in the axon from which they are released. In contrast, genes encoding most peptide transmitters give rise to a prohormone, which is incorporated into secretory granules, after which the prohormone is acted on by peptidases to form the peptide transmitter (Fig. 6.4). This process typically occurs in the cell body, and the peptide-containing vesicles are then transported to the axon; a small number of peptide transmitters are synthesized enzymatically.

In neurons that use classical transmitters, demands for increased amounts of transmitter are met by increasing local transmitter synthesis or activity at the axon terminal. However, increasing the amount of a peptide transmitter requires an increase in gene expression to yield a prohormone, with a subsequent delay in delivery to the axon terminal of the peptide. Thus, classical transmitters respond to increased demand rapidly, but peptide transmitters cannot.

The storage of peptides and classical transmitters also differs. Classical neurotransmitters are usually stored in small (~50 nm) synaptic vesicles, while neuropeptide transmitters are stored in large (~100 nm) dense-core vesicles. Because peptide transmitters are usually released at a high neuronal firing frequency or when neurons show a burst-firing pattern, different mechanisms may be involved in the release of peptide- and classical transmitter-containing vesicles. Although the release of both classical and peptide transmitters is calcium-dependent, distinct but related molecular mechanisms subserve the release of small and large dense-core vesicles (Sieburth, Madison, & Kaplan, 2007).

Inactivation of Peptide Transmitters

There are major differences in how peptide and classical transmitters are inactivated. Classical transmitter

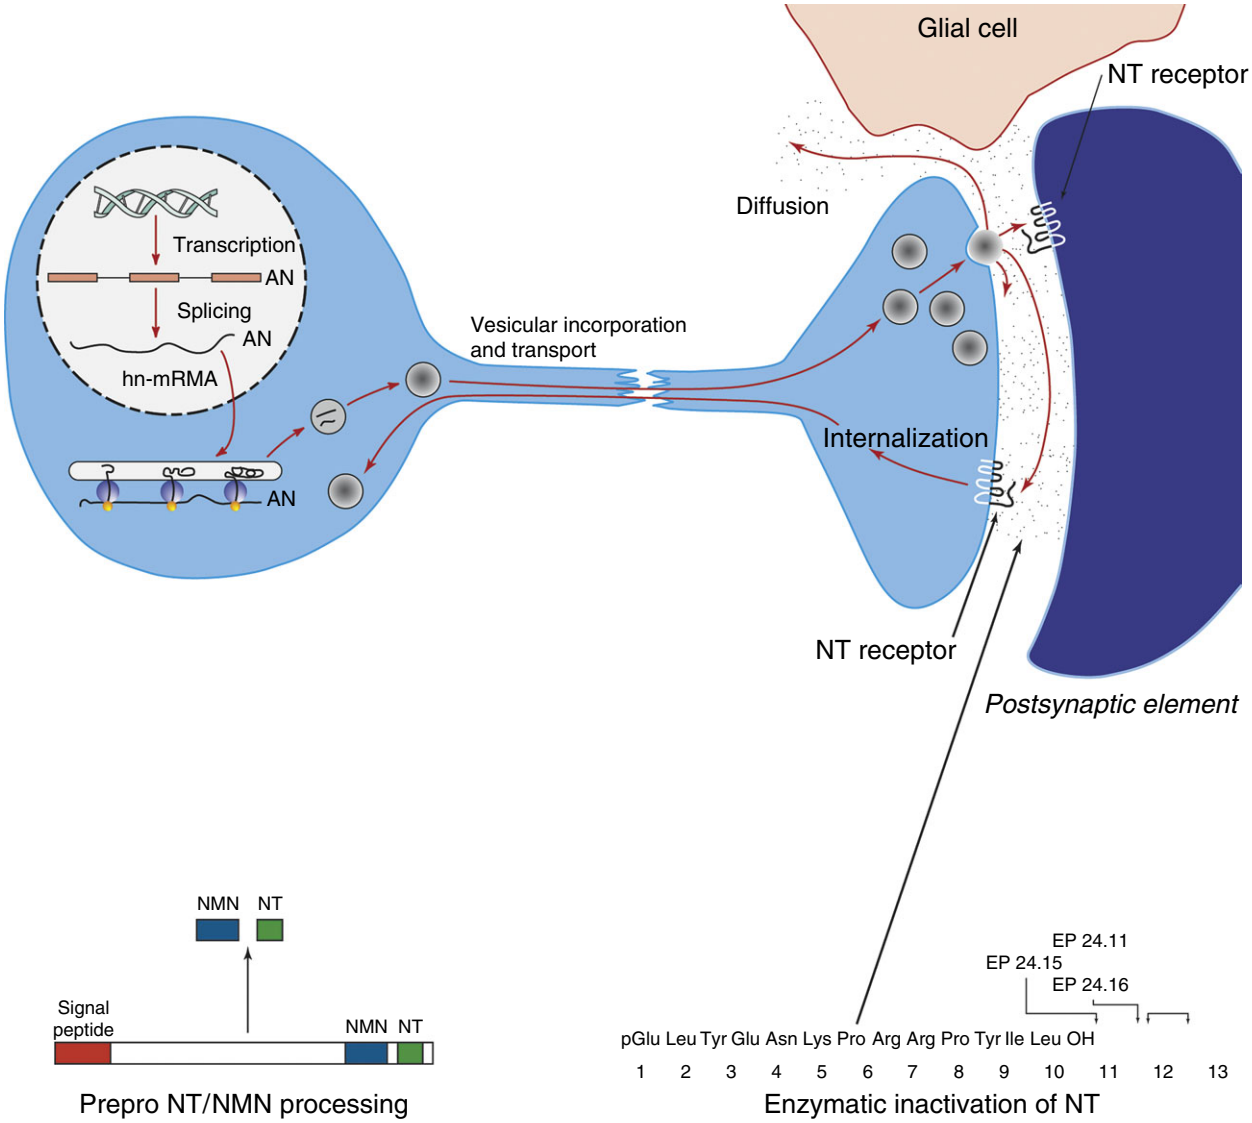

FIGURE 6.4 Schematic illustration of the synthesis, release, and termination of action of the peptide transmitter neurotensin (NT). The illustrative panels on the bottom show processing of NT from the prohormone (left) and enzymatic inactivation of NT (right).

actions primarily depend on a high-affinity reuptake process to remove the transmitter from the extracellular space. There are no such transporters for peptide transmitters, which are inactivated enzymatically or by diffusion.

Enzymatic inactivation of peptide transmitters differs from that of classical transmitters. Peptide transmitters are short chains of amino acids, but the inactivating enzymes are specific for certain dipeptide sequences and are not specific to any single peptide. For example, an enzyme that inactivates small opioid-like peptide transmitters (enkephalins) is often referred to as enkephalinase, but also cleaves other peptide transmitters.

A final difference between the inactivation of peptide and classical transmitters is the nature of the final product. When classical transmitters are broken down enzymatically, the metabolites are inactive at the transmitter's receptor. However, certain peptide fragments derived from the enzymatic "inactivation" of peptide transmitters are biologically active. An example is angiotensin, in which angiotensin I is metabolized to yield angiotensin II and III, each successively more active than the parent angiotensin I. It can therefore sometimes be difficult to distinguish between transmitter synthesis and transmitter inactivation. The peptide that is stored in vesicles and then released is therefore considered the transmitter, although the actions of certain peptidases may lead to other biologically active fragments. As a means of exploring aspects of the life cycle of peptide transmitters, we will now examine as a representative example the neuropeptide neurotensin.

Neurotensin Synthesis

Neurotensin (NT) is widely expressed in the central nervous system and in certain peripheral tissues, such as the small intestine. A related peptide, neuromedin N (NMN), is also present. A 170 amino acid prohormone precursor of NT is the product of a single gene that is transcribed to yield two mRNAs. The smaller transcript is the major form in the intestine; the two mRNA species are equally abundant in most brain areas. The precursor contains one copy each of NT and NMN. The molar ratios of NT/NMN vary across different tissues, suggesting different enzymatic processing of the prohormone or, alternatively, the generation of different transcripts. Because NT and NMN are contained in the same exon of the NT-NMN gene, differences in relative abundance of the two are due to differential processing of the precursor.

NT and other peptide transmitters are stored in large dense-core vesicles. Although there are some differences in the mechanisms controlling release of the contents of small and large dense-core vesicles, the general characteristics of NT release are similar to those of classical transmitters. Thus, depolarization evokes the Ca^{2+}-dependent release of both NT and NMN (Kitabgi, De Nadal, Rovere, & Bidard, 1992). The impulse-dependent release of NT varies as a function of frequency and pattern of impulses, with higher frequencies of firing or burst firing patterns eliciting greater peptide release (Bean & Roth, 1992).

Inactivation of Neurotensin

Peptides are inactivated by enzymatic actions or diffusion, or both. NT is degraded by three endopeptidases, grandly named 24.11, 24.15, and 24.16. Endopeptidase 24.11 cleaves NT at two specific sites to yield a decapeptide, as does endopeptidase 24.16 (Fig. 6.4); the other endopeptidase acts at a different set of amino acid residues. Because these enzymes act at dipeptides that are found in many peptides and proteins, and two of the three act at the same site, it is obvious that enzymes that inactivate peptides are not very specific.

Although there are no known membrane transporters for peptide transmitters, peptides can be accumulated by neurons. This occurs by internalization of a neuropeptide bound to its receptor. G protein-coupled receptors undergo internalization via an endocytotic mechanism, where they are either recycled to the membrane after various steps or shipped to lysosomes for degradation (Hanyaloglu & von Zastrow, 2008). However, once inside the cells the peptide and its receptor can dissociate, leaving the free neuropeptide to exert some actions.

Coexistence of Neurotensin and Classical Transmitters

Neurotensin is colocalized with dopamine in certain hypothalamic and midbrain neurons. The colocalization of NT and DA has provided a useful system in which to explore the interrelationships between two colocalized transmitters. In the prefrontal cortex of the rat, NT is found only in DA axons, although there are some DA axons that do not contain NT. Neurotensin release in the prefrontal cortex is increased when neuronal firing is increased or when DA neurons display a burst-like firing pattern (Bean & Roth, 1992). In addition, the release-modulating dopamine autoreceptor on DA axons regulates NT release, but in a very different manner than it regulates DA release: DA agonists (which decrease DA release) *enhance* NT release from colocalized DA-NT axons. Conversely, antagonists at the DA autoreceptor decrease NT release but enhance DA release. Thus, the release of NT and DA are reciprocally regulated by actions at release-modulating DA autoreceptors.

UNCONVENTIONAL TRANSMITTERS

The differences between peptide and classical transmitters substantially delayed the general acceptance of peptides as transmitters. However, once peptides were recognized as neurotransmitters, a gate opened for the consideration of radically different molecules as transmitters.

Remarkable technical advances have allowed us to measure substances in the brain that are present in minute quantities or are very unstable. The early "classical" neurotransmitters were present in relatively high concentrations, at least in some brain sites, permitting the measurement of these compounds by neurons after electrical or chemical stimulation. Peptide transmitters are usually found in smaller amounts, and sensitive biochemical assays for measuring neuropeptides were not widely used until the 1970s. When it became clear that there were many compounds, including certain peptides, that might potentially serve as chemical messengers between neurons, the basic criteria for designation of a molecule as a neurotransmitter came into question.

What should be the key attribute(s) of a neurotransmitter? One simple approach would be to designate as a neurotransmitter any compound that permits information flow from one neuron to another. However, this definition could encompass hormone signaling and does not address the temporal characteristics of transmitter action. Moreover, it does not address the possibility of a neurotransmitter being a molecule that conveys information between neurons and non-neuronal brain cells, such as glia. Finally, this definition does not accommodate unconventional roles for transmitters, such as the

regulation of neuronal development or intracellular trafficking of proteins. We will now discuss what we call, for lack of a better term, "unconventional" transmitters.

Endocannabinoids

The psychoactive properties of marijuana have been known for thousands of years. Marijuana contains dozens of structurally related cannabinoids. Cannabinol was the first of the cannabinoids to be structurally characterized. The major psychoactive cannabinoid, Δ-9-tetrahydrocannabinol (THC), was subsequently identified. The fact that marijuana and THC had psychoactive properties in humans led to search for a receptor for THC, the first of which, CB1, was cloned a full half century after the structure of cannabinol was first elucidated. As has been the case for other "orphan" receptors, the search for an endogenous ligand that binds to the CB1 receptor culminated two years after the cloning of CB1 with the identification of a compound that bound with high affinity to the receptor. Over the past 15 years, the identification of multiple endocannabinoids (ECs), the enzymes involved in synthesizing and degrading endocannabinoids, and the characterization of two cannabinoid receptors have led to the realization that ECs serve as chemical messengers between neurons.

Synthesis, Inactivation, and Release of Endocannabinoids

Endocannabinoids are hydrophobic lipids that pass easily through plasma membranes. This free diffusion across membranes means that ECs cannot be stored in vesicles. Instead, they are synthesized and released when needed from lipid precursors located in neuronal membranes. The basic mechanisms involved in the synthesis of ECs are reasonably well characterized, although some issues regarding regulation of EC synthesis have not been resolved (Alger & Kim, 2011).

There are two major ECs in brain, N-arachidonoylethanolamide (anadamide) and 2-arachidonoylglycerol (2-AG). The synthesis of the latter has been reasonably well characterized. An increase in intracellular calcium stimulates phospholipase C (PLC), which metabolizes membrane phosphoinositides to diacylglycerol (DAG). In turn, DAG is metabolized by DAG lipase to 2-AG. There is also a second minor route through which DAG can be produced from phosphatidic acid.

Anandamide is a fatty acid amide and is the best characterized of the ECs. However, the synthesis of anadamide can be accomplished through alternative pathways, and it is unclear which of these multiple synthetic routes predominates *in vivo*.

The membrane localization of the EC precursors for anandamide and 2-AG, coupled with the highly permeable nature of the two ECs, initially led to controversy concerning the ability of ECs to be synthesized only when the ("on-line") need for their release occurs. However, newer data favor the idea that ECs are indeed synthesized on demand.

Three proteins play prominent roles in EC inactivation. Two are enzymes (fatty acid amide hydrolyase [FAAH] and monoacylglycerol lipase [MGL]); the third protein is an anadamide transporter. 2-AG is metabolized primarily by MGL, but it can also be acted on by another enzyme (β hydrolase 6). In contrast, anandamide is metabolized by fatty acid hydrolase. The availability of mice with genetic deletions of EC synthetic or degradative enzymes has been critical in establishing the functional roles of anandamide and 2-AG. The anandamide transporter is a sodium- and energy-dependent carrier protein that facilitates diffusion.

Recent studies have demonstrated that ECs act as retrograde messengers at synapses. Thus, ECs are produced on demand in an activity-dependent manner by a neuron through the cleavage of membrane lipids. The resultant ECs travel backward (retrogradely) across the synapse to activate presynaptic cannabinoid receptors on axon terminals, resulting in a suppression of transmitter release. Because the presynaptic CB1 cannabinoid receptor is found on both GABAergic and glutamatergic nerve endings, EC signaling can modulate both excitatory and inhibitory transmission. EC-mediated retrograde signaling appears to be crucial for certain types of short- and long-term synaptic plasticity that underlie learning and memory.

Although still early, studies of ECs have inspired the development of novel treatment strategies for neuropsychiatric disorders. Consistent with subjective reports that marijuana increases eating (the "munchies"), early clinical trials reported some success of CB1 receptor antagonists in the treatment of obesity. However, other potential behavioral side effects of CB1 antagonists led to a halt in the development of these drugs, at least for the time being. Similarly, CB1 antagonists have been advanced as an aide to smoking cessation.

Gases as Unconventional Transmitters

Nitrates such as nitroglycerine have long been used to treat angina pectoris, in which pain arises because of insufficient blood delivery to the heart. Nitrates dilate cardiac blood vessels, thereby increasing blood flow and diminishing or relieving the pain. However, the mechanism by which nitrates dilate coronary arteries was not known until relatively recently. In 1980, a "relaxing" factor contained in the cells lining blood vessels was found to potently and rapidly dilate blood vessels. This factor was soon shown to be the gas nitric oxide (NO). Other studies found that the transmitter glutamate released a factor that caused blood vessels

in the brain to dilate. It then became apparent that endothelial-derived relaxing factor and the glutamate-induced factor that caused vasodilation were the same compound, NO. Thus, NO was present in neurons as well as cells forming blood vessels. These data led to the proposal that NO may take part in intercellular communication (see Box 6.2).

Nitric oxide is a well-known air pollutant. The idea that an unstable toxic gas could serve as a transmitter led to several incredulous but pointed questions, including "how can a gas be stored for release in an impulse-dependent manner?" The answer is simple: it is not stored. If one accepts the argument that NO is a transmitter, the classical definition of a neurotransmitter becomes untenable. Many theories can accommodate one exception. However, NO is not the only gaseous neurotransmitter. Other gases, including carbon monoxide and hydrogen sulfide, also play transmitter-like roles (Mustafa, Gadalla, & Snyder, 2009), leading to the introduction of the term gasotransmitter!

Synthesis of Nitric Oxide

Nitric oxide synthesis involves a single step, the conversion of L-arginine to NO and citrulline. The enzyme responsible for NO synthesis is aptly named nitric oxide synthase (NOS). There are three isoforms of NOS. Endothelial is found in the cells lining blood vessels, where the NO story began. Macrophage-inducible NOS is present in microglia, while the third isoform is localized to neurons (nNOS). All three isoforms require tetrahydrobiopterin as a cofactor and NADPH as a coenzyme. The presence of NADPH explains why the enzyme NADPH diaphorases, which had been described well before NOS was known, is found in high concentration in nNOS-positive neurons.

Storage and Release of Nitric Oxide

The subheading "Storage and Release of Nitric Oxide" promises a discussion of the storage of NO. As previously discussed, storage of a compound (usually in a place poised for release) was originally considered to be necessary for designation of a molecule as a transmitter. However, there is no storage of NO. Instead of NO being synthesized in a neuron and released in a calcium-dependent exocytosis from vesicles, NO is an uncharged molecule that diffuses freely across cellular membranes, including the membranes of vesicles.

The ability of NO to diffuse across cell membranes opens the possibility that NO serves as a chemical messenger to convey information regarding the activity of

BOX 6.2

GOING FOR GASES AS NEUROTRANSMITTER

One of the most rewarding experiences for a scientist is to find that long-held prejudices are altogether wrong and that a new, correct insight reveals a novel scientific principle. In the late 1950s, only acetylcholine and the biogenic amines were known to be neurotransmitters. The next decade saw amino acids acknowledged as neurotransmitters. The discovery of enkephalins and endorphins in the mid-1970s reinforced gradually accumulating evidence that peptides are transmitters, and now we find that there are over 100 different bioactive brain peptides.

In the 1970s and early 1980s, nitric oxide (NO) was found to mediate the ability of macrophages to kill tumor cells and bacteria and to regulate blood vessel relaxation. A short report suggested that NO can be formed in brain tissue. Progress in the NO field at that time was slow because assaying NO synthase (NOS), the enzyme that oxidizes the amino acid arginine to NO, was quite tedious, based on the accumulation of nitrite formed from the NO. A much simpler approach was to monitor the conversion of [^{3}H]arginine into [^{3}H]citrulline, which is formed simultaneously with NO; this assay could process 100 or more samples in an hour. Research on blood vessels revealed that NO acts by stimulating cyclic GMP formation. In the brain, the excitatory neurotransmitter glutamate was known to augment cyclic GMP levels. Glutamate, acting through its NMDA receptor, triples NO synthase activity in a matter of seconds, and arginine derivatives that inhibit NOS activity block the elevation of cyclic GMP. This finding causally linked the actions of so prominent a neurotransmitter as glutamate to NO.

To determine if NO was a neurotransmitter, it was necessary to ascertain whether NOS was localized in neurons. The most straightforward approach would be to generate an antibody to use in anatomical studies. However, purifying NOS protein to generate an antibody proved very difficult because the enzyme lost its activity in attempts to purify it. The addition of calmodulin was found to stabilize the enzyme. Because calmodulin is a calcium-binding protein, this finding immediately explained how NO formation can be triggered rapidly by synaptic activation through glutamate. When glutamate activates its NMDA receptor, Ca^{2+} rushes into the cell, binds to calmodulin, and activates NOS.

The ability of purified NOS led to antibodies being developed and NOS being localized by immunohistochemistry. The neuronal form of NOS (nNOS) is present

BOX 6.2 (*cont'd*)

in only about 1% of the neurons in the brain. However, these cells give rise to processes that ramify so extensively that probably every neuron in the brain is exposed to NO. The purified NOS protein also allowed an amino acid sequence to be obtained and the gene for the enzyme cloned. The structure of NOS revealed that it is regulated by many more factors than virtually any other enzyme in biology, including at least five oxidative-reductive cofactors, four phosphorylating enzymes, and three binding proteins. This makes sense because of the unique properties of NO as a gaseous neurotransmitter. Most neurotransmitters are stored in vesicles with large storage pools so that only a small amount of the transmitter is released with each nerve impulse. In contrast, every time a neuron wishes to release a molecule of NO, it must activate NOS—hence, a requirement for exquisitely subtle regulation of the enzyme.

Neurotransmitters come in chemical classes such as biogenic amines, amino acids, and peptides. Might there be at least one other gaseous neurotransmitter? Carbon monoxide (CO) is normally formed in the body by the enzyme heme oxigenase, which is primarily responsible for degrading heme in aging red blood cells. It cleaves the heme ring to form biliverdin, which is reduced rapidly to bilirubin, the pigment that accounts for jaundice in patients with a degradation of red blood cells. When the enzyme cleaves the heme ring, CO is released as a single carbon fragment.

The biosynthetic enzyme for a transmitter should be localized to selected neuronal populations. Heme oxigenise-2, the neuronal form of the enzyme, was shown to be localized to discrete neuronal populations throughout the brain. To seek a neurotransmitter function, the peripheral nervous system (in which synaptic transmission is characterized more readily than in the brain) was used. The myenteric plexus of nerves regulates intestinal peristalsis. A previously unidentified neurotransmitter of myenteric plexus neurons accounts for the relaxation phase of peristalsis. nNOS had already been localized to neurons of the myenteric plexus, and some functional evidence showed that NO might be a neurotransmitter of this pathway. Heme oxigenise-2 was found to be localized to the same myenteric plexus neurons as NOS. Mice with targeted deletions of the genes for nNOS or heme oxigenise-2 were used to elucidate function. In both types of gene knockout mice, intestinal relaxation evoked by neuronal depolarization was reduced about 50%, implying that NO and CO each contribute half of the relaxation. This finding, along with other evidence, established transmitter functions for both NO and CO and suggested that they are functioning as cotransmitters, although exactly how they interact remains a mystery. Such a cotransmitter role reminds us of the fact that most neurons in the brain contain at least two and sometimes more neurotransmitters. Thus, in addition to overturning a number of dogmas about neurotransmission, NO and CO may help resolve the riddle of cotransmission.

Solomon H. Snyder

one cell to a number of other cells, which can be pre- or postsynaptic to the neuron from which NO is liberated, or even be non-neuronal cells (in which case it is not synaptic transmission in the original sense of the phrase). Nitric oxide release from neurons occurs in response to glutamate release and subsequent activation of N-methyl-D-aspartate (NMDA) receptors (and voltage-dependent calcium channels) on the postsynaptic cell that allows calcium to enter the neuron. The increase in intracellular calcium in turn activates the enzyme nNOS, resulting in diffusion of NO to reach nearby cells.

Termination of Action of Nitric Oxide

The formation and diffusion of NO mean that it can affect many nearby cells. Although no receptors for NO have been identified, cell surface receptors are not necessary for a molecule that freely diffuses; once inside of nearby neurons and other cells NO can act on second messenger cascades (notably cGMP-mediated events; see Chapter 8).

We previously noted that unrestrained release of a neurotransmitter does not convey to the receptive follower cells information regarding the activity of a presynaptic neuron and is often deleterious. Because NO is a gas, one might envision a molecule of NO careening through neurons like a crazed arrow. There are no degradative enzymes that inactivate NO, nor are there transporters that accumulate NO that is in the extracellular space for a fleeting time. Instead, the inactivation of NO is passive, with NO spontaneously decaying to a nitrate, with a half life of about 30 seconds.

Actions of NO on Neurons

Once in the cytosol of neurons and other cells in the brain, NO can exert function effects by stimulating guanylyl cyclase to produce cGMP levels and initiating a cascade of intracellular effectors. Because NO is produced in response to activation of nNOS by a glutamate-mediated increase in intracellular calcium levels, NO is mainly synthesized in the dendrites of neurons. The

diffusion of NO starts from the dendrites and then moves unpredictably to nearby cells, many of which are presynaptic to the released glutamate that started NO's brief wandering. We have previously discussed a number of mechanisms that inform the presynaptic neuron of its activity, allowing for feedback modulation; these include processes ranging from release-modulating autoreceptors to end-product inhibition of biosynthetic enzymes. Because NO diffuses freely and can influence neurons both pre- and postsynaptic to the cell from which it originates, NO (like endocannabinoids) can provide a "report" to the presynaptic neuron about the physiological effect NO is having on the postsynaptic cell. In this way, "synaptic transmission" becomes bidirectional.

Nitric Oxide as a Neurotransmitter

The list of exceptions posed by NO to the dogma of traditional neurotransmitters is long. NO is not stored in cells, is not released in an exocytotic manner, lacks an active process that terminates its action, does not interact with specific membrane receptors on target cells, and often acts as a retrograde transmitter to regulate axon terminals presynaptic to the neuron in which NO is synthesized. It is not difficult to understand the skepticism that first met the hypothesis that NO is a neurotransmitter, or to have some sympathy for those who expressed the view that NO is not a transmitter but an alien event, benign or otherwise, intent on making neuroscientists question their most cherished beliefs (Fig. 6.5).

Summary

We have discussed two "unconventional" transmitters, one a gas and the other a lipid. This growing category of transmitters contains many other similarly unconventional molecules, including growth factors, neuroactive steroids, and others still to be uncovered. All offer a significant challenge to our definitions of what constitutes a neurotransmitter, but with the advantage of expanding our knowledge of how the nervous system works in health and disease.

THE EXPANDING SYNAPSE AND GLIOTRANSMISSION

Our discussion of neurotransmission has been focused on the molecular signaling between pre- and postsynaptic neurons necessitated by the presence of a synaptic cleft that separates the two neurons. However, there are cells in the brain other than neurons, including different types of glial cells. The processes of one of these glial cells, the astrocyte, have long been known to be closely positioned near synapses and to be closely apposed to blood vessels. The latter structural arrangement was thought to contribute to, in part, the blood–brain barrier. The astrocyte was also known to play important roles in potassium homeostasis in the brain, as well as in scavenging cellular debris after brain injury.

However, as noted in earlier parts of this chapter, various molecules involved in the life cycle of classical

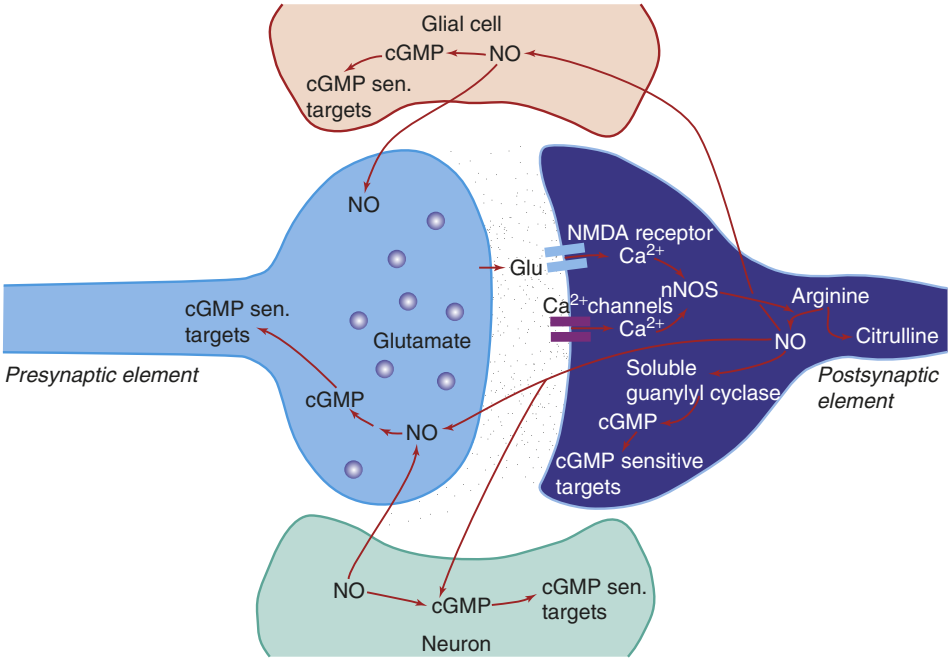

FIGURE 6.5 Schematic representation of a nitric oxide (NO)-containing neuron. NO is formed from arginine by the actions of different nitric oxide synthases (NOS). NO diffuses freely across cell membranes and can thereby influence both presynaptic neurons (such as the glutamatergic presynaptic neuron in the figure) or other cells that are not apposed directly to the NOS-containing neuron; these other cells can be neurons or glia.

transmitters, particularly glutamate and GABA, are expressed not only by neurons but also by astrocytes. For example, the major glutamate transporter involved in termination of action of glutamate is expressed by astrocytes rather than neurons. A metabotropic glutamate receptor that functions as a glutamate autoreceptor is also expressed by astrocytes, as is the enzyme responsible for the synthesis of kynurenic acid. These and similar observations raised the possibility that astrocytes play an important role in synaptic transmission, and coupled with structural data led to the formulation of the "tripartite synapse" (Araque, Parpura, Sanzgiri, & Haydon, 1999) involving classic pre- and postsynaptic neuronal elements and astrocytes.

The past decade has seen a dramatic rise in our understanding of the multiple roles played by astrocytes (see Allen & Barres, 2009; Halassa & Haydon, 2010; Panatier et al., 2011). Astrocytes repond to neuronal activity by increases in intracellular calcium, which can lead to the release of several transmitters from astrocytes; the precise mechanisms of the release of these gliotransmitters are not completely understood. Among these transmitters are glutamate, D-serine (which binds to a site on the glutamatergic NMDA receptor complex), kynurenic acid, and ATP. Because astrocytic processes of a single astrocyte can envelope thousands of synapses, gliotransmitters can coordinately regulate a very large number of neurons. In addition, the astrocytic "end feet" apposed to capillaries, which were thought to be a structural compartment of the blood–brain barrier, are now thought to be involved in glucose transport from the microvasculature to the brain and thus be critical to the metabolism and activity of neurons. Finally, glia have recently been shown to be critically involved in synaptogenesis and the pruning of synapses seen in the brain during development (Eroglu & Barres, 2010).

These transmitter-like roles played by astrocytes have recently been explored in the context of neuropsychiatric disorders, including substance abuse, schizophrenia, depression, and sleep disorders. Thus, in a very short period of time, glia have been shown to be critical partners with neurons and be involved in the pathophysiology of a large (and growing) number of disorders.

Concluding Remarks

Several of the key proteins involved in different aspects of chemical neurotransmission in mammals were originally identified on the basis of homologies to proteins found in invertebrates, such as the worm *C. elegans* or the fly *Drosophila melanogaster*. Some of the same molecules used as neurotransmitters in animals can be found in plants, along with their receptors. Although we tend to think of neurotransmitters, their synthesizing and degradative enzymes, and their transporters as having a single or very restricted roles, as nervous systems have evolved, many transmitter-related proteins have maintained roles that are not directly related to transmitter function or, alternatively are involved in less discrete and more spatially elaborate signaling.

A good example of this is acetylcholine, the synthesis of which depends on the enzyme choline acetyltransferase. The mRNA for ChAT is not only found in the brain, but is also present in the testes, where it is functional and contributes to the appearance of acetylcholine in spermatozoa. ChAT mRNA has also been reported to be present in lymphocytes, as have certain muscarinic cholinergic receptors. Also found in these white blood cells is the mRNA encoding AChE. Decreases in both acetylcholinesterase and butyrylcholinesterase enzyme activity have been reported in lymphocytes in Alzheimer's disease. Still another example is the presence of AChE in bone marrow and peripheral blood cells in certain leukemias; recent data indicate that inhibition of AChE gene expression in bone marrow suppresses programmed cell death (apoptosis; see Chapter 17). These examples clearly indicate that although a neurotransmitter may have one role in the brain, the same molecule may play a totally different role in other tissues. Such multifunctional roles of transmitters and related proteins should at the very least encourage us to attend to developments in diverse fields.

We have discussed chemically coded synaptic transmission. However, one cannot discuss the biochemistry and pharmacology of synaptic transmission without referring to and appreciating critical information about the structure (anatomy) and function (physiology and behavior) of neurons. Neuroscience is multidisciplinary, requiring an understanding of different aspects of cellular function to come to grips with the basic principles of synaptic communication.

Our concepts of synaptic transmission are in a greater degree of flux than ever before, and require frequent reevaluation and revision. Although some aspects of neurotransmission have been known for about a 100 years, others have become apparent only within the past year. Classical transmitters are but one branch of the family of transmitters, with other relatives including peptides, gases, growth factors, and lipid-derived transmitters such as endocannabinoids. The synapse has historically been viewed as the close apposition of two neurons. It is now clear that astrocytes, once viewed as structural support elements of the brain, play critical roles in transmitter function, ranging from terminating the actions of glutamate to promoting organized multineuronal activation patterns. The use of the terms "conventional" and "unconventional" in discussing transmitters is indicative of our

unease with the expanding definition of neurotransmitters. Because our knowledge of neuroscience is constantly changing we must be open and receptive to challenges to long-taught dogma.

CHAPTER

7

Release of Neurotransmitters

The synapse is the primary place at which information is transmitted from neuron to neuron or from neuron to peripheral target, be it a gland or a muscle. Most synapses rely on a chemical intermediary, or transmitter, secreted in response to an action potential in the presynaptic cell in order to influence the activity of the postsynaptic cell. In chemical transmission, a single action potential in a small presynaptic terminal can generate a large *postsynaptic potential* (PSP) (as large as tens of millivolts). This is accomplished by the release of thousands to hundreds of thousands of molecules of transmitter that can bind to postsynaptic receptor molecules and open (or close) thousands of ion channels in about 1 ms. The effect can be either excitatory or inhibitory, depending on the ions that permeate the channels operated by the receptor. The resulting responses are either *excitatory postsynaptic potentials* (EPSPs) or *inhibitory postsynaptic potentials* (IPSPs), depending on whether they drive the cell toward a point above or below its firing threshold, as discussed in Chapter 10.

Why are most synapses chemical? The simpler alternative might appear to be the electrical synapse (see Chapter 9) in which the electrical signal from one cell can cross directly into the next through the electrically conducting pathway of the gap junction. Even when pre- and postsynaptic elements are coupled in this manner, however, a presynaptic spike of 100 mV would likely cause only a 1-mV change in the postsynaptic cell because relatively little current can flow through these junctions to charge the large membrane capacitance of the postsynaptic cell. More efficient electrical transfer can be had if the connection between the cells is large; the presynaptic terminal needs to be as large as or larger than the postsynaptic element and therefore only a few presynaptic cells could converge on a given postsynaptic cell. Moreover, such synapses could only induce excitation, not inhibition, in response to a presynaptic action potential and the computational capacity of a brain operated with just electrical synapses would be very low. Chemical synapses are characterized by great flexibility. Different afferents can have different effects, with different strengths and time courses, on each other as well as on postsynaptic cells. These differences depend on the identity of the transmitter(s) released and the receptors present (see Chapters 6 and 8). Chemical synapses often are modified by prior activity in the presynaptic neuron. Chemical synapses are also particularly subject to the modulation of presynaptic ion channels by substances released by the postsynaptic or neighboring neurons. This flexibility is essential for the complex processing of information that neural circuits must accomplish, and it provides an important locus for modifying neural circuits in adaptive processes such as learning (Chapters 47 and 48).

TRANSMITTER RELEASE IS QUANTAL

In order to secrete thousands of transmitter molecules rapidly and simultaneously, nerve terminals, like other secretory cells, package the transmitter into membrane-enclosed organelles. When one of these *synaptic vesicles* fuses with the plasma membrane (a process called *exocytosis*), the contents of the vesicle (approximately 5000 molecules) can diffuse into the extracellular space and encounter receptors on the postsynaptic cell within hundreds of microseconds. A consequence of releasing transmitter by the exocytosis of vesicles is that synaptic transmission is *quantal*: responses are built from signals with a discrete amplitude corresponding to a single vesicle. In the absence of presynaptic electrical activity, transmitter is released spontaneously as individual quanta. Each packet generates a small postsynaptic signal—either a *miniature excitatory* or a *miniature inhibitory postsynaptic potential* (MEPSP or MIPSP, respectively,

© 2013 Elsevier Inc. All rights reserved.

or just "mini")—that can be detected by microelectrode recording (Katz, 1969). An action potential accelerates tremendously, but very briefly, the rate of secretion of quanta and synchronizes them to evoke a PSP. At a synapse between two neurons, this might represent the release of 1 to 10 vesicles. At the vertebrate neuromuscular junction, a remarkably large and specialized synapse, hundreds of vesicles can be released, and the response is, to a first approximation, the sum of the individual quanta.

The anatomical specializations of the synapse and the properties of the presynaptic ion channels and postsynaptic receptors unite to achieve fast, quantal transmission (Figs. 7.1 and 7.2). The chief anatomical feature of the terminal is the profusion of synaptic vesicles, typically 50 nm in diameter, that cluster near the synapse and dock at specialized sites called *active zones* along the presynaptic membrane (Fig. 7.1). The vesicles may differ in their appearance depending on the transmitter they enclose: thus glutamate and acetylcholine are stored in small clear vesicles, whereas peptide neurotransmitters occupy large dense-cored vesicles. Although it may appear as indistinct fuzz on electron micrographs, the active zone is likely to be a highly structured specialization of the membrane and cytoskeleton (Fig. 7.1; also, see discussion later). Action potentials release transmitter by triggering the exocytosis of vesicles (Fig. 7.1B and 7.1C) and the release of their contents into the narrow *synaptic cleft* (about 100 nm wide) separating the presynaptic terminal from high concentrations of receptors on the postsynaptic membrane. At neuromuscular junctions, one of the best studied synapses, transmitter from one vesicle diffuses across the synaptic cleft in 2 ms and reaches a concentration of about 1 mM at the postsynaptic receptors. A large number of these receptors (up to 2000) will bind transmitter rapidly. Activation of a receptor entails the opening of an ion channel (see Chapter 8). Each channel has a 25 pS conductance and remains open for about 1.5 ms, admitting a net inflow of 35,000 positive ions. Thus, a single vesicle by opening 2000 channels can cause 70 million ions to cross the membrane and give rise to a mini of a few millivolts, the individual quantal response. The neuromuscular junction also is specialized for efficiency; a single nerve ending will have about 1000 active zones and a single action potential will cause a vesicle to fuse at about a third of those. The consequence is the release of about 300 quanta within 1.5 ms. The resulting postsynaptic depolarization begins after a synaptic delay of about 0.5 ms, reaches a peak of tens of millivolts, and is typically sufficient to generate an action potential in the muscle fiber.

The anatomy and physiology are somewhat different at fast central synapses. Postsynaptic cells make contact with presynaptic axon swellings that are called *varicosities* when they occur along fine axons and are called *boutons* when they are located at the tips of axons. The postsynaptic cell can be contacted on the cell body, but often the synapse is made onto a fine dendritic branch or tiny spine with a length of a few micrometers. A typical varicosity or bouton contains one to four active zones. At any single active zone, an action potential may release zero, one, or perhaps two vesicles. However, with multiple active zones between two cells, the action of each zone will be additive in determining the response of the postsynaptic cell. At a representative excitatory glutamatergic synapse, each action potential releases from 5 to 10 vesicles. Each vesicle that is released elevates transmitter concentration in the cleft to about 1 mM, as at the neuromuscular junction, but because there are fewer receptors clustered beneath these synapses, each released vesicle activates only 30 or so ion channels as compared with the 1000–2000 channels activated at the neuromuscular junction. At excitatory synapses, the release of a vesicle may be sufficient to generate EPSPs of 1 mV or less in amplitude, clearly subthreshold for generating action potentials. However, central neurons often receive thousands of inputs, each of which has a "vote" on how the cell should respond.

A comparison of these excitatory synapses onto small neurons with the vertebrate neuromuscular junction at the much larger skeletal muscle fiber illustrates two important points: (1) the fundamental quantal nature of the chemical synapse is universal and (2) the different physiological requirements of particular synapses, such as synapses onto small or large cells, can be met by

FIGURE 7.1 Ultrastructural images of exocytosis and active zones. (A–C) Synapses from frog sartorius neuromuscular junctions were quick-frozen milliseconds after stimulation in conditions that enhance transmission. (A) A thin section showing vesicles clustered in the active zone (arrows), some docked at the membrane. (B) Shortly (5 ms) after stimulation, vesicles were seen to fuse with the plasma membrane. (C) After freezing, presynaptic membranes were freeze-fractured and a platinum replica was made of the external face of the cytoplasmic membrane leaflet. Vesicles fuse about 50 nm from rows of intramembranous particles thought to include Ca^{2+} channels. (D–F) The fine structure of the active zone at a frog neuromuscular junction as seen with electron tomography. (D) In a cross-sectional image from tomographic data, two vesicles are docked at the plasma membrane and additional electron-dense elements are seen. When these structures are traced and reconstructed through the volume of the EM section (E), proteins of the active zone (gold) appear to form a regular structure adjacent to the membrane that connects the synaptic vesicles (silver) and plasma membrane (white). Viewed from the cytoplasmic side (E, lower image), proteins are seen to extend from the vesicles and connect in the center. (F) Schematic rendering of an active zone based on tomographic analysis. An ordered structure aligns the vesicles and connects them to the plasma membrane and to one another. *Parts A and B from Heuser (1977) and Heuser et al. (1979). FIGURE 7.2 The life cycle of synaptic vesicles. Transmitter-filled vesicles can be observed in clusters in the vicinity of the active zone. Some vesicles are recruited to sites within the active zone in a process called docking. These vesicles subsequently are primed for release. The rise in cytosolic Ca^{2+} that occurs during an action potential triggers the opening of a fusion pore between some of the primed, docked vesicles and the plasma membrane. Transmitter exits through this fusion pore. Three pathways are proposed by which the now empty vesicle can be recovered and returned to the releasable pool: (1) by a direct reclosing of the fusion pore and reformation of the vesicle, often called "kiss and run"; (2) by complete fusion (i.e., the flattening of the vesicle onto the membrane surface) followed by clathrin-mediated endocytosis, removal of the clathrin coat, and return of the vesicle to the releasable pool; and (3) by complete fusion and recycling as in the second pathway, but the endocytosed vesicle fuses first with an endosome and mature vesicles are subsequently formed by budding from the endosome. After or during this recycling process, the vesicle must be refilled with transmitter.

differences in any of several parameters, including the number of receptors activated per vesicle released, the number of active zones connecting two cells, the probability of a given active zone releasing a vesicle, and the conductance of the postsynaptic receptor channel. In describing synaptic transmission, two parameters are particularly important. *Quantal size* or quantal amplitude describes the unitary response to release of a single quantum (vesicle), whereas *quantal content* refers to the average number of quanta (vesicles) released by a single impulse. These parameters are discussed further later.

EXCITATION–SECRETION COUPLING

The action potential is an electrical event—a change in the voltage gradient across the plasma membrane. How is this electrical change converted to the fusion of synaptic vesicles and the release of neurotransmitter? The classic studies of Bernard Katz and colleagues (Katz, 1969) established that this coupling is achieved by the use of Ca^{2+} as an intracellular messenger. Ca^{2+} inside the cell normally is buffered to very low levels (~100 nM) although the extracellular Ca^{2+} concentration will be in the millimolar range. Thus both concentration and electrical gradients provide a strong driving force for Ca^{2+} entry and, when a voltage-dependent Ca^{2+} channel opens in response to the depolarization of the membrane during an action potential, there is the potential for the intracellular Ca^{2+} concentration to increase 1000-fold. In this manner, the electrical signal is converted to a large chemical signal, and Ca^{2+} sensors in the fusion machinery can trigger vesicle fusion. The mechanism of fusion itself is discussed later, but the nature of the Ca^{2+} signal and the evidence for its centrality must be understood first.

It has been known for over 100 years that Ca^{2+} must be present in the extracellular saline for transmission to occur. Subsequently (Katz, 1969), it was shown that Ca^{2+} need be present only at the moment of invasion of the nerve terminal by the action potential. Changing the

timing of the influx of Ca^{2+} or the amount of influx (by changing the extracellular Ca^{2+} concentration or blocking Ca^{2+} channels with divalent cations such as Co^{2+} and Mn^{2+}) will change the timing and amplitude of the synaptic response. Similarly, an ionophore that lets Ca^{2+} ions flow across the membrane will cause a sustained increase in intracellular Ca^{2+} and the sustained outpouring of quanta of transmitter. It is also possible to fill a terminal with a caged form of the Ca^{2+} ion; that is, with Ca^{2+} ions bound up within a chemical carrier. A flash of light can rearrange this carrier, uncaging the Ca^{2+}, and thereby cause an abrupt increase in cytosolic Ca^{2+} and a sudden increase in secretion as well. Finally, loading the terminal with Ca^{2+} chelators to prevent increases in cytosolic Ca^{2+} can prevent release. Thus a rise in intracellular Ca^{2+} is the essential trigger for vesicle fusion.

Vesicles are Released by Calcium Microdomains

The opening of Ca^{2+} channels during a single action potential allows in enough Ca^{2+} to raise the concentration in the bouton from approximately 100 to 110 nM. How can a mere 10% change in the concentration cause a 1000-fold shift in the activity of the fusion machinery? Furthermore, because Ca^{2+} pumps and exchangers on the plasma membrane work relatively slowly, this small rise in Ca^{2+}, which can be detected with fluorescent Ca^{2+} indicator dyes, persists for hundreds of milliseconds after the action potential. Why then does transmitter secretion occur only for a millisecond or so? The answer to both of these questions lies in the fact that the release mechanism is *not* responding to the general concentration of Ca^{2+} in the bouton, but rather to the concentration in a *microdomain* in the immediate vicinity of the Ca^{2+} channels (Fig. 7.3). In these microdomains, very high concentrations of Ca^{2+} are reached very quickly and drop rapidly to near resting levels within microseconds of the closing of the channels. Presently, there are no Ca^{2+} dyes that are sufficiently local, sensitive, and fast that one can measure the concentration changes in these microdomains directly. Instead, our understanding of these signals comes from diffusion modeling, from modifying the buffering capacity of the cytosol, and from indirect indicators of the local Ca^{2+} concentration, such as transmitter release itself (Schneggenburger & Neher, 2000).

In the brief period for which the Ca^{2+} channels are open, the cytosol that lies within 100 nm of the mouth of each channel is flooded with Ca^{2+}, and the local Ca^{2+} concentration is likely to reach 100 μM or higher; the closer to the channel, the higher the concentration (Fig. 7.3A and 7.3B). The further from the channel, the more dilute the Ca^{2+} becomes and the greater the chance that it has been bound up by the high Ca^{2+}-buffering capacity of the cytosol. After the channels close, diffusion and buffering bring the Ca^{2+} concentration of the microdomains to near resting levels within a few milliseconds: the concentration gradient that existed around the mouth of the channel completely dissipates, and only the small net rise of total Ca^{2+} in the terminal remains (Fig. 7.3C). This signal, sometimes called residual Ca^{2+}, is what is detected by fluorescent indicator dyes. The effect may be compared to dumping a bucket of water into a swimming pool—a dramatic rise in water level occurs at one spot but it is very transient and gives rise to just a small net rise in the level of the entire pool.

A single active zone may have more than 100 channels in its membrane and a single vesicle may therefore be within 50 nm of as many as 10 Ca^{2+} channels. Though not all these channels will open during each action potential, more than one channel is likely to open, and therefore Ca^{2+} entering through several nearby channels can sum in overlapping microdomains to influence a vesicle (Fig. 7.3). Of the subtypes of Ca^{2+} channels that have been described, N and P/Q types of Ca^{2+} channels appear to be the most prevalent at CNS synapses, although R and L types are also reported at certain synapses.

The Exocytosis Trigger Must Have Fast, Low-Affinity, Cooperative Ca^{2+} Binding

The sensor that detects the Ca^{2+} so as to trigger release must also have special properties to achieve fast and transient exocytosis. Estimates at several synapses suggest that the Ca^{2+}-sensor has an affinity in the range of 10–100 μM, as appropriate for the relatively high concentrations of Ca^{2+} in the microdomains near channels. The on rate must be particularly fast. This is confirmed by the finding that presynaptic injection of relatively slow Ca^{2+} chelators such as ethylene glycol bis(b-aminoethyl ether)-*N*,*N*′-tetraacetic acid (EGTA) have almost no effect on transmitter release to single action potentials. Only fast Ca^{2+} chelators, such as 1,2-bis(2-aminophenoxy)ethane-*N*,*N*, *N*′,*N*′-tetraacetic acid (BAPTA), with on rates of about 5×10^8 $M^{-1}s^{-1}$, can capture Ca^{2+} ions before they bind to the secretory trigger, indicating that the on-rate of Ca^{2+} binding to this trigger is similarly fast. The off rate of Ca^{2+} dissociation from these sites must also be fast, at least 10^3 s^{-1}, to account for the rapid termination of transmitter release (0.25 ms time constant) after Ca^{2+} channels close and Ca^{2+} microdomains collapse. If microdomains did not dissipate as quickly, or if the affinity of the sensor were higher (the off rate slower), transmitter release would persist too long after the action potential had passed.

Importantly, the relationship of Ca^{2+} influx or cytosolic Ca^{2+} in microdomains to the amount of release is not linear at most synapses. By plotting this relationship on a log-log plot, a Hill coefficient can be determined, and values as high as 3 or 4 commonly are obtained. This

value implies a high cooperativity in the action of Ca^{2+} inside the terminal, perhaps because multiple Ca^{2+}-binding sites must be occupied in order to trigger release efficiently (Schneggenburger & Neher, 2000). The interesting physiological consequence of this steep relationship is that small modulations of Ca^{2+} channels that increase or decrease Ca^{2+} influx can have a large effect on the strength of a synapse. For example, at a synapse from a parallel fiber onto a Purkinje cell in the cerebellum, when the activation of modulatory presynaptic GABA receptors inhibits Ca^{2+} channels sufficiently to reduce Ca^{2+} influx by 25%, the amplitude of transmission decreases by 70%.

Summary

Chemical synapses permit one neuron to rapidly and effectively excite or inhibit the activity of another cell. A diversity of transmitters and receptors allows varied postsynaptic responses. The packaging of transmitter into vesicles and its release in quanta enable a single action potential to secrete hundreds of thousands of molecules of transmitter almost instantaneously onto another cell. Ca^{2+} acts as an intracellular messenger tying the electrical signal of presynaptic depolarization to vesicle release. At fast synapses, Ca^{2+} enters through clusters of channels near docked synaptic vesicles in active zones. This Ca^{2+} acts at extremely short distances (tens of nanometers) in remarkably little time (200 μs) and at very high local concentrations (~100 μM), in calcium microdomains, by binding cooperatively to a low-affinity receptor with fast kinetics to trigger exocytosis. When Ca^{2+} channels close, these microdomains of high Ca^{2+} return to near resting concentrations quickly and the evoked response is terminated. Speed, efficiency, and flexibility are the hallmarks of this process.

FIGURE 7.3 Microdomains with high Ca^{2+} concentrations form in the cytosol near open Ca^{2+} channels and trigger the exocytosis of synaptic vesicles. (A) In this adaptation of a model of Ca^{2+} dynamics in the terminal, a set of Ca^{2+} channels is spaced along the x axis, as if in a cross section of a terminal. The channels have opened and, while they are open, the cytosolic Ca^{2+} concentration (y axis) is spatially inhomogeneous. Near the mouth of the channel, the influx of Ca^{2+} drives the local concentration to as high as 800 μM, but within just 50 nm of the channel, the concentration drops off to 100 μM. Channels are spaced irregularly but are often sufficiently close to one another that their clouds of Ca^{2+} can overlap and sum. (B) In the active zone (gray), an action potential has opened a fraction of the Ca^{2+} channels, and microdomains of high cytosolic Ca^{2+} (pink) arise around these open channels as Ca^{2+} flows into the cell. In the rest of the cytoplasm, the Ca^{2+} concentration is at resting levels (0.10 μM), but within these microdomains, particularly near the channel mouth, Ca^{2+} concentrations are much higher, as in (A). Synaptic vesicles docked and primed at the active zone may come under the influence of one or more of these microdomains and thereby be triggered to fuse with the membrane. (C) A few milliseconds after the action potential, the channels have closed and the microdomains have dispersed. The overall Ca^{2+} concentration in the terminal is now slightly higher (0.11 μM) than before the action potential. If no other action potentials occur, the cell will pump the extra Ca^{2+} out across the plasma membrane and restore the initial condition after several 100 ms.

MOLECULAR MECHANISMS OF THE NERVE TERMINAL

To release neurotransmitter in response to an action potential, a synaptic vesicle must fuse with the plasma membrane with great rapidity and fidelity, and thus the synapse requires an effective and well-regulated molecular machine. This machine must include the means to load the vesicle with transmitter, to dock the vesicle near the membrane so that it can fuse with a short latency, to define a release site on the plasma membrane, and to cause the release itself. Additionally, a reserve of synaptic vesicles must be held near the active zone (e.g., Fig. 7.1A) and those vesicles must be recruited to the plasma membrane as needed. The number of vesicles that are ready to fuse must be strictly determined, and the protein and lipid components of the vesicle must be recycled to form a new vesicle after fusion has occurred. For each of these processes, a molecular understanding remains incomplete, but rapid progress in this field has resulted in considerable headway.

Most Neurons Require a Cycle of Membrane Trafficking

Active neurons are in constant need of transmitter-filled vesicles ready to release their contents. A bouton in the CNS, for example, may contain a store of 200 vesicles, but if it releases even one of these with each action potential and if the cell is firing at an unexceptional rate such as 5 Hz, the store of vesicles would be consumed within less than a minute. Transport of newly synthesized vesicles from the cell body would be far too slow to support such a demand and the axonal traffic needed to supply an entire arbor of nerve terminals would be staggering.

In short, active neurons need an efficient mechanism to recycle and reload vesicles within the terminal. The exception is peptidergic neurons because peptides must be synthesized in the endoplastic reticulum (ER), chiefly in the cell body. Not surprisingly, therefore, peptide vesicles are released at very low rates. For most neurotransmitters, however, the exocytosis of a synaptic vesicle is followed rapidly by endocytosis and within approximately 30 s the vesicle is again available for release. This pathway is sometimes referred to as the exo-endocytic cycle (Fig. 7.2). If we start with a transmitter-filled vesicle in the cytosol, we can outline its progression through this cycle. The vesicle will be mobilized from the reserve pool

in the cytosol to the readily releasable pool by translocating to the active zone and becoming "docked" at the plasma membrane. Biochemical priming steps may occur at this point that will enable the vesicle to fuse within microseconds once the Ca^{2+} signal is given. Exocytosis often involves a complete merging of the vesicle membrane with the plasma membrane, though some research supports the coexistence of a second pathway involving only a transient connection of the two. In the latter case (see later), the vesicle, having emptied its contents, may return directly to the vesicle pool and be refilled with transmitter. If fusion is complete, however, the vesicle needs to be reformed with a clathrin cage and pinched off the plasma membrane. In some cases, these endocytosed vesicles seem to fuse with endosomes or large membranous sacs called cisternae, and mature synaptic vesicles then bud from this compartment. In other cases, the mature vesicle may be formed directly from the plasma membrane. In either case, the vesicle must be reloaded with transmitter prior to its reuse. The pathways for neurotransmitters are discussed in Chapter 6.

Histological tracers have provided a means to follow the vesicle cycle. One such tracer is the enzyme horseradish peroxidase (HRP), which could be placed in the extracellular solution and which would be internalized into intracellular compartments, including synaptic vesicles, when the synapse was stimulated. Another set of useful tracers are lipophilic dyes, including FM1-43, which partition into the surface membrane of the cell and are similarly internalized as membrane vesicles endocytosis. When the dye is washed from the extracellular space, the surface destains, but dye remains trapped in internal compartments. Loading of this dye upon stimulation and subsequent release of the dye with further stimulation has been an important method for examining the kinetics of the cycle.

A defect in any single step in the exo-endocytic cycle will halt transmitter release. Moreover, each step in this cycle represents a potential control point for modulating the efficacy of the synapse. For example, regulation by Ca^{2+} and other second messenger systems is known to affect the docking, fusing, and recycling of vesicles at some synapses and is also likely to regulate the balance between reserve stores and those vesicles actively engaged in the exo-endocytic cycle. Understanding the mechanisms of this modulation is an important goal and will certainly require the detailed understanding of the fundamental machinery itself.

The Fusion Mechanism is Rapid

As discussed earlier in this chapter, the delay between the arrival of an action potential at a terminal and the secretion of the transmitter can be less than 200 μs. This places severe constraints on the fusion mechanism. Vesicles must already be present at the release sites, as there is no time to mobilize them from a distance. A catalytic cascade during fusion, such as that involved in phototransduction or in excitation-contraction coupling in smooth muscle, would also be far too slow for excitation-secretion coupling at the nerve terminal. Models therefore favor the idea that a fusion-ready complex of the vesicle and plasma membrane is preassembled at release sites and that Ca^{2+} binding need only trigger a simple conformation change in this complex to open a pathway for the transmitter to exit the vesicle.

Because the volume of the synaptic vesicle is small, the diffusion of transmitter from the vesicle proceeds almost instantaneously as soon as a pore has opened up between the vesicle lumen and the extracellular space. This structure is referred to as the fusion pore, but its biochemical nature is unknown. Thus, the time-critical steps come between the influx of Ca^{2+} and the formation of the fusion pore, and these steps establish the latency between arrival of the action potential and transmitter diffusion into the cleft. Any further step, such as the complete merging of the vesicle and plasma membrane, can occur on a slower time course, after the transmitter has left the vesicle. The tethering of the vesicle at the release site (often called docking) and any biochemical events that need to occur in order for the vesicle to reach the fusion-ready state (often called priming) can also be slower. Docking and priming a vesicle cannot be *too* slow, however; a central nervous system (CNS) synapse is estimated to have 2 to 20 vesicles in this fusion-ready state; therefore, if a synapse is to respond faithfully to a sustained train of action potentials, it must be able to replace the fusion-ready vesicles with a time course of seconds. The rate at which this occurs may determine some of the dynamic properties of the synapse.

The short latency of transmission would seem to preclude the involvement of ATP hydrolysis at the fusion step because such a reaction would be too slow. Indeed, fusion can proceed without ATP present and thus, if energy is needed to fuse the membranes, it must be stored in the fusion-ready state of the vesicle-membrane complex and released upon addition of Ca^{2+}.

Transmitter Release is a General Cell Biological Question with Particularly Neuronal Refinements

Exocytosis and endocytosis are not unique to neurons; these processes go on in every eukaryotic cell. Moreover, exocytosis itself is only one representative of a general class of membrane-trafficking steps in which one membrane-bound compartment fuses with another. Other examples would include transport from the ER to

the Golgi, or transport from endosomal compartments to lysosomes. In each case, the same biophysical problem must be overcome to bring the membranes close together and drive fusion.

At present, it appears that all the membrane-trafficking steps within the cell use a similar set of proteins to accomplish this task (Fig. 7.6). Indeed, it appears that representatives of this core set of proteins are present on every trafficking vesicle or target membrane and are required for every fusion step, whether it be in yeast, an epithelial cell, or a neuron. This discovery, which grew from the conjunction of independent studies of different model systems (Bennett & Scheller, 1993), has led to the exciting hypothesis that all intracellular membrane fusions will be united by a single and universal mechanism. This has been a great boon to cell biology: experiments in one model system, for example, the highly developed genetic analysis of membrane fusion in yeast, could be absorbed into neuroscience. Similarly, the abundance of synaptic vesicles for biochemical analysis and the unparalleled precision of electrophysiological assays of single vesicle fusions could inform the understanding of other cellular events.

The disparate membrane fusion events within a cell, however, are not identical in their mechanisms. Different membrane fusions present variations on a common theme; the fundamental process is adapted to the specific requirements of each physiological step. The need for extremely tight control of fusion in the nerve terminal—for rapid rates of fusion with very short latencies to occur in brief bursts at precise points on the plasma membrane—must require some important differences in how the synaptic isoforms of these proteins function compared to the isoforms involved in general cellular traffic. The fusion of peptide-containing vesicles in nerve terminals appears to follow different rules from those that govern the release of small-molecule transmitters and must therefore entail mechanistic differences. Moreover, recent findings suggest that the spontaneous release of vesicles at nerve terminals may have important mechanistic differences from the release that is triggered by an action potential. Thus, for a full understanding of the mechanisms of the nerve terminal, we will need to understand not only the common fundamentals of vesicle fusion, but also the regulatory mechanisms that may be specialized for different classes of transmission and determine the individual characteristics of a synapse.

Synaptic Proteins Have Been Identified from Purified Vesicles

Synaptic vesicles are abundant in nervous tissue and, due to their unique physical properties (uniform small diameter and low buoyant density), they can be purified to homogeneity by subcellular fractionation techniques. As a result, at a biochemical level, synaptic vesicles are among the most thoroughly characterized organelles. Indeed, with the advent of highly sensitive mass spectrometric methods of protein identification, a very comprehensive and quantitative analysis of the proteins in purified synaptic vesicles has been possible (Takamori et al., 2006). The protein compositions of synaptic vesicles from different sources are remarkably similar, demonstrating that many of the proteins present on the synaptic vesicle membrane perform general functions that are not restricted to a single class of transmitter.

Our knowledge of many of the important proteins in vesicle fusion commenced with the characterization of purified synaptic vesicles from which individual proteins could be isolated and subsequently cloned. The major constituents of the synaptic vesicle are shown in Figure 7.4. For some of these proteins, there are well-established functions, but for others, the functions remain uncertain (Table 7.1). The proton transporter, for example, is an ATPase that acidifies the lumen of the vesicle. The resulting proton gradient provides the energy by which transmitter is moved into the vesicle. This task is carried out by another vesicular protein, a vesicular transporter that allows protons to move down their electrochemical gradient and out of the vesicle in exchange for transmitter that moves into the lumen. Several vesicular transporters are known, all structurally related, and by their substrate selectivity they help equip a terminal for release of the appropriate transmitter (see later). Two other large proteins with multiple transmembrane domains are abundant in vesicles: synaptic vesicle protein 2 (SV2) and synaptophysin. The mechanism of action of these proteins remains elusive despite extensive biochemical and genetic

TABLE 7.1 Function of Synaptic Vesicle Proteins

Protein	Function
Proton pump	Generation of electrochemical gradient of protons
Vesicular transmitter transporter	Transmitter uptake into vesicle
VAMP/synaptobrevin	Component of SNARE complex; acts in a late, essential step in vesicle fusion
Synaptotagmin	Ca^{2+}-binding trigger for fusion and component of vesicle docking at release sites via interactions with SNARE complex and lipid; promotes clathrin-mediated endocytosis by binding AP-2 complex
Rab3	Possible role in regulating vesicle targeting and availability
Synapsin	Likely to tether vesicle to actin cytoskeleton
Cysteine string protein	Promotes reliable coupling of action potential to exocytosis
SV2	Unknown
Synaptophysin	Unknown, endocytosis?

characterization. Other vesicular proteins are discussed later in this chapter.

Transmitter release depends on more than just vesicular proteins, however; proteins of the plasma membrane and cytoplasm are also important. In many cases, the identification of these additional components or an appreciation of their importance to the synapse derived from investigations of vesicular proteins. Two examples will serve to illustrate this point. The first example begins with synaptotagmin, an integral membrane protein of the synaptic vesicle that was purified from synaptic vesicles and cloned. The portion of synaptotagmin that extends into the cytoplasm (the majority of the protein; see Fig. 7.4) was subsequently used for affinity column chromatography. In this manner, a protein called syntaxin was identified as a synaptotagmin-binding protein. This protein resides in the plasma membrane and is now appreciated as one of the critical players in vesicle fusion (see later). The interactions of syntaxin with many other synaptic proteins have been studied intensively to shed light on fusion and its regulation. Thus, subsequent to the isolation of an abundant vesicular protein, biochemical assays have led to a fuller picture.

A second and similar example (Gonzalez & Scheller, 1999) began with the realization that an abundant small GTP-binding protein, rab3, was present on the vesicle surface. This protein, discussed further later, may regulate vesicle availability or docking to release sites. Subsequently, rabphilin was identified on the basis of its affinity for the GTP-bound form of rab3. Rabphilin lacks

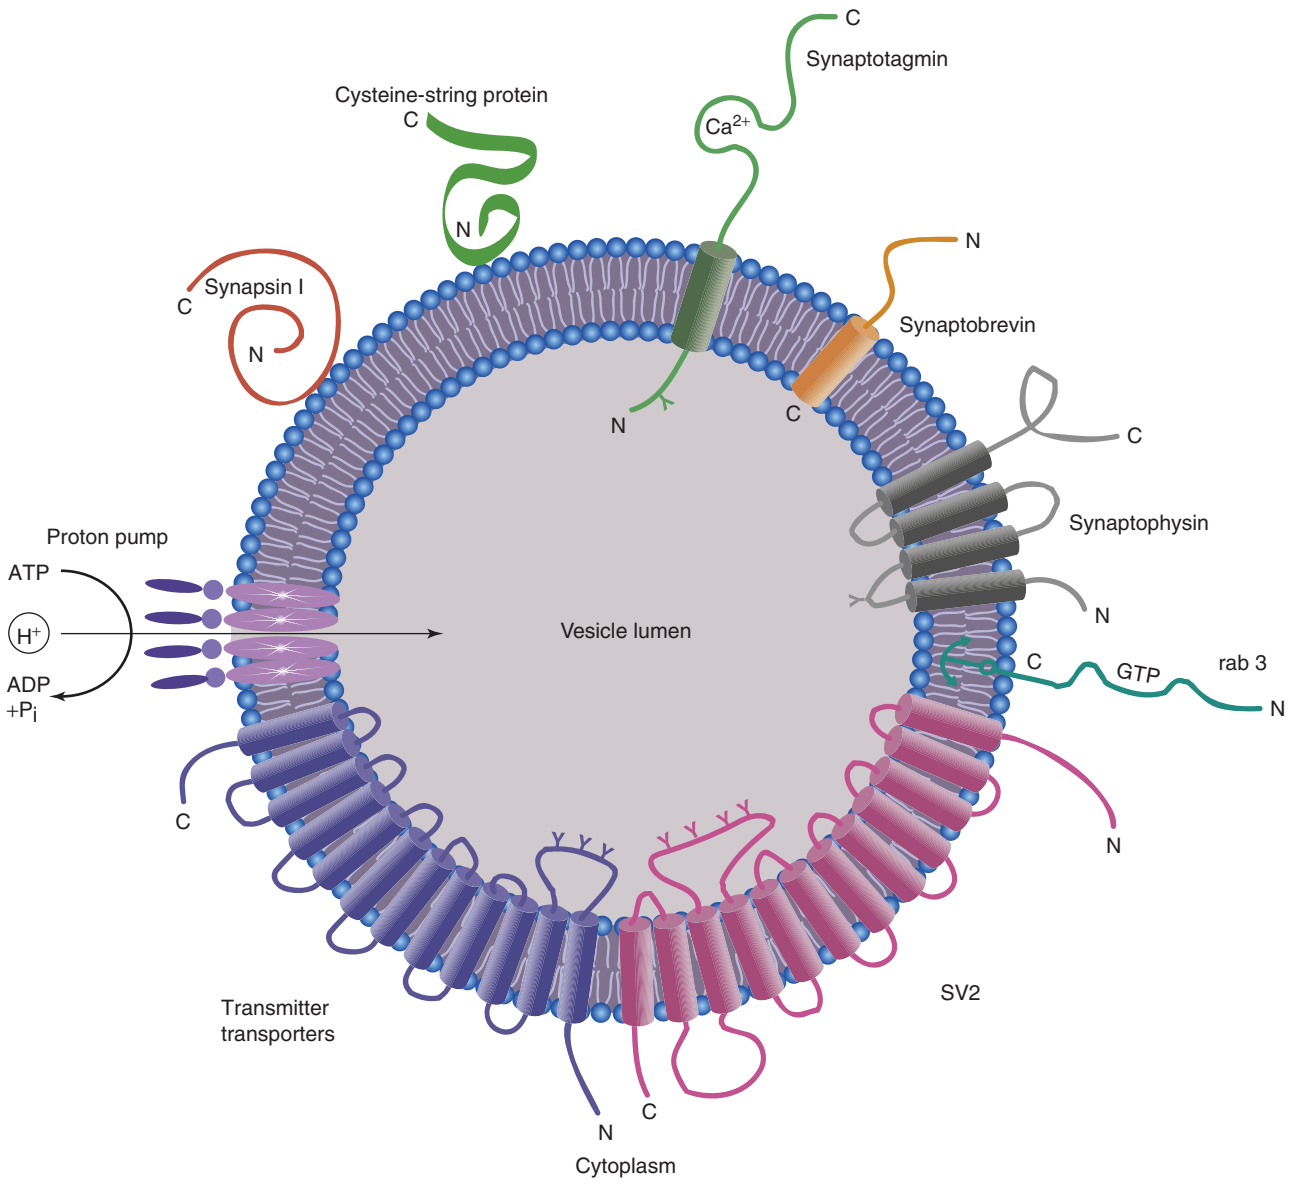

FIGURE 7.4 Schematic representation of the structure and topology of major synaptic vesicle membrane proteins (see also Table 8.1).

a transmembrane domain but is recruited to the surface of the synaptic vesicle by binding to rab3. Rabphilin may have a role in modulating transmission, particularly in mossy fiber terminals of the hippocampus. Still later, many additional rab3-binding proteins were identified, including RIM, a component of the active zone. Rab3 can exist in either GTP- or GDP-bound states, and additional factors that regulate these states were also identified: a GDP dissociation inhibitor (GDI), a GDP/GTP exchange protein (GEP), and a GTPase activating protein (GAP). Thus, from the identification of a synaptic vesicle protein, an array of additional factors has come to light, all of which are likely to figure in the exo-endocytic cycle.

Genetic Screens Have Led to the Identification of Synaptic Proteins

Genetic screens have provided an independent method for identifying the machinery of transmitter release. One of the most fertile screens was carried out not in the nervous system, but in yeast. Because membrane trafficking in yeast is closely parallel to vesicle fusion at the terminal, mutations that alter the secretion of enzymes from yeast can be a springboard for the identification of synaptic proteins. In the early 1980s, a series of such screens was carried out, and a collection of over 50 mutants was obtained. Many of these caused post-Golgi vesicles to accumulate in the cytoplasm and thus appeared to block a late stage of transport, such as the targeting or fusion of these vesicles at the plasma membrane. Screens for suppressors and enhancers of these secretion mutations uncovered further components. Subsequently, excellent *in vitro* assays have been established in which to study the fusion of vesicles derived from yeast with their target organelles. Among the secretion mutants and their interacting genes were homologues of some of the proteins discussed earlier: sec4 encodes a small GTP-binding protein like rab3, and Sso1 and Sso2 encode plasma membrane proteins that are homologues of syntaxin. The sec1 gene encodes a soluble protein with a very high affinity for Sso1, and the mammalian homologue of this protein, n-sec1, is bound tightly to syntaxin in nerve terminals and has an essential function in transmission. The convergence of neuronal biochemistry with yeast genetics has built a strong case for a common mechanism of vesicle fusion.

Yeast is not the only organism in which a genetic screen uncovered an important protein for the synapse: the unc-13 mutation of *Caenorhabditis elegans*, for example, identified a component of the active zone membrane that is important in priming vesicles for fusion and in modulation of the synapse.

Genetics has further contributed to our understanding of synaptic proteins by allowing tests of the significance of an identified protein for synaptic transmission. Such studies have been carried out in *C. elegans*, *Drosophila*, and mice, and can reveal either an absolute requirement for the protein (as in the case of syntaxin mutants in *Drosophila*) or relatively subtle effects (as in the case of rab3 mutations in mice).

From biochemical purifications, *in vitro* assays, genetic screens, and fortuitous discoveries, a list of nerve terminal proteins has been assembled (Tables 7.1 and 7.2). The manner in which these proteins coordinate the release of transmitter, as well as all the other cell biological functions of the exo-endocytic cycle, remains uncertain, but a consensus has emerged in recent years that puts one set of proteins at the core of the vesicle fusion.

TABLE 7.2 Additional Proteins Implicated in Transmitter Release

Protein	Function
Syntaxin	SNARE protein present on plasma membrane (and on synaptic vesicles to a lesser extent); forms core complex with SNAP-25 and VAMP/synaptobrevin; essential for late step in fusion
SNAP-25	SNARE protein present on plasma membrane (and on synaptic vesicles to a lesser extent); forms core complex with syntaxin and VAMP/synaptobrevin; essential for late step in fusion
Nsec-l/munc-18	Syntaxin-binding protein required for all membrane traffic to the cell surface
Complexin	Syntaxin-binding protein; may stabilize an intermediate in core complex formation
Snapin	Binds SNAP-25; associated with synaptic vesicles; unknown function
NSF	ATPase that disassembles SNARE complex; likely to disrupt complexes after exocytosis
a-SNAP	Cofactor for NSF in SNARE complex disassembly
unc-13/munc-13	Active zone protein; vesicle priming for release; modulation of transmission by diacyl glycerol and Protein Kinase C
Rabphilin	C2 domain protein; Ca^{2+}-binding protein; binds rab3 and associates with synaptic vesicle; modulation of transmission (?)
DOC2	Ca^{2+}-binding C2 domain protein; binds munc-18 and SNAREs; regulates spontaneous fusions and asynchronous release
RIM1 and related proteins	Active zone proteins; bind rab3; modulation of transmission
Piccolo	Likely scaffolding protein at active zones
Bassoon	Likely scaffolding protein at active zone
Exocyst (sec6/8 complex)	Marks plasma membrane sites of vesicle fusion; not needed for synaptic vesicle fusion

SNAREs and the Core Complex are Key to Membrane Fusions

Three synaptic proteins, vesicle-associated membrane protein (VAMP), syntaxin, and the synaptosome-associated protein of 25 kDa (SNAP-25), are capable of forming an exceptionally tight complex with one

another that generally is referred to as either the *core complex* or the *SNAP receptor (SNARE) complex* (Sollner, Bennett, Whiteheart, Scheller, & Rothman, 1993a, 1993b; Sutton, Fasshauer, Jahn, & Brunger, 1998). The interaction of these three proteins is essential for synaptic transmission and is likely to lie very close to or indeed at the final fusion step of exocytosis (Figs. 7.5 and 7.6). What are these proteins?

VAMP (also called synaptobrevin) was among the first synaptic vesicle proteins to be cloned. It is anchored to the synaptic vesicle by a single transmembrane domain and has a cytoplasmic domain that contributes a coiled-coil strand to the core complex. Syntaxin has a very similar structure but is located primarily in the plasma membrane (although some is present on vesicles as well). SNAP-25 is also a protein primarily of the plasma membrane but, unlike the others, lacks a transmembrane domain and instead is anchored in its central region by acylations. SNAP-25 contributes two strands to the SNARE coiled coil. The interactions of these proteins can be envisioned as closely juxtaposing the two membranes meant to fuse. The proteins of this complex are archetypes of a class of membrane-trafficking protein collectively called *SNAREs*. Vesicle-associated proteins, such as VAMP, are referred to as *v-SNAREs*, and those of the target membrane, such as SNAP-25 and syntaxin, are referred to as *t-SNAREs*.

A SNARE complex is found at each membrane-trafficking step within a eukaryotic cell (Fig. 7.6). Through a combination of SNARE proteins on the opposing membranes, a four-stranded coiled-coil is formed. Alongside the example of the synapse in Figure 7.6A, three analogous cases are shown from exocytosis in yeast (Fig. 7.6B), the fusion of late endosomes with one another (Fig. 7.6C), and the fusion of vesicles that form the yeast vacuole (Fig. 7.6D).

Abundant genetic and biochemical data argue for an essential role of SNAREs, and the combination of yeast genetics, *in vitro* assays, biochemical analyses, and synaptic physiology has had a synergistic effect in advancing the field. For example, the discovery that secretory mutations in yeast were homologues of synaptic SNAREs provided some of the first functional data on these proteins (Bennett & Scheller, 1993), whereas data from synapses first placed the proteins on vesicles and the plasma membrane. In addition, the crystal structure was solved first for synaptic proteins (Sutton et al., 1998). Because transmembrane domains and, of course, the membranes themselves were absent from the crystallized samples, it was not possible to conclude from the structure alone that SNAREs form a bridge between the membranes rather than forming complexes within the same membrane. Instead, an *in vitro* assay with purified yeast vesicles established this point.

Some of the strongest evidence for an essential role of SNAREs at the synapse has come from the study of a potent set of eight neurotoxins produced by clostridial bacteria. These toxins (tetanus toxin and the family of related botulinum toxins) have long been known to block the release of neurotransmitter from the terminal. The discovery that they do so by proteolytically cleaving individual members of the SNARE complex provided neurobiologists with a set of tools with which to probe SNARE function (Fig. 7.5).

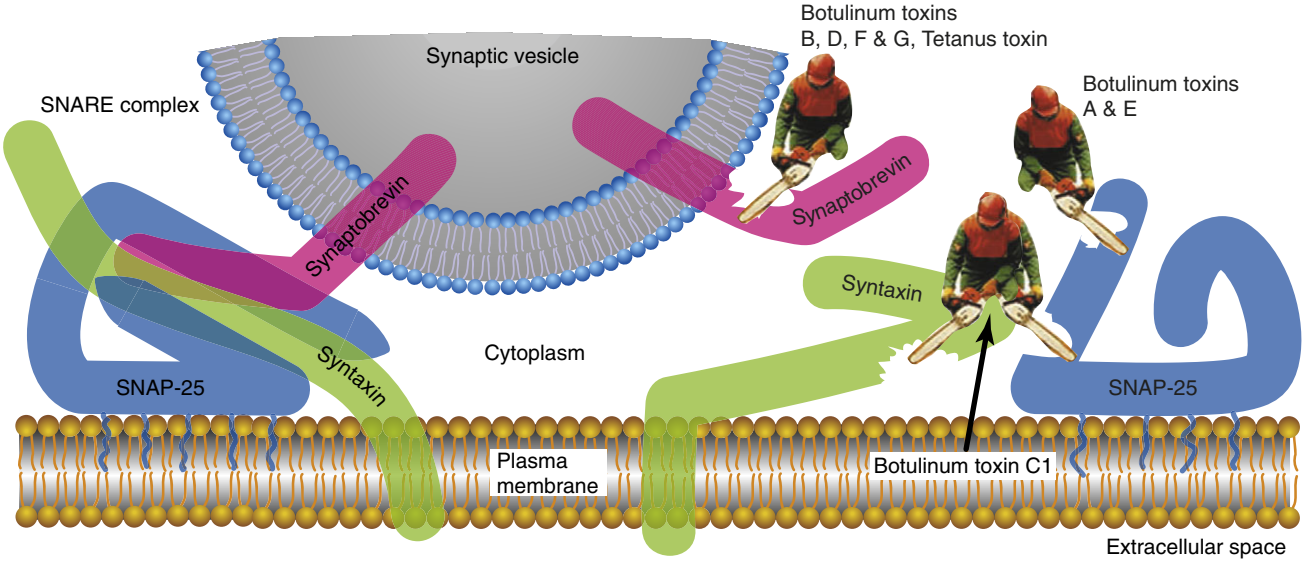

FIGURE 7.5 SNARE proteins and the action of clostridial neurotoxins. The SNARE complex shown at the left brings the vesicle and plasma membranes into close proximity and likely represents one of the last steps in vesicle fusion. Vesicular VAMP, also called synaptobrevin, binds with syntaxin and SNAP-25 that are anchored to the plasma membrane. Tetanus toxin and the botulinum toxins, proteases that cleave specific SNARE proteins as shown, can block transmitter release.

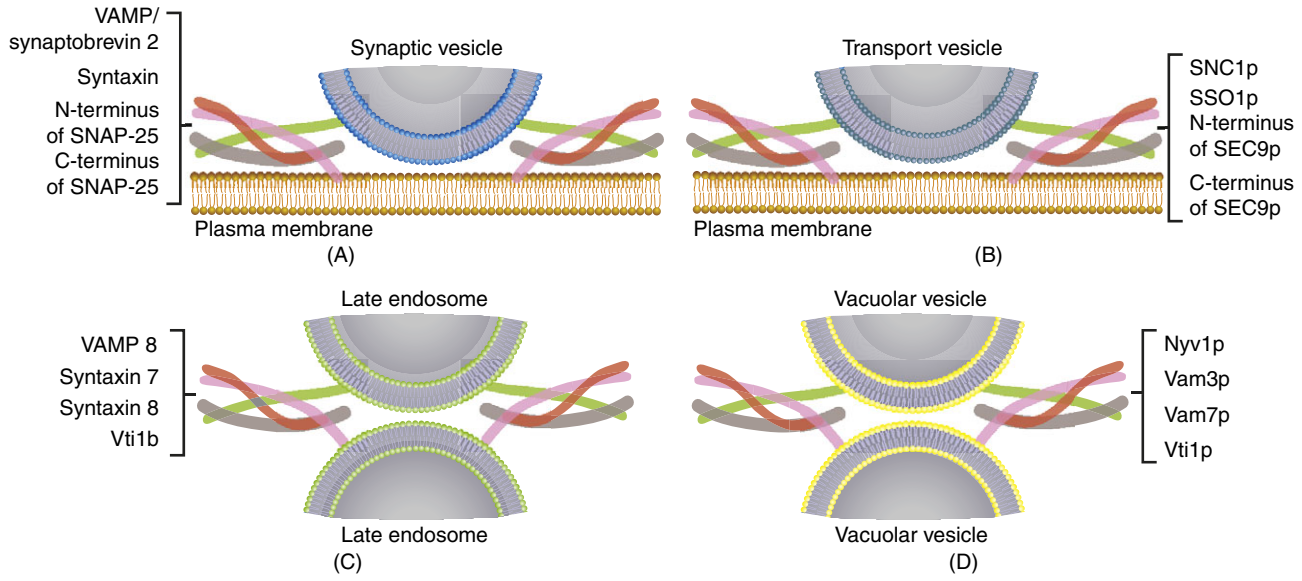

FIGURE 7.6 Neurotransmitter release shares a core mechanism with many membrane fusion events within eukaryotic cells. The fusion of synaptic vesicles (A) is driven by a particular complex of four coiled-coil domains contributed by three different proteins. Exocytosis in yeast (B), the fusion of late endosomes in mammalian cells (C), and the fusion of vacuolar vesicles in yeast (D) exemplify the closely related four-stranded coiled-coil complexes required to drive fusion in other membrane-trafficking steps.

Each of the toxins comprises a heavy and a light chain that are linked by disulfide bonds. The heavy chain binds the toxin to surface receptors on neurons, thereby enabling the toxin to be endocytosed. Once inside the cell, the disulfide bond is reduced and the free light chain enters the cytoplasm of the cell. This light chain is the active portion of the toxin and is a member of the Zn^{2+}-dependent family of proteases. The catalytic nature of the toxin accounts for its astonishing potency; a few tetanus toxin light chains at a synapse can suffice to proteolyse all the VAMP/synaptobrevin, thereby shutting down transmitter release. The toxins are highly specific, recognizing unique sequences within an individual SNARE protein, as summarized in Fig. 7.5. VAMP/synaptobrevin can be cleaved not only by tetanus toxin but by the botulinum toxins of types B, D, F, and G, and each toxin cleaves at a different peptide bond within the structure. SNAP-25 is cleaved by botulinum toxins A and E, but again at different sites from one another. Botulinum toxin C1 cleaves both syntaxin and, less efficiently, SNAP-25.

What precisely is the function of SNARE proteins in promoting transmitter release? How does the assembly of this complex relate to membrane fusion? Studies with botulinum toxins, yeast mutants, mutants of *Drosophila* and *C. elegans*, and permeabilized mammalian cells all place SNAREs late in the process. Synapses that lack an individual SNARE—for example, synapses whose VAMP has been mutated or cleaved by toxin—have the expected population of synaptic vesicles, and these vesicles accumulate at active zones in the expected manner. Indeed, as judged by electron microscopy, there may even be an excess of vesicles in close proximity to the plasma membrane at the active zone. Yet these synapses are incapable of secreting transmitter in response to an action potential. Thus, SNAREs appear to be essential for a step that comes after the arrival of the vesicle to the release site, but before the fusion pore opens and transmitter can diffuse into the cleft. The details of how the complex functions, however, are less certain.

One attractive model is that the energy released by the formation of this very high-affinity complex is used to drive together the two membranes. A loose complex of the SNARES would form, probably involving the N-terminal portions of the SNARE proteins and this might represent a fusion-ready but stable intermediate state. The SNARE proteins would then "zipper up" into the full core complex structure in response to the triggering signal Ca^{2+} signal. The zippering up will pull the membranes together and this in turn will allow a fusion pore to form that will connect the vesicle lumen to the extracellular space. Vesicles consisting of only lipid bilayers and SNAREs can fuse *in vitro*, suggesting that this machinery may be sufficient for the fusion step although *in vivo* additional proteins are required.

One additional function may reside with SNARE proteins: identification of an appropriate target membrane. Within a cell, there are myriad membrane compartments with which a transport vesicle can fuse: how then is specificity achieved? The great diversity of SNAREs (Fig. 7.6) may account for some of this specificity because not all combinations of vesicle-associated and

target-associated SNAREs (v- and t-SNAREs) will form functional complexes. This potential mechanism, however, is likely to be only a part of the story. Particularly in the nerve terminal, it appears that synaptic vesicles can find the active zone even in the absence of the relevant SNAREs—for example, when a SNARE has been cleaved by a clostridial toxin or in a mutant lacking a SNARE. In addition, the t-SNAREs' syntaxin and SNAP-25 can be present along the entire axon and thus are inadequate to explain the selective release of transmitter at synapses and active zones.

NSF—An ATPase for Membrane Trafficking

At some point as vesicles move through their exo-endocytic cycle, energy must be added to the system. *N*-Ethylmaleimide sensitive factor (NSF), an ATPase involved in membrane trafficking, is one likely source. NSF was first identified as a required cytosolic factor in an *in vitro* trafficking assay. The importance of NSF was confirmed when it was found to correspond to the yeast sec18 gene, an essential gene for secretion. NSF hexamers bind a cofactor called a-SNAP (Soluble NSF Attachment Protein), or sec17, and this complex in turn can bind to the SNARE complex. When Mg-ATP is hydrolyzed, the SNARE complex is disrupted into its component proteins (Sollner et al., 1993a, 1993b). If SNARE complexes form between VAMP, syntaxin, and SNAP-25 all in the same membrane, these futile complexes can be split apart by NSF so that productive complexes bridging the membrane compartments can be formed. After fusion, the tight SNARE complex needs to be disrupted so that the VAMP can be recycled to synaptic vesicles while the other SNAREs remain on the plasma membrane. If, indeed, the energy of forming a tight SNARE complex is part of the energy that drives fusion, NSF, by restoring the SNAREs to their dissociated, high-energy state, will be an important part of the energetics of membrane fusion.

Docking and Priming Vesicles Prepares Them for Fusion

As discussed earlier and outlined in Figure 7.2, many preparatory and regulatory steps may precede the action of SNAREs and the membrane fusion step at which SNAREs appear to act. These preparatory steps must tether the vesicle at an appropriate release site in the active zone and hold the vesicle in a fusion-ready state. These mechanisms remain among the most obscure of the processes involved in exocytosis, but there is a growing list of proteins that may participate (Table 7.2). One example is the syntaxin-binding protein munc-18 (also called nsec1), the neuronal homologue of the product of the yeast secl gene. Mutations of this protein prevent trafficking in both yeast and higher organisms. It appears likely that munc18 serves two functions and binds to SNARE complexes in more than one fashion: it may promote membrane fusion by binding to syntaxin in a manner that will subsequently promote SNARE complex formation, but it may also be a negative regulator, keeping syntaxin inert until an appropriate vesicle or signal displaces it and allows a SNARE complex to form. The sequencing of when and how it binds and unbinds remains a topic of study, but munc18 is clearly essential for transmitter release.

Rab3, a small GTP-binding protein mentioned earlier, is another protein for which a priming or regulatory role often is invoked at the synapse. In yeast, and at other membrane-trafficking steps within mammalian cells, rab proteins have essential roles. They appear to help a vesicle to recognize its appropriate target and begin the process of SNARE complex formation. At the synapse, however, the significance of rab3 is still uncertain. Although it is clearly associated with synaptic vesicles, genetic disruption of rab3 has a surprisingly slight phenotype and causes only subtle alterations in synaptic properties. Whether this is due to additional, redundant rab proteins or whether the rab family has been relegated to a more minor role at the synapse remains to be determined. Interestingly, in *Drosophila*, the chief phenotype of *rab3* mutants is in the assembly of the proteins of the active zone rather than in the fusion steps themselves.

Because synaptic vesicles dock and fuse specifically at the active zone, this region of the nerve terminal membrane must have unique properties that promote docking and priming. The special nature of this domain is easily discernible in electron micrographs: an area of electron-dense material can be observed opposite the postsynaptic density (Fig. 7.1). In some synapses, such as photoreceptors, hair cells, and many insect synapses, the structures are more elaborate and include ribbons, dense bodies, and T bars that extend into the cytoplasm and appear to have a special relationship with the nearby pool of vesicles. Advances in electron microscopy have allowed a more detailed look at the association of vesicles and plasma membrane at the active zone (Harlow, Ress, Stoschek, Marshall, & McMahan, 2001). At the neuromuscular junction of the frog (Fig. 7.1), the electron-dense material adjacent to the presynaptic plasma membrane is actually a highly ordered structure—a lattice of proteins that connect the vesicles to a cytoskeleton, to one another, and to the plasma membrane. The molecules that correspond to these structures are not yet known. A few proteins, however, are known to be concentrated in the active zone or in the cloud of vesicles near the active zone. These proteins, piccolo, bassoon, RIM1, DOC2, and unc-13, may be a part of the machinery that defines the active zone as the appropriate target for

synaptic vesicle fusion. In addition, these proteins, by docking and priming vesicles for release can establish the number of vesicles available for rapid fusion upon arrival of an action potential. Because the size of that pool helps determine how many vesicles actually will fuse, the proteins of the active zone are important regulatory components of the synapse.

In addition to the specializations of the active zone, additional machinery must be present to preserve a dense cluster of synaptic vesicles extending approximately 200 nm back from the active zone (Fig. 7.1). The vesicles in this domain are not likely to be releasable within microseconds of the arrival of an action potential but are instead likely to represent a reserve pool from which vesicles can be mobilized to release sites on the plasma membrane. The equilibrium between this pool and vesicles actually at the membrane may be an important determinant of the number of vesicles released per impulse, but remains poorly understood.

One protein family likely to play a role in the maintenance of the reserve pool is the synapsins, a set of peripheral membrane proteins on synaptic vesicles. Synapsins can also bind actin filaments and thus may provide a linker that tethers the vesicles in the cluster to the synaptic cytoskeleton. Disruption of this link can cause the vesicle cluster to be diminished and reduce the number of vesicles in the releasable pool of the terminal. Synapsin has attracted considerable interest because it is the substrate for phosphorylation by both cAMP and Ca^{2+}-dependent protein kinases. These phosphorylations may influence the availability of reserve vesicles for recruitment to release sites.

Ca^{2+}-Binding Proteins are Candidates for Coupling the Action Potential to Exocytosis

The most striking difference between synaptic transmission and traffic between other cellular compartments is the rapid triggering of fusion by action potentials. As discussed previously, the opening of Ca^{2+} channels and the focal rise of intracellular Ca^{2+} activate the fusion machinery. How does the terminal sense the rise in Ca^{2+}? What is the Ca^{2+} trigger and how does it open the fusion pore? Is it a single Ca^{2+}-binding protein or do several components respond to the altered Ca^{2+} concentration? Does Ca^{2+} remove a brake that normally prevents a docked, primed vesicle from fusing or does Ca^{2+} induce a conformational change that is actively required to promote fusion? How does the steep, exponential relationship of release to intracellular Ca^{2+} arise? These questions are an active area of investigation and debate.

The leading candidate for being the synaptic Ca^{2+} sensor is synaptotagmin, an integral membrane protein of the synaptic vesicle (Fig. 7.4). Synaptotagmin has a large cytoplasmic portion that comprises two Ca^{2+}-binding C2 domains, called C2A and C2B. These domains can also interact with the SNARE complex proteins and with phospholipids in a Ca^{2+}-dependent manner. It has been hypothesized that one or more of these interactions is the molecular correlate of the triggering event for fusion. Consistent with this hypothesis, mutations that remove synaptotagmin profoundly reduce synaptic transmission in flies, worms, and mice, while having little effect on or enhancing the rate of spontaneous release of transmitter. Synaptotagmin is likely to be involved in endocytosis and potentially in vesicle docking as well, which has complicated the analysis. These processes, as mentioned earlier, are also likely to be regulated by Ca^{2+}, and the Ca^{2+}-binding sites on synaptotagmin may be relevant for this regulation as well.

Recently, an intriguing model has emerged in which the fusion of membranes is arrested at an intermediate state by the binding of a small protein called complexin to the assembled SNARE complex. Complexin appears to stabilize an intermediate step in the fusion pathway, perhaps partially zippered SNARE complexes, and the unbinding of complexin through the action of synaptotagmin and Ca^{2+} is thought to allow the fusion reaction to proceed. In this model, complexin serves as a brake and the primary function of synaptotagmin in exocytosis is to release that brake. In other models, the insertion of synaptotagmin domains into the lipid bilayer is also essential for membrane destabilization and fusion pore opening (Rizo & Rosenmund, 2008). Another complication for analysis of the Ca^{2+}-sensing trigger is that there may well be more than one. Loss of synaptotagmin isoforms always leaves some residual transmitter release, although it tends not to be as synchronous or as efficiently evoked by individual action potentials. Recent experiments have indicated that another protein containing two C2 domains, DOC2, may be the sensor for this slower phase of release and may confer Ca^{2+} sensitivity on the mini frequency (Yao, Gaffaney, Kwon, & Chapman, 2011).

Transmitter Must Be Packaged into the Vesicle

To achieve the synchronous release of thousands of molecules of transmitter from the presynaptic nerve terminal, synaptic vesicles accumulate and store high concentrations of transmitter. In cholinergic neurons, for example, the concentration of acetylcholine within the synaptic vesicle can reach 0.6 M, more than 1000-fold greater than that in the cytoplasm. Two synaptic vesicle proteins mediate the uptake of transmitter: the vacuolar proton pump and a family of transmitter transporters. The vacuolar proton pump is a multisubunit ATPase that catalyzes the translocation of protons from

the cytoplasm into the lumen of a variety of intracellular organelles, including synaptic vesicles. The resulting transmembrane electrochemical proton gradient is utilized as the energy source for the active uptake of transmitter by transmitter transporters.

Transmitter uptake has been characterized in isolated synaptic vesicle preparations in which at least four types of distinct transporters have been identified: one for acetylcholine, another for catecholamines and serotonin, a third for the excitatory amino acid glutamate, and the fourth for the inhibitory amino acids GABA and glycine. At least one gene for each of these classes of transmitter transporter has now been cloned. As expected, these distinct transporters are expressed differentially by neurons. The type of transporter in a cell dictates the type of transmitter stored in the synaptic vesicles of a particular neuron, and when investigators drive the expression of a glutamate transporter, for example, in a GABA-releasing neuron, they can trick the cell into releasing glutamate.

Vesicular transporters are integral membrane proteins with 12 membrane-spanning domains that display sequence similarity with bacterial drug-resistance transporters. Synaptic vesicle transporters are clearly distinct from the plasma membrane transmitter transporters that remove transmitter from the synaptic cleft and thereby contribute to the termination of synaptic signaling. The distinguishing characteristics include their transport topology, energy source, pharmacology, and structure. The sequestration of transmitter into vesicles, in addition to its obviously essential role for transmitter exocytosis, has some further benefits to the cell. Sequestration can prevent high cytosolic concentrations of the transmitter from inhibiting the biosynthetic enzymes for transmitter synthesis and can protect the transmitter from catabolic enzymes. In addition, in some cell types, sequestration may protect the cell from damage caused by the oxidation of labile transmitters, particularly dopamine.

In contrast to small chemical transmitters, proteinaceous signaling molecules, including neuropeptides and hormones, typically are stored in granules that are larger and have a higher electron density than synaptic vesicles. The contents of these granules are not recycled at the release sites; as a result, their replenishment requires new protein synthesis followed by packaging into secretory vesicles in the cell body. Because of the slow kinetics of their release, the slow responsiveness of their postsynaptic receptors, and their inability to be recycled locally, proteinaceous signaling molecules typically mediate regulatory functions.

Endocytosis Recovers Synaptic Vesicle Components

After exocytosis, the components of the synaptic vesicle membrane must be recovered from the presynaptic plasma membrane, as discussed previously. Vesicle recycling theoretically could be accomplished by either of two mechanisms (Fig. 7.2). The first is simply a reversal of the fusion process. In this case, a fusion pore opens to allow transmitter release and then closes rapidly to reform a vesicle. Often nicknamed "kiss and run," it has the theoretical advantage that it would allow all the vesicular components to remain together on a single vesicle that would be available immediately for reloading with transmitter. The mechanism is potentially quick and energetically efficient. This mechanism is employed in some nonneuronal cells, but its relevance for the synapse is an unresolved and highly controversial issue.

The predominant pathway for synaptic vesicle recycling is more likely to be a second mechanism: endocytosis. When a vesicle fuses completely with the plasma membrane, its protein constituents become a part of the plasma membrane and at least many of them appear to diffuse laterally in the membrane, mixing with other plasma membrane components. The reformation of a vesicle requires that the appropriate proteins of the synaptic vesicle be reassembled in the proper ratios. For some proteins, including SNAREs, there are significant populations of these proteins in the surface membrane and the particular copy of the protein that is endocytosed is unlikely to be that which was just exocytosed. Other vesicular proteins may remain together in a cluster to facilitate reassembly into a vesicle. This reassembly and subsequent endocytosis, in many cases, will occur at a site near the active zone, but not at the active zone itself. The assembly of the constituents is facilitated by adaptor proteins in the cytoplasm such as AP-2 and stonin. In addition, very local changes in the composition of the lipid membrane, in particular an increase in $PI(4,5)P_{2,}$ is important for assembly at the endocytic site. In the next stage of endocytosis, the membrane begins to bud inward and a lattice of clathrin forms on it. Clathrin-coated vesicles are the hallmark of the classical endocytic pathway in every cell. Other proteins such as epsin contribute to the recruitment of clathrin and to controlling the shape of the forming vesicle. In a nerve terminal, the shape is a crucial determinant of the volume of the vesicle and therefore the amount of transmitter held. Another class of proteins, characterized by the shared structural feature of a BAR domain, are also needed to shape vesicles and in particular to convert the invaginating bud into a spherical structure with only a narrow neck connecting it to the plasma membrane. The BAR proteins include amphiphysin and endophilin and they associate with a third protein called synaptojanin which increases the efficiency of the endocytic process. The final pinching off of a clathrin-coated vesicle requires the protein dynamin, which can form a ring-like collar around the neck of an endocytosing vesicle.

Dynamin is a GTPase and the hydrolysis of GTP causes the dynamin ring to constrict and thereby drive the scission of the vesicle from the plasma membrane. The importance of dynamin is demonstrated most clearly in *Drosophila* via a temperature-sensitive dynamin mutant known as *shibire*: at the nonpermissive temperature, *shibire* flies become paralyzed rapidly due to a nearly complete depletion of synaptic vesicles from their nerve terminals. Once the components of the synaptic vesicle membrane have been recovered in clathrin-coated vesicles, recycling is completed by vesicle uncoating and, perhaps, passage through an endosomal compartment in the nerve terminal (Fig. 7.2).

Summary

The life of the synaptic vesicle involves much more than just the Ca^{2+}-dependent fusion of a vesicle with the plasma membrane. It is a cyclical progression that must include endocytosis, transmitter loading, docking, and priming steps as well. In many regards, this cell biological process shares mechanistic similarities with membrane trafficking in other parts of the cell and with simpler organisms such as yeast. Interaction of vesicular and plasma membrane proteins of the SNARE complex—VAMP/synaptobrevin, syntaxin, and SNAP-25—is an essential late step in fusion. Many other proteins have been identified that are likely to precede the action of the SNAREs, regulate the SNAREs, and recycle them. Components of the synaptic vesicle membrane, the presynaptic plasma membrane, and the cytoplasm all contribute to the regulation of synaptic vesicle function. Together, these proteins build on the fundamental core apparatus to create an astonishingly accurate, fast, and reliable means of delivering transmitter to the synaptic cleft.

QUANTAL ANALYSIS: PROBING SYNAPTIC PHYSIOLOGY

A quantitative description of the signal passing across a synapse can be a source of insight into the biophysics of transmission and its regulation. As discussed earlier, the response to an action potential in the presynaptic cell reflects the release of discrete packets of transmitter, called quanta, that are a direct consequence of the vesicular release of transmitter. A given synapse, however, will not secrete exactly the same number of vesicles in response to each stimulus. Instead, the probabilistic nature of the presynaptic apparatus typically causes the amount released to fluctuate from trial to trial in a quantal manner; that is, the postsynaptic response adopts preferred levels, which arise from the summation of various numbers of vesicle fusions (Katz, 1969). Thus, although a particular synapse may release an average of two vesicles per action potential, it may release one vesicle in response to one stimulation and three vesicles in response to the next. To the third stimulus, the synapse may fail to release any transmitter at all. From a full description of the properties of the synapse, the size of the individual quantum response can be estimated, as well as the average number of quanta released for a given presynaptic action potential. This approach, called quantal analysis, is also a source of insight into the probabilistic processes underlying transmitter release from the presynaptic terminal and into the mechanisms by which transmission can be modified by physiological, pharmacological, and pathological phenomena.

A Standard Model of Quantal Transmission Can Describe Many Synapses

The quantal nature of transmission was first demonstrated in the early 1950s by Bernard Katz and colleagues, who recorded from the frog neuromuscular junction. Spontaneous signals that were approximately 1/100 of the signal evoked by stimulating the presynaptic axon were observed to occur at random intervals. These spontaneous minis were of roughly constant amplitude, with a coefficient of variation of 30%. As discussed previously, a neuromuscular junction normally releases hundreds of quanta per impulse, but when extracellular Ca^{2+} was lowered to reduce transmitter release to very low levels, the evoked response fluctuated from trial to trial between preferred amplitudes, which coincided with integral multiples of the mini amplitude (Fig. 7.7).

We now understand this to arise from the fact that minis are the fusion of a single vesicle and that evoked responses can represent one or more of these same vesicles. Before the vesicle hypothesis was established, however, Katz and colleagues inferred that the mini is the quantal building block, variable numbers of which are released to make up the evoked signal. The relative numbers of trials resulting in 0, 1, 2, . . . quanta were well described by a Poisson distribution—a statistical distribution that arises in many instances where a random process operates. On the basis of this evidence, Katz and colleagues proposed the following model of transmission, which has gained wide acceptance and will be referred to as the standard Katz model.

- Arrival of an action potential at the presynaptic terminal briefly raises the probability of release of quanta of transmitter (i.e., the fusion of synaptic vesicles).
- Several quanta (synaptic vesicles) are available to be released, and every quantum gives roughly the same electrical signal in the postsynaptic cell. This is the

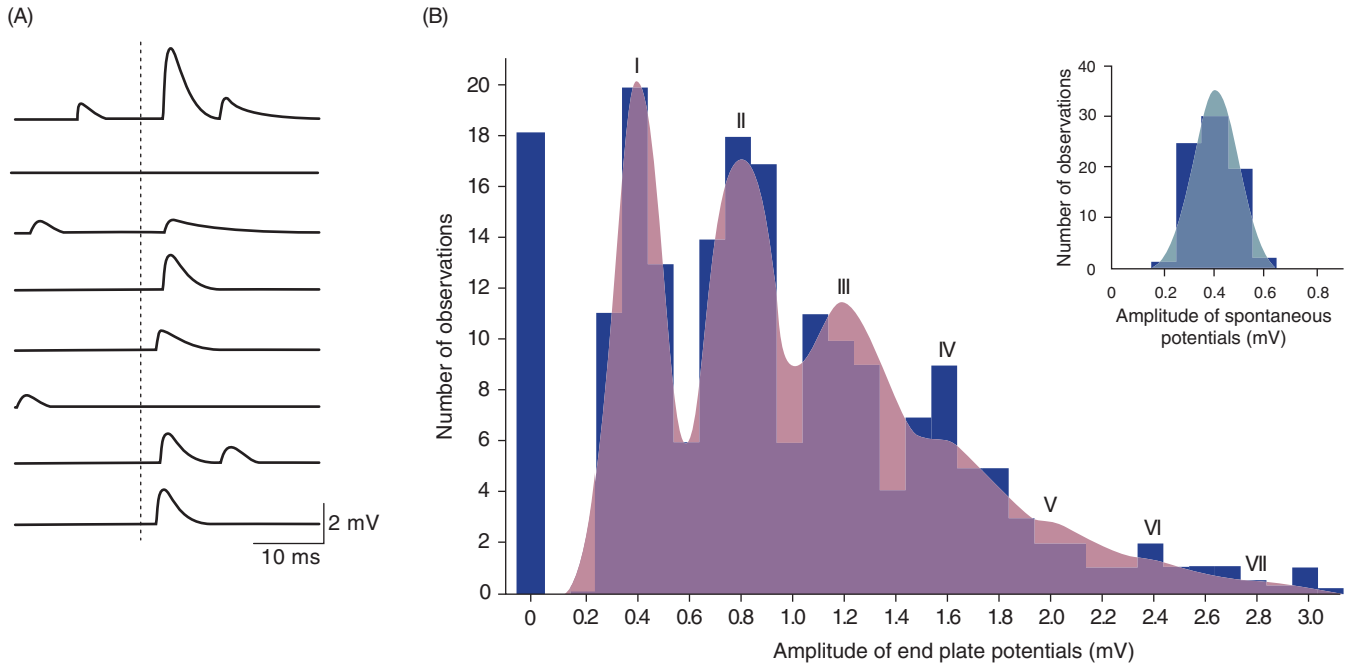

FIGURE 7.7 Quantal transmission at the neuromuscular junction. (A) Intracellular recordings from a rat muscle fiber in response to repeated presynaptic stimulation of the motor axon. Low extracellular [Ca^{2+}] and high [Mg^{2+}] restricted Ca^{2+} entry and so kept transmission to a very low level. The stimulus was given at the time marked by the dotted line. The size of the postsynaptic response fluctuated from trial to trial, with some trials giving failures of transmission. Spontaneous minis occurring in the background (e.g., those events that occur before the dotted line) had approximately the same amplitude as the smallest evoked responses, implying that they arose from the release of single quanta of acetylcholine. *From Liley (1956).* (B) Peak amplitudes of 200 evoked responses [end plate potentials (EPPs)] from a similar experiment, plotted as an amplitude histogram. Eighteen trials resulted in failures of transmission (indicated by the bar at 0 mV), and the rest gave EPPs whose amplitude tended to cluster at integral multiples of 0.4 mV. This coincides with the mean amplitude of the spontaneous minis, whose amplitude distribution is shown in the insert together with a Gaussian fit. Shading through the EPP histogram is a fit obtained by assuming a Poisson model of quantal release. Roman numerals indicate the number of quanta corresponding to each component in the distribution. *From Boyd and Martin (1956).*

quantal size or amplitude, Q, which sums linearly with all other quanta released.

- The average number of quanta released, m, is given by the product of n, the number of available quanta, and p, the average release probability: $m = np$. The average response to a stimulus is the product of the quantal size and the average number of quanta per stimulus, Qm or Qnp.
- The relative probability of observing 0, 1, 2, . . . , n quanta released is then given by a binomial distribution, with parameters n and p.

The value of Q has a clear underlying basis: the efficacy of an individual synaptic vesicle fusion in altering the conductance of the postsynaptic membrane. The binomial parameters, n and p, however, are formalisms whose underlying meanings are harder to pin down. n may correspond to the number of vesicles in a primed, fusion-ready state at the active zone or to discrete release sites competent for release, or even to the number of active zones. Correspondingly, p may represent the probability of fusion of any individual vesicle or the probability of fusion at a given release site or active zone. For some mechanisms, therefore, it is difficult to say whether n or p is altered. For example, if additional vesicles are recruited to release sites, that change may be manifest as a change in n because there are more releasable quanta or as a change in p because the probability of fusion at a given release site has increased because it is more likely to be charged with a vesicle.

These quantal parameters remain a useful description of the synapse, however, despite their obscurity on a mechanistic level. For example, it is often useful to classify synapses as having a high or low probability of release (p) to explain their behavior during trains of stimuli (see later). In a synapse with few releasable vesicles and a high p, a train is predicted to deplete the releasable pool rapidly and the strength of transmission declines, a phenomenon known as synaptic depression. Another synapse might have the same average quantal content, but accomplish this with a large releasable pool and a low probability of fusion for any individual vesicle in the pool. Such a synapse would be less prone to depression and indeed both types of synapse are encountered.

A major impetus for the accurate measurement of quantal parameters is that it may help determine the

locus of modulatory effects on synaptic transmission, or the site of action of a drug. A blocker of postsynaptic receptors, for example, will not alter the mini frequency or the number of quanta released, but will decrease the amplitudes of both spontaneous minis and the quantal components of evoked responses. A change in the loading of transmitter into a vesicle could cause a similar change. In contrast, a synaptic modulator that decreased Ca^{2+} channel opening or a blocker of those channels would decrease the probability of presynaptic release and be recognized as a decrease in quantal content, m. Many modulators of presynaptic transmission cause a parallel change in quantal content and in the frequency of spontaneous minis. This sort of analysis has been instrumental in understanding synaptic plasticity and in determining whether a given alteration occurs at the presynaptic terminal or the postsynaptic membrane.

The Standard Katz Model Does Not Always Apply

Incorrectly applying the Katz model and quantal analysis to synapses at which its assumptions do not hold has been a frequent source of error. Although a superb description of transmission at the neuromuscular junction, it is not uniformly applicable to central nervous system synapses, and the technical difficulties of isolating and accurately sampling the physiology of an individual synapse in the CNS can make the determination of quantal parameters exceptionally difficult.

In particular, five issues arise at CNS synapses with which the standard Katz model cannot deal adequately. These are *nonuniformity of quanta*, *nonuniformity of release sites*, *postsynaptic membranes that distort responses*, *saturation of receptors*, and *silent synapses*.

For quantal analysis to work, individual quanta should be roughly equivalent in size—that is, with the same amount of transmitter in each vesicle and with similar populations of receptors facing their release sites, as is true at the frog neuromuscular junction. But in the CNS, both vesicle content and receptor populations may differ widely, particularly where more than one synapse connects two cells. The resulting *nonuniformity of quanta* means that mini amplitudes will not have a normal distribution and will not sum to tidy peaks like those shown in Figure 7.7. Mini amplitude in the CNS can also be very hard to measure: the smallest events may be lost in the noise and the large variety of inputs converging on a postsynaptic cell makes it difficult to determine which responses derive from an individual presynaptic input. *Nonuniformity of release sites* can similarly prevent responses from falling in a simple binomial distribution. For example, the Ca channels at a nerve terminal may be of different isoforms or differentially phosphorylated and vesicles will therefore vary in their release probability depending on the channels closest to them. As evidence mounts that spontaneously fusing minis may arise from distinct vesicle pools and may activate different pools of receptors on postsynaptic cells, new questions arise as to whether the amplitude of spontaneous events can be used to infer the amplitude of the units underlying evoked responses.

Postsynaptic membranes that distort responses introduce another problem: the voltage-dependent properties of the postsynaptic cell and the particular electrical properties of dendritic spines can prevent vesicles from summing in a simple linear fashion. Equally problematic is the *saturation of receptors* on the postsynaptic membranes of many CNS synapses. A glutamatergic CNS synapse may have fewer than 100 receptors present, and if a single quantum activates most of these, it is impossible for quanta to sum linearly. Indeed, a major difference between some vertebrate CNS synapses and the neuromuscular junction is that the quantal amplitude often is determined not by the vesicle contents, but by the number of available receptors. In the extreme case of a developing synapse, the variation from impulse to impulse might depend as much on whether one, two, or three receptors were activated per vesicle fusion as whether one, two, or three vesicles fused.

Silent synapses represent an extreme form of the variability of postsynaptic responses and may be an important consideration for AMPA receptors at glutamatergic synapses (see Chapter 8). At these synapses, active zones may be secreting transmitter without producing a physiological response because no receptors are present in the postsynaptic membrane. These so-called silent synapses can spring to life when a set of receptors is inserted into the postsynaptic membrane in a concerted fashion. Because more active zones now are contributing to the detected physiological response, mini frequency will be higher and evoked release increased, although the quantal size will not have changed. Whereas the Katz model from the neuromuscular junction would consider these changes to be the hallmarks of a presynaptic change in release, the "un-silencing" of these CNS synapses is a postsynaptic event.

Thus, many of the requirements for the standard Katz model cannot realistically be expected to hold in all cases and the evidence that these simple probabilistic models are correct is far from compelling. However, despite the technical difficulties and theoretical caveats, the analysis of mini frequency, quantal size, quantal content, and synaptic probability has been the foundation of our description of synaptic transmission and the source of great insight into synaptic modulation.

It has been possible to augment this understanding with independent methods, including the ability to monitor vesicle fusion optically from the unloading of

the lipophilic dyes discussed earlier, and thereby to describe presynaptic activity without depending on the postsynaptic membrane to report the event. Another method of indirectly estimating release probability at glutamatergic synapses makes use of a blocker of NMDA receptors, MK-801, that will act only in the open state. From the rate of blockade during a train of stimuli, the probability of the channel having been opened by a given impulse can be inferred.

Summary

Quantal analysis has improved our understanding of biophysical and pharmacological mechanisms of transmission by describing normal transmission and by offering a tool to distinguish and characterize presynaptic and postsynaptic actions of drugs or endogenous agents that modify the strength of a synapse. Although these methods must be applied with caution, they yield a unique insight into the mechanisms of synaptic plasticity. The nature of transmission at CNS synapses can be quite different from what is encountered at the classical synapse of the neuromuscular junction.

SHORT-TERM SYNAPTIC PLASTICITY

Chemical synapses are not static transmitters of information. Their effectiveness waxes and wanes, depending on the frequency of stimulation and the history of prior activity. Because information processing in the nervous system in not conducted by individual action potentials at widely spaced intervals, this plasticity is of the utmost importance to the function of the synapse within its physiological circuit. At most synapses, repetitive high-frequency stimulation (called a *tetanus*) initially is dominated by a growth in successive PSP amplitudes, called synaptic *facilitation* (Fig. 7.8). This process builds to a steady state within about 1 s and decays equally rapidly when stimulation stops. Decay is measured by single test stimuli given at various intervals after a conditioning train. Facilitation does not require a train to be observed; at many synapses it can be seen after a single action potential. Thus, when two stimuli are given with very close spacing, the second one can be as much as twice the amplitude of the first. This is called *paired-pulse facilitation* (Fig. 7.8). At most synapses, a slower phase of increase in efficacy, which has a characteristic time constant of several seconds (called *augmentation*), succeeds facilitation. Finally, with prolonged stimulation, some synapses display a third phase of growth in PSP amplitude that lasts minutes (called *potentiation*). Potentiation often is visible in isolation only long after a tetanus and is thus called *posttetanic potentiation* (PTP).

Often, a phase of decreasing transmission, called synaptic *depression*, is superimposed on these processes (Fig. 7.8). Synaptic depression leads to a dip in transmission during repetitive stimulation, which often tends to overlap and obscure the augmentation and potentiation phases. At some synapses, it is manifest after only a single action potential and gives rise to *paired-pulse depression*.

Additional forms of use-dependent plasticity, called long-term potentiation and long-term depression (LTP and LTD), have received considerable attention as likely correlates of some forms of learning and are discussed elsewhere (Chapter 47). Most frequently, at synapses in which a quantal analysis has been done, all these forms of synaptic plasticity (except some forms of cortical LTP) are due to changes in the number of quanta released by action potentials.

The propensity to facilitation or depression can be quite different at different types of synapse and thus contributes to the diversity of synaptic communication and the flexibility of information processing by synapses. At a given synapse, the frequency and duration of a train can alter whether facilitation or depression is most in evidence. In a physiologically realistic setting of irregularly spaced stimuli, all these phenomena may be simultaneously at play and one or another may predominate for any given response, depending on the preceding history of stimulation. Thus, responses in the postsynaptic cell will be anything but a constant response to each action potential that comes along.

Synaptic Depression May Arise from Depletion of Readily Releasable Vesicles, Autoinhibition, or Receptor Desensitization

The rate at which synaptic depression develops usually depends on stimulation frequency. At many synapses, depression is relieved when transmission is reduced by lowering Ca^{2+} or raising Mg^{2+} in the medium—when little or no release occurs, there is little depression of the subsequent response. These characteristics are consistent with depression being due to the depletion of a readily releasable store of docked or nearly docked vesicles and recovery being due to their replenishment from a nearby supply (Fig. 7.9). The parameters of such a depletion model can be estimated from the rate of recovery from depression, which gives the rate of refilling the releasable store, and the fractional drop in PSPs given at short intervals, which gives the fraction of the releasable store liberated by each action potential.

As mentioned previously, synapses with a high probability of release from a relatively small pool of vesicles

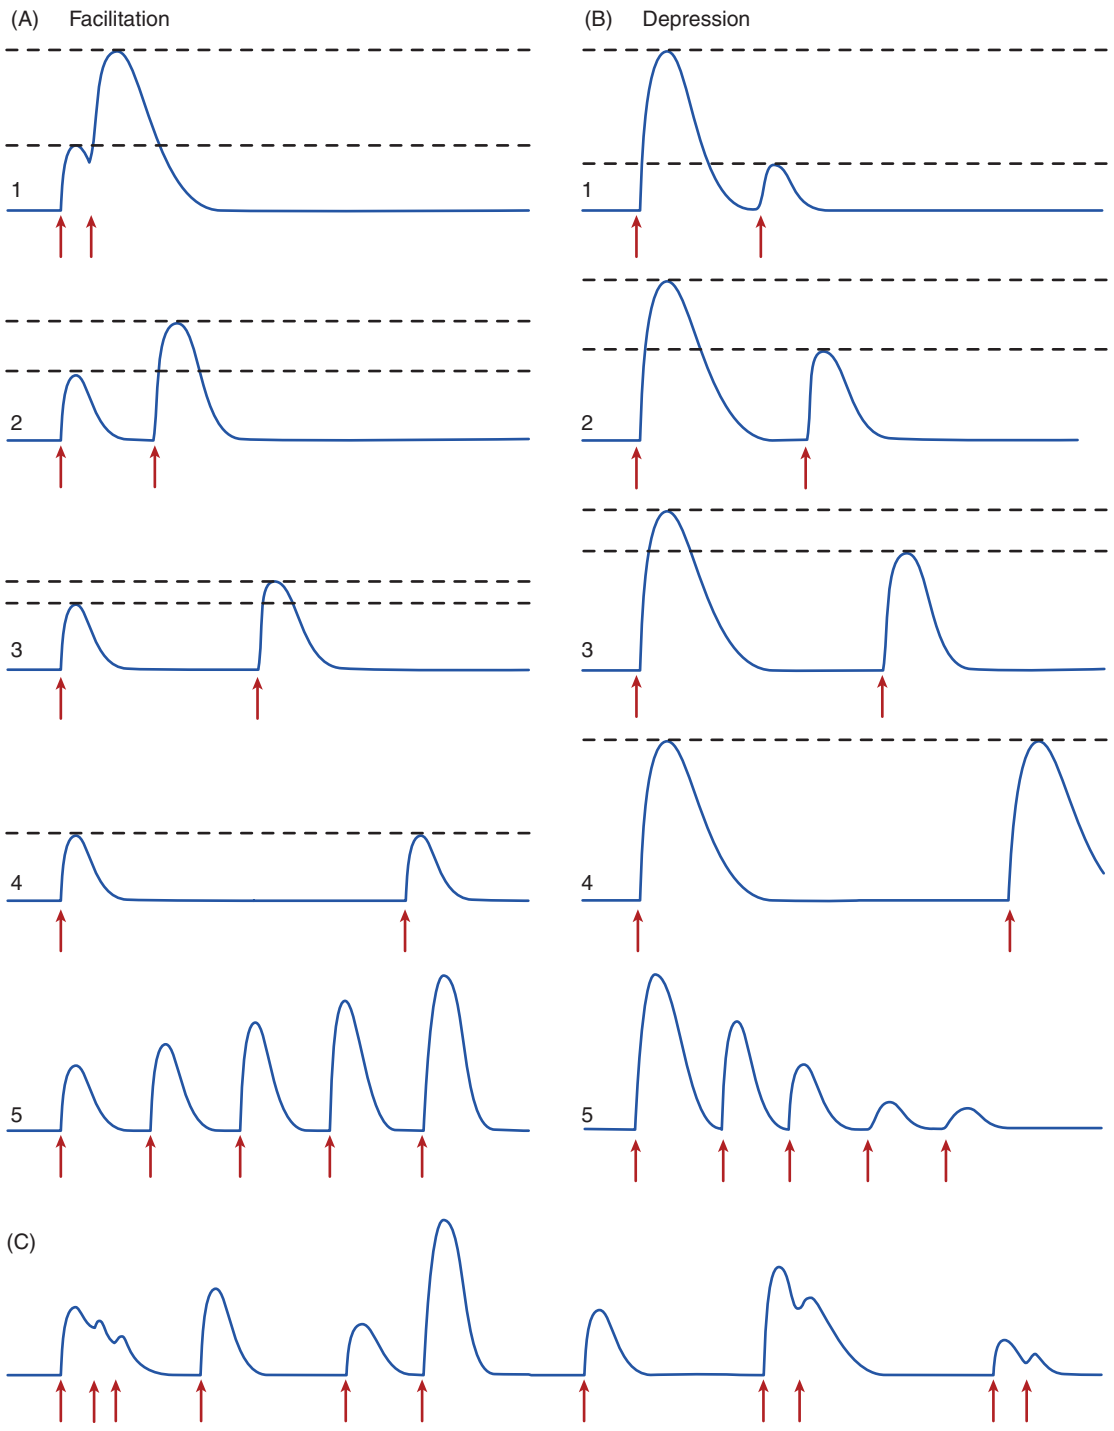

FIGURE 7.8 Short-term synaptic plasticity. (A) An idealized synapse in which facilitation predominates. Two stimuli (paired pulses) are given to the presynaptic nerve in each line and postsynaptic voltage responses are shown. Closely spaced stimuli (top line) facilitate strongly but as the interval between stimuli increases, the degree of facilitation diminishes. The fifth line illustrates how facilitation can accumulate during a train of stimuli. (B) An idealized synapse in which synaptic depression predominates. (C) At most synapses, both depression and facilitation occur and, depending on the nature of the individual synapse and the time course of facilitation, depression, augmentation, and potentiation, any of these phenomena may predominate at a given moment. Thus, in a realistic pattern of activity, with unevenly spaced action potentials arriving at a terminal, the strength of transmission can depend greatly on the previous history of the synapse.

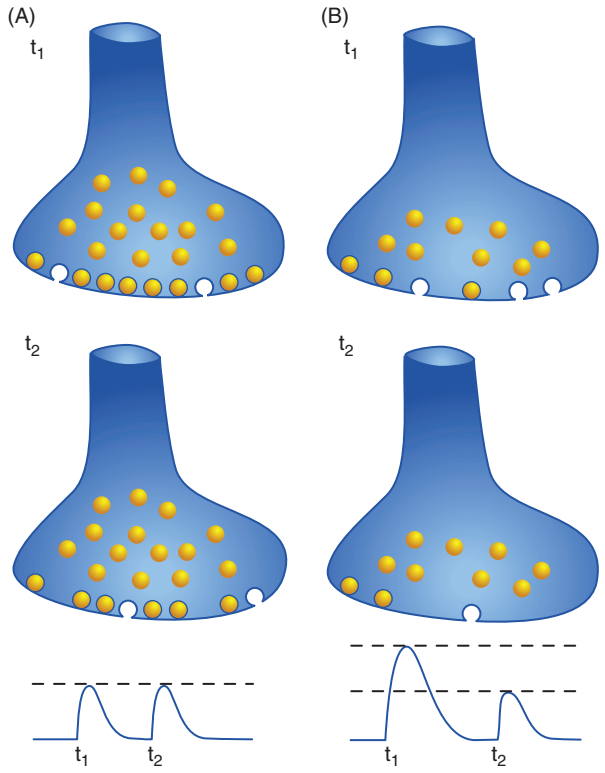

FIGURE 7.9 Depletion model of synaptic depression depicting the action of two stimuli (t_1 and t_2) that arrive so closely spaced that no vesicles have been recruited to the releasable pool to replace those that fused in response to the first stimulus. (A) A synapse in which the releasable pool (n) is large and the probability of fusion for a given vesicle (p) is low shows little or no depression. Because only a small fraction of the docked, releasable vesicles fused in response to the first stimulus, the second response is comparable in amplitude. (B) A synapse in which the releasable pool (n) is small but the probability of fusion (p) is high is likely to be strongly depressing. Vesicles released by the first impulse deplete half the fusion-competent pool, leaving n at t_2 equal to half its value at t_1. If p has not changed at t_2, the second stimulus will release half as many quanta.

will be the most prone to this form of depression (Fig. 7.9B). Recovery from this form of depression appears to be influenced by cytosolic Ca^{2+} as well, consistent with a hypothetical ability of elevated Ca^{2+} in the cytosol to enhance the recruitment of reserve vesicles to release sites.

Vesicle depletion cannot account for all forms of synaptic depression. At some synapses, depression is due to an inhibitory action of released transmitter on presynaptic receptors called autoreceptors. For example, in rat hippocampal cortex, the depression of GABA responses is blocked by antagonists of presynaptic $GABA_B$ receptors. Presumably, GABA acts to hyperpolarize nerve terminals and block transmitter release. At other synapses, desensitization of postsynaptic receptors contributes heavily to the observed depression; although the same amount of transmitter is released with each impulse, the postsynaptic receptors have a diminished ability to respond (Chapter 8).

Facilitation, Augmentation, and Potentiation Are Due to Effects of Residual Ca^{2+}

With few exceptions, all the phases of increased short-term plasticity are Ca^{2+}-dependent in the sense that little or no facilitation, augmentation, or potentiation is generated by stimulation in Ca^{2+}-free medium. Originally, these phases of increased transmission were thought to be due to the effect of residual Ca^{2+} remaining in active zones after presynaptic activity and summating with Ca^{2+} influx during subsequent action potentials to generate slightly higher peaks of Ca^{2+} (Katz & Miledi, 1968). Due to the highly nonlinear dependence of transmitter release on Ca^{2+}, a small residual amount could activate a substantial increase in phasic transmitter release during an action potential, while having only a small effect on mini frequency itself. However, as this relationship was examined more closely and with Ca^{2+} indicators to actually measure the residual intracellular Ca^{2+}, this hypothesis became unlikely. These findings led to the proposal that, in addition to summating with peak Ca^{2+} transients to drive fusion, Ca^{2+} acts to increase transmission at one or more targets distinct from the sites triggering exocytosis. Unlike the triggering site, the facilitation site for Ca^{2+} binding should be a high-affinity site that can be influenced by the relatively low levels of residual Ca^{2+}. Other second messenger systems and kinases may also be involved.

Potentiation lasts for a long period after a strong tetanus because residual Ca^{2+} is present for the duration of PTP, presumably due to overloading of the processes responsible for removing excess Ca^{2+} from neurons. These processes include Ca^{2+} extrusion pumps, such as plasma membrane ATPase and Na^{2+}-Ca^{2+} exchange, and Ca^{2+} uptake into organelles such as endoplasmic reticulum and mitochondria.

Summary

Short-term synaptic plasticity allows synaptic strength to be modulated as a function of prior activity and can cause large changes in responses during physiologically relevant patterns of stimulation. Synapses may show a decline in transmission (depression) or an increase in synaptic efficacy with time constants ranging from seconds (facilitation and augmentation) to minutes (potentiation or PTP) to hours (LTP); many synapses show a mixture of several of these phases. Synaptic depression may be due to depletion of a readily releasable supply of vesicles, to the inhibitory action of transmitter on presynaptic autoreceptors, or to the desensitization of postsynaptic receptors. Depression makes synapses selectively responsive to brief stimuli or to changes in level of activity. Frequency-dependent increases in synaptic efficacy are due to the effects of residual presynaptic Ca^{2+} acting to modulate the release process, probably through

a high-affinity binding site. These frequency-dependent increases in synaptic efficacy allow synapses to distinguish significant signals from noise and to respond to selected patterns of activity.

CHAPTER

8

Neurotransmitter Receptors

Chemical synaptic transmission plays a fundamental role in neuron-to-neuron and neuron-to-muscle communication and is mediated by receptors embedded in the plasma membrane. The cellular response is determined by which specific receptor(s) the transmitter binds, and the response can be either excitatory or inhibitory. This important feature of chemical synaptic transmission is termed *sign inversion* because excitation of one neuron in the circuit can cause inhibition of the follower neuron. The response magnitude is ultimately determined by receptor number, the "state" of the receptors, and the amount of transmitter released. Finally, the temporal and spatial summation of information conveyed by the activation of multiple receptors is the determinant of whether that neuron will fire an action potential or the muscle will contract. As one can see, there is remarkable flexibility and diversity in molding the response to neurotransmitter by constructing a synapse with the desired receptor types.

Two broad classifications exist for receptors: ionotropic and G-protein coupled (GPCR). An *ionotropic receptor* is a relatively large, multisubunit complex typically composed of four or five individual proteins that combine to form an ion channel through the membrane (Fig. 8.1A). In the absence of neurotransmitter, these ion channels exist in a closed state and are largely impermeable to ions. Neurotransmitter binding induces rapid conformational changes that open the channel, permitting ions to flow down their electrochemical gradients. Changes in membrane current resulting from ligand binding to ionotropic receptors generally are measured on a millisecond time scale. The ion flow ceases when the transmitter dissociates from the receptor or when the receptor becomes desensitized. In contrast, a GPCR is typically composed of a single polypeptide (Fig. 8.1B), although dimeric forms exist, and exerts its effects not through the direct opening of an ion channel but through binding to and activating GTP-binding proteins (G-proteins). Transmitters that activate GPCRs typically produce responses of slower onset and longer duration (from tenths of seconds to potentially hours) due to the series of enzymatic steps involved. However, faster responses can occur through actions of activated G-proteins, or their associated subunits, directly on ion channels.

IONOTROPIC RECEPTORS

All ionotropic receptors are membrane-bound protein complexes that form an ion-permeable pore in the membrane. By comparing the amino acid sequence of cloned ionotropic receptors, one can deduce that they are similar in overall structure, although two independent ancestral genes gave rise to two distinct families (Fig. 8.2). One family includes the nicotinic acetylcholine (Ach) receptor (nAChR), the γ-aminobutyric acid (GABA) receptor ($GABA_A$), the glycine receptor, and one subclass of serotonin (5-HT) receptor, the 5HT3 receptor. The other family comprises the set of ionotropic glutamate receptors (Hollmann & Heinemann, 1994; Traynelis et al., 2010).

The nAChR is a Heteromeric Protein Complex with Distinct Architecture

The nAChR is so named because the plant alkaloid nicotine can bind to the ACh-binding site and activate the receptor. The nAChR purified from the electric organ of *Torpedo* ray is composed of five subunits (Fig. 8.1A) and has a native molecular mass of approximately 290 kDa. The subunits are designated α, β, γ, and δ, and each receptor complex contains two copies of the α subunit. The subunits are homologous membrane-bound proteins that assemble in the bilayer to form a ring enclosing a

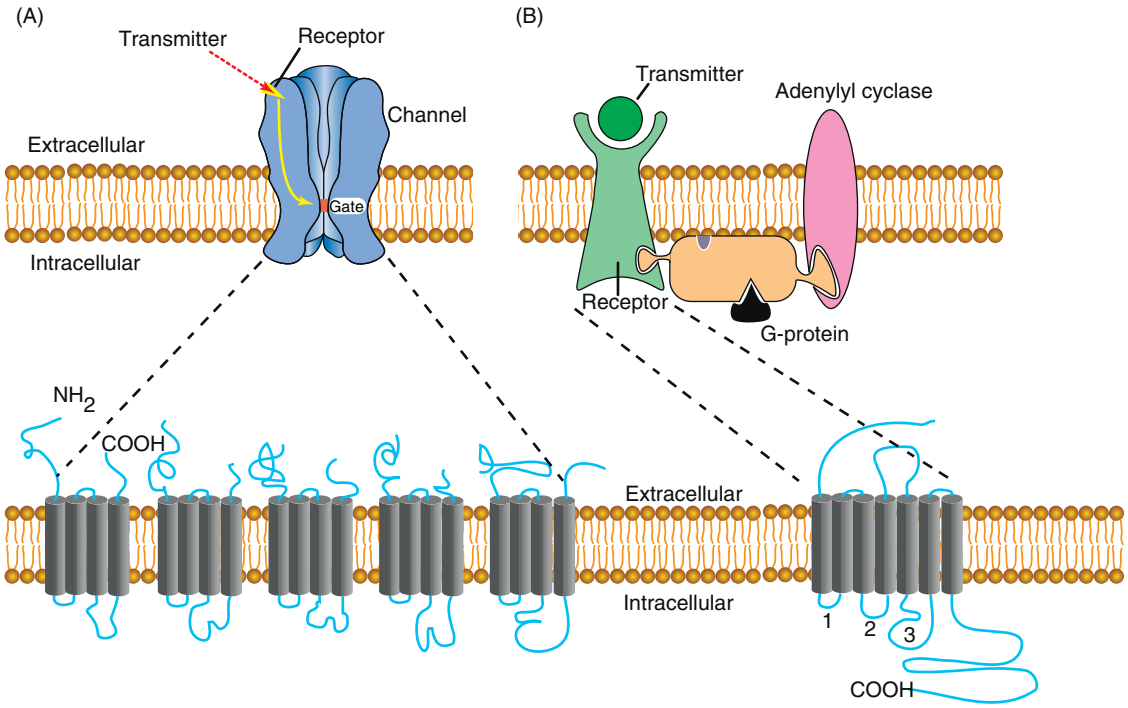

FIGURE 8.1 A comparison of the general structural features of ionotropic and G-protein couples receptors. (A) *Ionotropic receptors* bind transmitter, and this binding translates directly into the opening of the ion channel through a series of conformational changes. Ionotropic receptors are composed of multiple subunits. The five subunits that together form the functional nAChR are shown. Note that each of the nAChR subunits wraps back and forth through the membrane four times and that the mature receptor is composed of five subunits. (B) *G-protein coupled receptors* bind transmitter and, through a series of conformational changes, bind to G-proteins and activate them. G-proteins then activate enzymes such as adenylyl cyclase to produce cAMP. Through the activation of cAMP-dependent protein kinase, ion channels become phosphorylated, which affects their gating properties. GPCRs are single subunits or dimers. They contain seven transmembrane-spanning segments, with the cytoplasmic loops formed between the segments providing the points of interactions for coupling to G-proteins.

central pore. The extracellular domain of each subunit together forms a funnel-shaped opening that extends approximately 100 Å outward from the outer leaflet of the plasma membrane. The funnel at the outer portion of the receptor has an inside diameter of 20–25 Å. The funnel shape is thought to concentrate and force ions to interact with amino acids in the limited space of the pore without producing a major barrier to diffusion. This funnel narrows near the center of the lipid bilayer to form the domain of the receptor that determines the opened or closed state of the ion pore (Fig. 8.1). The intracellular domain of the receptor forms short exits for ions traveling into the cell and an entrance for ions traveling out of the cell. The intracellular domain also establishes the association of the receptor with other intracellular proteins that determine the subcellular localization of the nAChR.

Each nAChR Subunit Has Multiple Membrane-Spanning Segments

The primary structure of each nAChR subunit was obtained by the efforts of Shosaka Numa and colleagues. The deduced amino acid sequence from cloned mRNAs indicates that nAChR subunits range in size from 40 to 65 kDa. Each subunit consists of four transmembrane (TM)-spanning segments referred to as TM1–TM4 (Fig. 8.3A). Each segment is composed mainly of hydrophobic amino acids that stabilize the domain within the hydrophobic environment of the lipid membrane. The four TM domains are arranged in an antiparallel fashion, wrapping back and forth through the membrane. The N terminus of each subunit extends into the extracellular space, as does the loop connecting TM2 and TM3, as well as the C terminus (Fig. 8.3A). Amino acids linking TM1 and TM2 and those linking TM3 and TM4 form short loops that extend into the cytoplasm.

Structure of the Channel Pore Determines Ion Selectivity and Current Flow

In the model shown in Figure 8.3B and 8.3C, each subunit of the nAChR can be seen to contribute one cylindrical component (representing a membrane-spanning segment) that presents itself to a central cavity that forms the ion channel through the center of the complex. The membrane-spanning segments that line the pore are

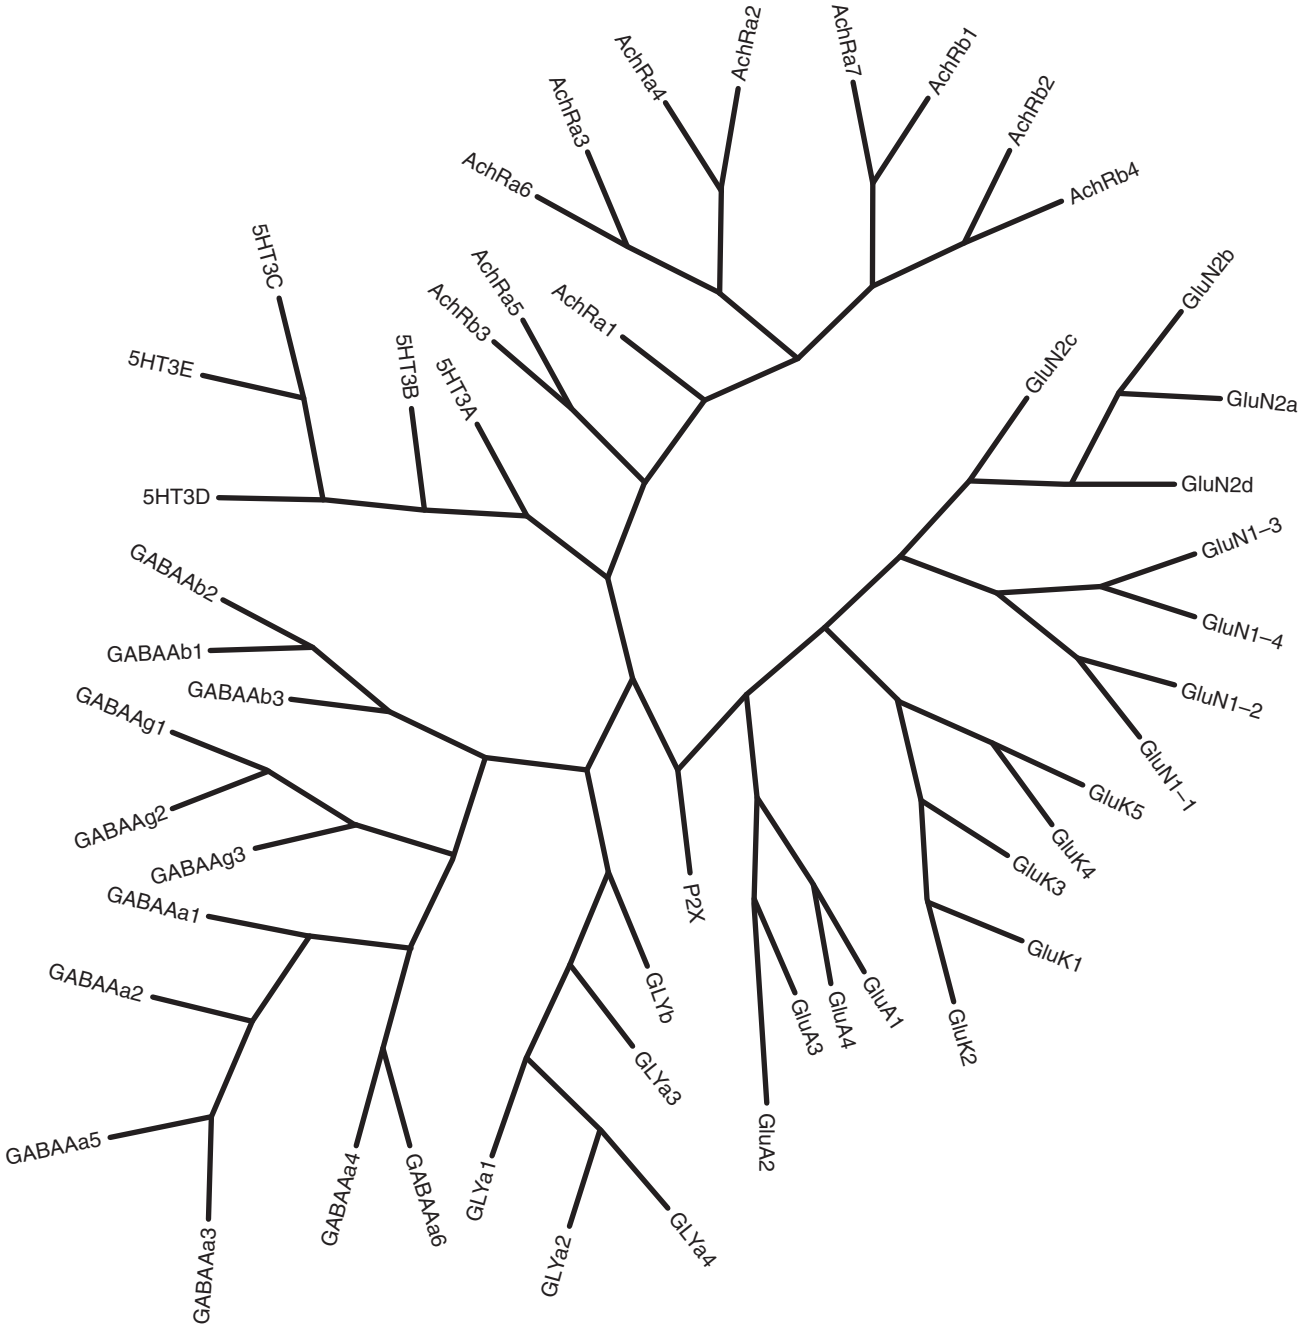

FIGURE 8.2 Evolutionary relationships of the ionotropic receptor family. The tree was constructed by aligning the protein sequences from each receptor family with the ClustalW program. Based on the alignment, the phylogenetic relationship was inferred with the maximum parsimony method and the tree was constructed using the Phylogeny Inference Package v 3.6 (distributed by J. Felsenstein, Department of Genome Sciences, University of Washington, Seattle, WA). Dr. Yin Liu (Department of Neurobiology and Anatomy, University of Texas Health Science Center-Houston, Houston, TX) kindly provided the phylogenetic tree and figure.

the five TM2 regions, one contributed by each subunit. The amino acids that compose the TM2 segment are arranged in such a way that three rings of negatively charged amino acids are oriented toward the central pore of the channel (Fig. 8.3A). These rings of negative charge appear to contribute to the selectivity filter of the channel, increasing the probability that only cations can pass through the pore. The nAChR is permeable to most cations, such as Na^+, K^+, and Ca^{2+}, although monovalent cations are preferred. The restricted physical dimensions of the pore—9–10 Å in the open state—contribute greatly to the selectivity for particular ions (Unwin, 1995, 2005). A coarse filtering that also influences selectivity appears to be a shielding effect produced by other negatively

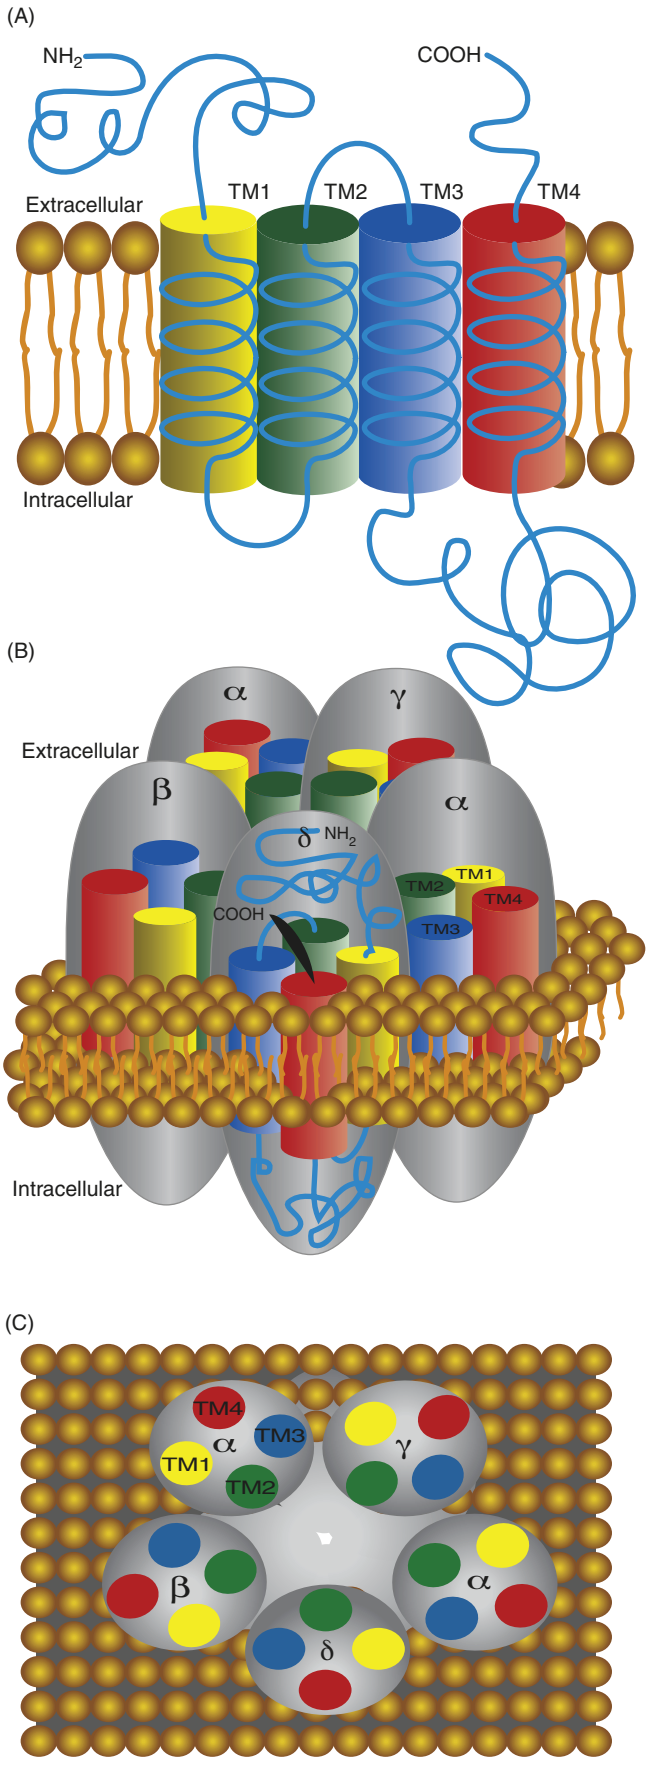

FIGURE 8.3 (A) Diagram highlighting the orientation of membrane-spanning segments of one subunit of the nAChR. The amino and carboxy termini extend in the extracellular space. The four membrane-spanning segments are designated TM1–TM4. Each forms an α helix as it traverses the membrane. (B) Side view of the five subunits in their approximate positions within the receptor complex. There are two α subunits present in each nAChR. (C) Top view of all five subunits highlighting the relative positions of their membrane-spanning segments, TM1–TM4, and the position of TM2 that lines the channel pore.

charged amino acids surrounding the outer channel region of the receptor. Collectively, these physical characteristics of the pore—together with the electrochemical gradient across the plasma membrane—determine the possibility and rate of ion movements. Thus, when the pore of the nAChR opens, anions are restricted from movement across the membrane, while positively charged cations move down their respective electrochemical gradients, resulting in an influx of Na^+ and Ca^{2+} and a small efflux of K^+.

Opening of the nAChR Occurs through Concerted Conformational Changes Induced by Binding of Two ACh Molecules

Each receptor complex has two ACh-binding sites that reside in the extracellular domain and are formed for the most part by six amino acids in α subunits; however, amino acids in both γ and δ subunits also contribute to binding. The two binding sites are not equivalent because of the asymmetry of the receptor produced by the different neighboring subunits (either γ or δ) adjacent to the α subunits. Significant cooperativity also exists within the receptor molecule, and so binding of the first molecule of ACh enhances binding of the second. When nAChR binds two molecules of ACh, the channel opens almost instantaneously (time constants for opening are approximately 20 μs), thus permitting the passage of ions. A model developed from electron micrographic reconstructions of the nicotine-bound form of the nAChR indicates that the closed-to-open transition is associated with a rotation of the TM2 segments (Fig. 8.4; Unwin, 1995, 2005). The TM2 segments are helical and exhibit a kink in their structure that forces a Leu residue from each segment into a tight ring that effectively blocks the flow of ions through the central pore of the receptor. When the TM2 segments rotate because of ACh binding, the kinks also rotate, relaxing the constriction formed by the Leu ring, and ions can then permeate through the pore. The rotation also orients a series of Ser and Thr residues (amino acids with a polar character) into the central area of the pore (compare Figs. 8.4B to 8.4C), which facilitates the permeation of water-solvated cations.

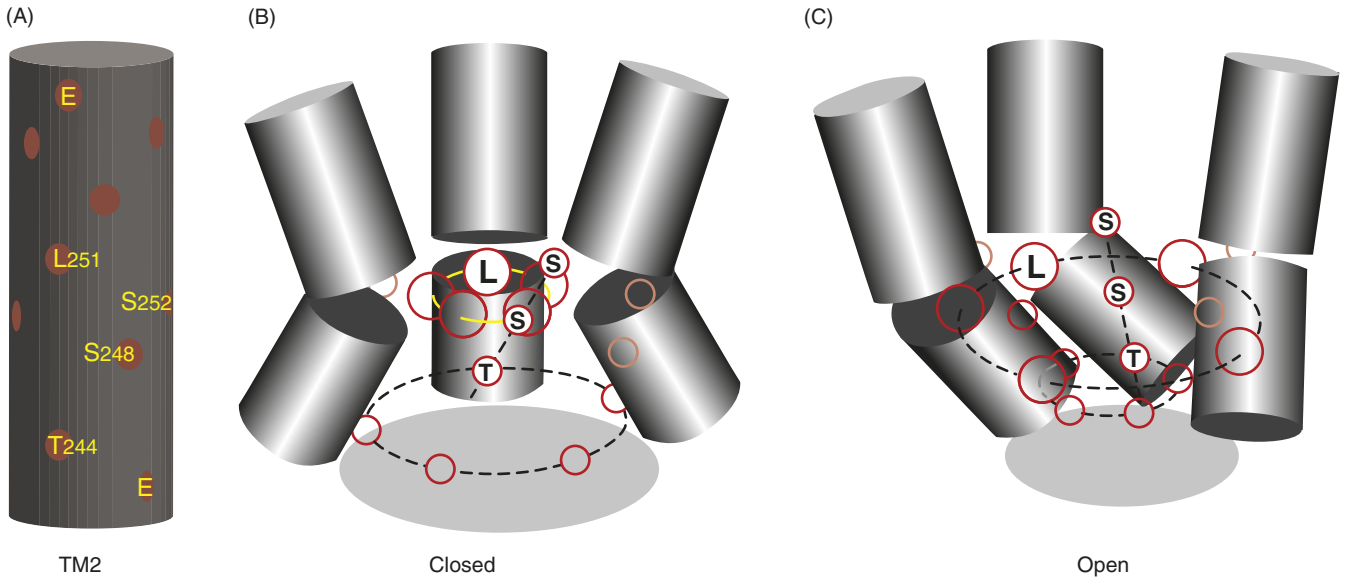

FIGURE 8.4 (A) Relative positions of amino acids in the TM2 segment of one of the nAChR *a* subunits modeled as an *a* helix. Glutamate residues (E) that form parts of the negatively charged rings for ion selectivity are shown at the top and bottom of the helix. (B) Arrangement of three of the five TM2 segments of the nAChR modeled with the receptor in the closed (ACh-free) configuration. In the closed configuration, leucine (L) residues form a right ring in the center of the pore that blocks ion permeation. (C) Arrangement of the three TM2 segments after ACh binds to the receptor. In the open configuration, construction formed by the ring of leucine (L) residues opens as the helices twist about their axes. Note that polar serine (S) and threonine (T) residues align when ACh binds, which apparently help the water-solvated ions travel though the pore. *Adapted from Unwin (1995).*

The Muscle Form of the nAChR is Very Similar to the nAChR from *Torpedo*

nAChRs at the neuromuscular junction are a concentrated collection of homogeneous receptors having a structure similar to that of the *Torpedo* electric organ. This similarity is not surprising because the electric organ is a specialized form of muscle tissue. The adult form of the muscle receptor has the pentameric structure $\alpha_2\beta\varepsilon\delta$ and is highly similar in structure to the nAChR from *Torpedo*. An embryonic form of the muscle receptor has an analogous structure, except that the ε subunit is replaced by a unique γ subunit. The embryonic and adult subunits of both mouse and bovine muscle receptors have been cloned and expressed and the receptors differ in both channel kinetics and channel conductance. These differences in channel properties that occur due to subunit swapping appear to be necessary for the proper function of the nAChRs during the transition from developing to mature neuromuscular junction synapses.

The nAChR Has Well-Ordered Assembly, is Post-translationally Modified, and is Concentrated and Anchored in the Postsynaptic Membrane

The pathway of nAChR assembly in muscle is a tightly regulated process. The five subunits of the nAChR have the potential to assemble randomly into 208 different combinations. Nevertheless, in vertebrate muscle, only one of these configurations ($\alpha_2\beta\varepsilon\delta$) is typically found in mature tissue, indicating a very high degree of coordinated assembly and, ultimately, little structural variability. The well-ordered assembly takes place within the endoplasmic reticulum, and during intracellular maturation, each subunit is glycosylated. Two highly conserved disulfide bonds in the *N*-terminal extracellular domain are essential for efficient assembly of the mature receptor. The first is between two adjacent Cys residues that reside very close to the ACh-binding site on the receptor. The second bond is between two Cys residues 15 amino acids apart, forming a loop that is spatially adjacent to the TM domains of the native receptor. This "Cys loop" is a structural signature of this family of receptors and is also found in the $GABA_A$ receptor, the glycine receptor, the 5HT3 receptor, and two members of the purinergic receptors.

Many ionotropic receptors, such as the nAChR, are phosphorylated, although the functional significance of the phosphorylation is not always evident. The nAChR is phosphorylated by at least three protein kinases. cAMP-dependent protein kinase (PKA) phosphorylates the γ and δ subunits, Ca^{2+}/phospholipid-dependent protein kinase (PKC) phosphorylates the δ subunit, and an unidentified tyrosine kinase phosphorylates the β, γ, and δ subunits. The phosphorylation sites are all found in the intracellular loop between TM3 and TM4

membrane-spanning segments. Phosphorylation by these three protein kinases increases the rate of desensitization of the receptor. Desensitization of receptors is common, and this process limits the amount of ion flux through a receptor by producing transitions into a closed state (one that does not permit ion flow) in the continued presence of neurotransmitter. For the nAChR, the rate of desensitization has a time constant of approximately 50–100 ms.

nAChRs are highly concentrated at the neuromuscular junction that ensures rapid and reliable communication between the presynaptic motor neuron and postsynaptic muscle cell to induce contraction (Fig. 8.5). The clustering of nAChRs begins during development, and is mediated in part by the release of agrin from the motor neuron that binds to a tyrosine kinase in the postsynaptic membrane called MuSK (Willmann & Fuhrer, 2002). MuSK activation recruits members of the Src family of kinases that phosphorylates the nAChR, leading to increased interactions with a multitude of postsynaptic signaling complexes ultimately leading to the recruitment of rapsyn. Rapsyn is a multidomain protein that binds directly to cytoplasmic tails of the nAChR subunits along with other proteins, including itself. Rapsyn thus forms the critical scaffolding function that clusters nAChRs at the NMJ. In addition to the nAChR, rapsyn binds to other important muscle proteins including MuSK and the dystrophin/utrophin glycoprotein complex (dystrophin is the molecule that when mutated leads to certain types of muscular dystrophy). Activity of the nAChR itself is also critical for its stabilization at the neuromuscular junction. For example, the lifetime of the nAChR at the junction decreases from 14 d to less than a day following block of the receptor with α-bungarotoxin. The interplay of signals coming from the presynaptic motor neuron is integrated by the postsynaptic receptors to concentrate and stabilize AChRs at the neuromuscular junction.

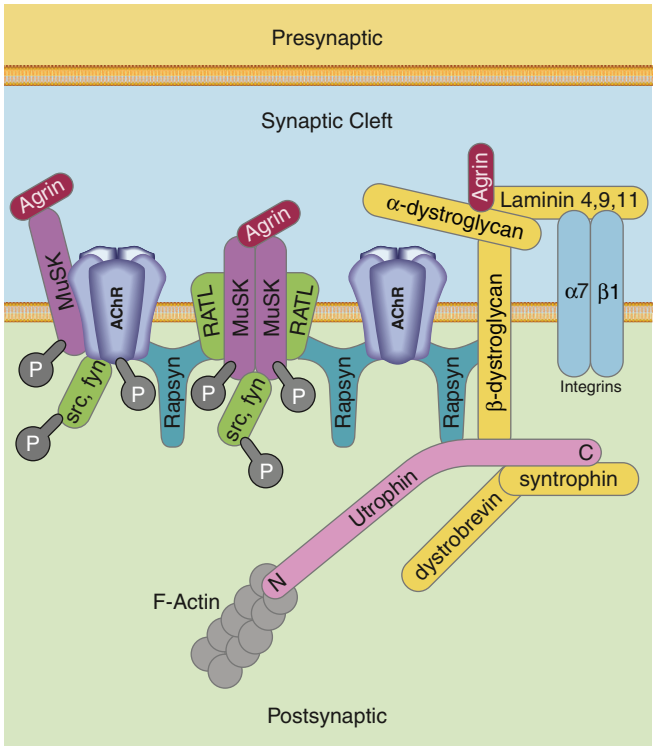

FIGURE 8.5 Diagram of nAChR clustering at the neuromuscular junction. Rapysn is a major anchoring protein at the neuromuscular junction that binds to itself and to the nAChR that concentrates and stabilizes nAChRs. The development and stabilization of the neuromuscular junction is mediated by a number of signaling cascades, only a few of which are shown. For example, agrin released from the presynaptic motor neuron binds to a number of proteins associated with the postsynaptic membrane including the tyrosine kinase MuSK (muscle specific kinase). MuSK activation by agrin recruits and activates the soluble tyrosine kinases src and fyn that further modify a number of proteins. RATL (rapsyn associated linker protein) is a membrane-bound protein that binds to both MuSK and to rapsyn to anchor MuSK at the neuromuscular junction. Agrin also interacts with the dystroglycans that make up the dystrophin complex important for the maintenance of the neuromuscular junction. Rapsyn also binds to the utrophin complex that anchors the overlying protein complex to the actin cytoskeleton. *Adapted from Willmann and Fuhrer (2002).*

Neuronal nAChRs Contain Two Types of Subunits and Their Assembly Leads to Functional Diversity

Neuronal nAChRs are similar yet distinct in structure to the *Torpedo* isoform of the receptor. For example, the neuronal nAChR is composed of only two types of subunits, α and β, which combine to produce the functional receptor, and the majority of these receptors do not bind to α-bungarotoxin. At least ten different α subtypes (α1 being the muscle α subunit) have been identified (see Fig. 8.2 for comparisons), and some are species-specific (α8 is found only in chicken and α9 is found only in rat). Four different β subtypes (β1 being the muscle β subunit) have been identified. The neuronal β subunits are distantly related to the muscle β1 subunit and sometimes are referred to simply as non-α subunits. All the α and β genes encode proteins with four transmembrane-spanning segments, and although the physical structure of this receptor family has not been well characterized, it appears that each functional receptor is a pentameric assembly.

Neuronal nAChRs have diverse functions and are the receptors presumed to be responsible for the psychophysical effects of nicotine addiction. One major function of nAChRs in the brain is to modulate excitatory synaptic transmission through a presynaptic action. The diversity in function of nAChRs can be related to the

heterogeneous structure contributed by the thousands of possible combinations between the different α and β subunits. Functional neuronal nAChRs can be assembled from a single subunit (e.g., $\alpha 7$, $\alpha 8$, or $\alpha 9$), or a single type of α subunit can be assembled with multiple types of β subunits (e.g., $\alpha 3$ with $\beta 2$ or $\beta 4$ or both) and vice versa. The mammalian high affinity nicotine-binding receptor appears to be formed by the $\alpha 4$ and $\beta 2$ subunits. These subunit-mixing possibilities produce a staggering array of potential receptor molecules, each with distinct properties, including differences in single-channel kinetics and rates of desensitization. It is also now established that subunit composition plays important roles in targeting the receptors to different intracellular locations.

Neuronal nAChRs exhibit a range of single-channel conductance between 5 and 50 pS, depending on the tissue or the specific subunits expressed. All the neuronal nAChRs are cation-permeable channels that, in addition to permitting the influx of Na^+ and the efflux of K^+, permit an influx of Ca^{2+}. The Ca^{2+} permeability for neuronal nAChR is greater than that for the muscle nAChR and is variable among the different neuronal receptor subtypes. Indeed, some receptors have very high Ca^{2+}/Na^+ permeability ratios; for example, $\alpha 7$ nAChRs exhibit a Ca^{2+}/Na^+ permeability ratio of nearly 20, whereas other neuronal isoforms exhibit Ca^{2+}/Na^+ permeability ratios of about 1.0–1.5. The Ca^{2+} permeability of the $\alpha 7$ nAChR can be eliminated by the mutation of a single amino acid residue in TM2 (Glu-237 for Ala) without significantly affecting other aspects of the receptor. This key Glu residue presumably lies at a critical position within the pore of the receptor and enhances the passage of Ca^{2+} ions through an interaction with its negatively charged side chain. Activation of $\alpha 7$ receptors through the binding of ACh therefore could produce a significant increase in the level of intracellular Ca^{2+} without the opening of voltage-gated Ca^{2+} channels. Subunits $\alpha 7$, $\alpha 8$, and $\alpha 9$ are also the α-bungarotoxin-binding subtypes of neuronal nAChRs.

For the nAChR from muscle, desensitization is minor and probably is not of physiological significance in determining the shape of the synaptic response at the neuromuscular junction. However, for some neuronal nAChRs, desensitization plays a major role in determining the effects of the actions of ACh. Receptors composed of $\alpha 7$, $\alpha 8$, and certain α/β combinations exhibit desensitization time constants of between 100 and 500 ms, whereas others exhibit desensitization constants between 2 and 20 s. Rapid desensitization eliminates that receptor from contributing to synaptic responses until the process is reversed. Given the diverse functions of neuronal nAChRs, the variable rates of desensitization likely play important roles whereby this inherent property of the receptor shapes the physiological response generated from binding ACh.

One Serotonin Receptor Subtype, 5-HT3, is Ionotropic and is a Close Relative of the nAChR

5-HT historically is thought to activate GPCRs (described in more detail later). The 5-HT3 subclass is an exception forming an ionotropic receptor activated by binding 5-HT. 5-HT3 receptors are distributed sparsely on primary sensory nerve endings in the periphery and are also distributed widely in the mammalian CNS. The 5-HT3 receptor is clinically significant because antagonists of 5-HT3 receptors have important applications as antiemetics, anxiolytics, and antipsychotics.

The 5-HT3 receptor is permeable to Na^+ and K^+ ions and is similar in many ways to the nAChR (see evolutionary tree; Fig 8.2) in that both desensitize rapidly and are blocked by tubocurarine. The 5-HT3 receptor is a homomeric complex composed of five copies of the same subunit. Each protein subunit is 487 amino acids long (56 kDa) and has a structure most analogous to the $\alpha 7$ subtype of neuronal nAChRs, which also forms a homo-oligomeric receptor. The 5-HT3 receptor is mostly impermeable to divalent cations. For example, Ca^{2+} is largely excluded from permeation and in fact effectively blocks current flow through the pore, even though the pore size of the channel (7.6 Å) is approximately the same as that for the nAChR (8.4 Å). Apparently, other physical or electrochemical barriers limit the capacity of divalent ions to permeate the 5-HT3 pore. Dose–response studies indicate that at least two ligand-binding sites must be occupied for the channel to open; however, the binding of agonist and/or opening of the channel appears to be approximately 10 times slower than for most other ligand-gated ion channels. The functional significance or physical explanation of this slow opening is not known. The native 5-HT3 receptor also exhibits desensitization (time constant 1–5 s), although the reported desensitization rate varies widely, depending on the methodology used for analysis and the source of receptor. Interestingly, this desensitization can be significantly slowed or enhanced by single amino acid substitutions at a Leu residue in the TM2 segment of the subunit.

$GABA_A$ Receptors Are Related in Structure to nAChRs but Exhibit an Inhibitory Function

Synaptic inhibition in the mammalian brain is mediated principally by GABA receptors. The most widespread ionotropic receptor activated by GABA is designated $GABA_A$. The subunits composing the $GABA_A$ receptor have sequence homology with the nAChR subunit family, and the two families have presumably diverged from a common ancestral gene. The evolutionary relationship of these two receptor families can be appreciated in Fig. 8.2. The $GABA_A$ receptor is composed of multiple subunits, forming a heteropentameric complex

of approximately 275 kDa. Seven different types of subunits are associated with $GABA_A$ receptors and are designated α, β, γ, δ, ε, π and θ. An additional subunit, ρ, is found predominantly in the retina, whereas the other subunits are distributed widely in the brain. Each subunit group also has different subtypes (see Fig 8.2); for example, six different α, three β, three γ, and two other ρ subunits have also been identified. The predicted amino acid sequences indicate that each of these subunits has a molecular mass ranging between 48 and 64 kDa. Like neuronal nAChR, these subunits mix in a heterogeneous fashion to produce a wide array of $GABA_A$ receptors with different pharmacological and electrophysiological properties. The predominant $GABA_A$ receptor in brain and spinal cord is α1, β2, and γ2, with a stoichiometry of two α1s, two β2s, and one γ2. Expression of subunit cDNAs in oocytes indicates that the α subunit is essential for producing a functional channel. The α subunit also appears to contain the high-affinity binding site for GABA.

The ion channel associated with the $GABA_A$ receptor is selective for the anion Cl^-, and the selectivity is provided by amino acid residues strategically positioned in the TM2 near the ends of the pore. When GABA binds to and activates this receptor, Cl^- flows into the cell, producing a hyperpolarization by moving the membrane potential away from the threshold for firing an action potential. The neuronal $GABA_A$ receptor exhibits multiple conductance levels, with the predominant conductance being 27–30 pS.

The $GABA_A$ Receptor Binds Drugs That Affect Its Properties

The $GABA_A$ receptor is an allosteric protein and the binding of a number of compounds modulates its properties. Two well-studied examples are barbiturates and benzodiazepines, both of which bind to the $GABA_A$ receptor and potentiate GABA binding, although they do this by binding to distinct sites. Benzodiazepines produce effects by increasing the frequency of channel opening, while barbiturates prolong channel burst durations. The net result is that in the presence of barbiturates, benzodiazepines, or both, the same concentration of GABA will cause increased inhibition by increasing the amount of Cl^- influx leading to increased hyperpolarization. Benzodiazepine binding is conferred on the receptor by the γ subunit, but the presence of α and β subunits is necessary for the qualitative and quantitative aspects of benzodiazepine binding. The benzodiazepine-binding site appears to lie along the interface between α and γ subunits and only certain subtypes are sensitive to benzodiazepines. Benzodiazepine binding to $GABA_A$ receptors requires α2 or α5 and γ2 or γ3; other subunit combinations are insensitive to benzodiazepines.

Picrotoxin, a potent convulsant compound, binds within the channel pore of the $GABA_A$ receptor and prevents ion flow. Single-channel experiments indicate that picrotoxin either slowly blocks an open channel or prevents the GABA receptor from undergoing a transition into a long-duration open state. Apparently, barbiturates produce similar changes in channel properties, but they potentiate rather than inhibit $GABA_A$ receptor function. Bicuculline, another potent convulsant, appears to inhibit $GABA_A$ receptor channel activity by decreasing the binding of GABA to the receptor. Steroid metabolites of progesterone, corticosterone, and testosterone also have potentiating effects on GABA currents that are similar in many ways to the action of barbiturates; however, the binding sites for steroids and barbiturates are distinct. Finally, penicillin directly inhibits GABA receptor function, apparently by binding within the pore.

The physiological effects of compounds such as picrotoxin, bicuculline, and penicillin are striking. Each of these compounds at a sufficiently high concentration can produce widespread and sustained seizure activity. Conversely, many, but not all, of the sedative properties associated with barbiturates and benzodiazepines can be attributed to their ability to augment inhibition in the brain through enhancing the inhibitory potency of GABA.

Interestingly, ρ-subunit-containing GABA receptors, found in abundance in the retina, are pharmacologically unique. They are resistant to the inhibitory action of bicuculline, although they remain sensitive to blockage by picrotoxin. In addition, these retinal receptors are not sensitive to modulation by barbiturates or benzodiazepines. Thus, ρ-containing receptors are distinct from $GABA_A$ receptors and are similar to receptors earlier designated $GABA_C$.

The Glycine Receptor is Closely Related to the $GABA_A$ Receptor

Glycine receptors are the major inhibitory receptors in the spinal cord and the brain stem. Glycine receptors are similar to $GABA_A$ receptors in that both are ion channels selectively permeable to the anion Cl^-. As one would anticipate, they both lie on the same main branch of the evolutionary tree of ionotropic receptors (Fig. 8.2) Interestingly, only three amino acid replacements in the TM1-TM2 loop and the TM2 segment can change the selectivity of the glycine receptor from anionic to cationic, pointing again to the critical nature of residues in the TM2 segment in determining a receptor's ion selectivity. The overall structure of the glycine receptor is indicative of this similarity in properties. The native complex is approximately 250 kDa and is composed of

two main subunits: α (48 kDa) and β (58 kDa). The receptor appears to be pentameric, most likely composed of three α and two β subunits. The glycine receptor has an open channel conductance of approximately 35–50 pS, similar to that of the $GABA_A$ receptor. The rat poison strychnine is a potent antagonist of the glycine receptor.

Four distinct α subunits and one β subunit of the glycine receptor have been cloned and are highly related (Fig. 8.2). Each exhibits the typical predicted four TMs and is approximately 50% identical to the others at the amino acid level. Expression of a single α subunit in oocytes is sufficient to produce functional glycine receptors, indicating that the α subunit is the pore-forming unit of the native receptor. β subunits play exclusively modulatory roles, affecting, for example, sensitivity to the inhibitory actions of picrotoxin. They are widespread in the brain but not always found in neurons expressing α subunits, suggesting β subunits may serve other functions independent of their association with glycine receptors.

The $GABA_A$ and Glycine Receptor Cluster at Synapses

During maturation of inhibitory synapses, gephyrin is found beneath the postsynaptic membrane and recruits and localizes $GABA_A$ or glycine receptors. Gephyrin appears to serve an analogous function for the stabilization of inhibitory receptors that rapsyn plays for nAChRs (Fig 8.5). Gephyrin is a multidomain protein that interacts with the cytoplasmic domains of the $GABA_A$ or glycine receptor subunits. Like rapsyn, gephyrin interacts with itself and other proteins in addition to the inhibitory receptors and these interactions serve to restrict the lateral mobility of $GABA_A$ and glycine receptors in the plasma membrane. Ultimately these interactions promote the formation of postsynaptic inhibitory specializations.

Certain Purinergic Receptors Are Also Ionotropic

Purinergic chemical transmission is distributed throughout the body and is considered in greater detail in a later section on GPCRs. Purinergic receptors bind to ATP (or other nucleotide analogs) or its breakdown product adenosine (Junger, 2011). ATP is released from certain synaptic terminals in a quantal manner and often is packaged within synaptic vesicles containing another neurotransmitter, the best described being ACh and catecholamines.

One class of ATP-binding purinergic receptors (P2X) has been discovered to be ionotropic, and there are at least seven members of this class (P2X1–P2X7). Note that the P2X receptors reside between the GABA/glycine and the glutamate family of ionotropic receptors on the evolutionary tree (Fig. 8.2). P2X receptors most often mediate a fast depolarizing response in neurons and muscle cells in response to ATP or other nucleotides by the direct opening of relatively nonselective cation channels. cDNAs encoding the P2X receptor indicate that its structure comprises only two transmembrane domains, with some homology in its pore-forming region with K^+ channels and the functional receptors seemed to be composed of three subunits in contrast to five for the nAChR. The P2X7 receptor is also a ligand-gated channel that permits permeation of either anions or cations and even molecules as large as 900 Da in the presence of high (millimolar) nucleotide levels.

Glutamate Receptors Are Derived from a Different Ancestral Gene and Are Structurally Distinct from Other Ionotropic Receptors

Glutamate receptors are widespread in the nervous system, where they are responsible for mediating the vast majority of excitatory synaptic transmission in the brain and spinal cord. Four agonists serve to distinguish different types of glutamate receptors; *N*-methyl-D-aspartate (NMDA), amino-3-hydroxy-5-methylisoxazolepropionic acid (AMPA), kainate, and quisqualate (Hollmann & Heinemann, 1994; Watkins, Krogsgaard-Larsen, & Honore, 1990). A convenient distinction for describing ionotropic glutamate receptors has been to classify them as either NMDA or non-NMDA subtypes, depending on whether they bind the agonist NMDA. Non-NMDA receptors also bind the agonist kainite or AMPA. Both NMDA and non-NMDA receptors are ionotropic. Quisqualate is unique within this group of agonists in having the capacity to activate both ionotropic and GPCR glutamate receptor subtypes (mGluRs; Hollmann & Heinemann, 1994). The nomenclature describing members of the glutamate receptor family has undergone transitions over the years but appears to have converged; receptors binding AMPA are termed GluA1–GluA4; those binding kainate are GluK1–GluK5 and those binding NMDA are GluN1, GluN2A–GluN2D, and GluN3A–GluN3B; and those that activate G-proteins are designated mGluR1–mGluR8 (Traynelis et al., 2010). A family tree highlighting the evolutionary relationship of the glutamate receptors between themselves and other members of the ionotropic receptor family is shown in Figure 8.2.

Non-NMDA Receptors Are a Diverse Family

The initial glutamate receptor clone was termed GluR-K1, and the cDNA encoded a protein with an estimated molecular mass of 99.8 kDa (Hollmann,

O'Shea-Greenfield, Rogers, & Heinemann, 1989). Not long after this original report, several groups (Boulter et al., 1990; Keinanen et al., 1990; Nakanishi, Shneider, & Axel, 1990) independently reported the isolation of families of glutamate receptor subunits, now termed GluA1–GluA4, GluK1–GluK5, and GluD1 and GluD2. Each GluR subunit consists of approximately 900 amino acids and has four predicted membrane-spanning segments (TM1–TM4);

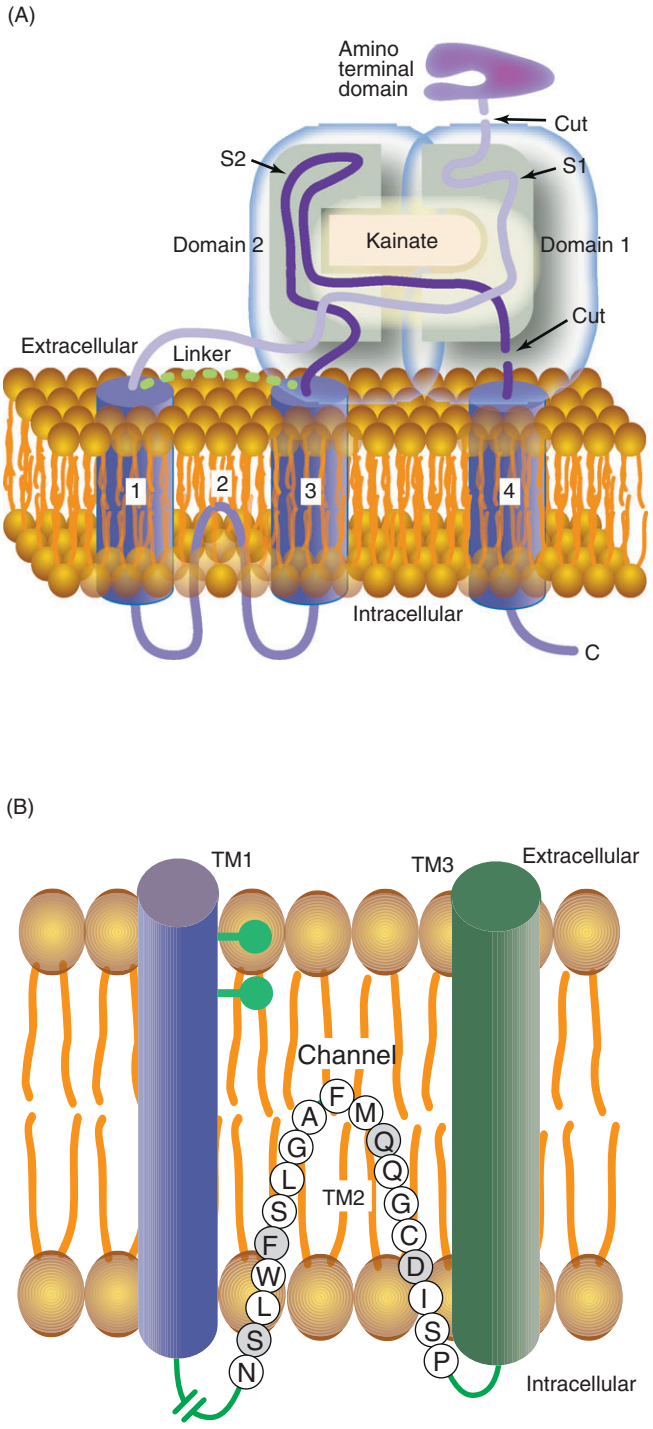

FIGURE 8.6 (A) Model of one of the subunits of the ionotropic glutamate receptor. Ionotropic glutamate receptors have four membrane-associated segments; however, unlike nAChR, only three of them completely traverse the lipid bilayer. TM2 forms a loop and exits back into the cytoplasm. This leaves the large N-terminal region extending into the extracellular space, whereas the C terminus extends into the cytoplasm. Two domains in the extracellular segments associate with each other to form the binding site for transmitter, in this example kainate, a naturally occurring agonist of glutamate. (B) Enlarged area of the predicted structure and amino acid sequence of the TM2 region of the glutamate receptor, GluR3. TM1 and TM3 are drawn as cylinders in the membrane flanking TM2. The residue that determines Ca^{2+} permeability of the non-NMDA receptor is the glutamine residue (Q) highlighted in gray. In NMDA receptors, an asparagine residue at this same position is the proposed site of interaction with Mg^{2+} ions that produce the voltage-dependent channel block. Serine (S) and phenylalanine (F), also shaded in gray, are highly conserved in the non-NMDA receptor family. The aspartate (D) residue is also conserved and is thought to form part of the internal cation-binding site. The break in the loop between TM1 and TM2 indicates a domain that varies in length among ionotropic glutamate receptors. *Adapted from Wo and Oswald (1995).*

however, there is an important distinction in the TM2 domain, making the GluRs distinct from the nAChR family (Figs. 8.6A and 8.6B). Native GluRs are tetrameric, as opposed to the pentameric nAChR family of receptors, and have approximate molecular mass of 600 kDa making them almost twice the size of the nAChR, mostly because of the large extracellular domain where glutamate binds.

Unique Properties of Non-NMDA Receptors Are Determined by Assembly of Different Subunits

When cDNAs encoding these receptors were expressed in either oocytes or HeK-293 cells, application of the non-NMDA receptor agonist AMPA produced substantial inward currents. A striking observation from these expression studies was that when the GluA2 subunit was expressed alone, little stimulated current was obtained, unlike the large currents found when either GluA1 or GluA3 was expressed (Nakanishi et al., 1990; Verdoorn et al., 1991). GluA2 subunits by themselves appear to form poorly conducting receptors. However, when GluA2 is expressed with either GluA1 or GluA3, the behavior of the heteromeric receptor is distinctly different. When GluA1 and GluA3 are expressed alone or together, they produce channels with strong inward rectification. Coexpression of GluA2 with either GluA1 or GluA3 produces a channel with little rectification. Further analyses indicated that GluA1 and GluA3 expressed channels were permeable to Ca^{2+} (Hollmann & Heinemann, 1994). In contrast, any combination of receptor that included the GluA2 subunit produced channels impermeable to Ca^{2+}. The replacement of a single amino acid (Arg for Gln) in TM2 of the GluA2 subunit (see Fig. 8.6B for identification of this amino acid) was shown to control Ca^{2+}-permeability

(Burnashev et al., 1992). Apparently, an Arg at this position blocks Ca^{2+} from traversing the pore formed in the center of the GluR channel.

Functional Diversity in GluRs is Produced by mRNA Splicing and RNA Editing

Analysis of mRNAs encoding GluR subunits indicated that each could be expressed in one of two splice variants, termed flip and flop. These flip and flop modules are small segments (38 amino acids) just preceding the TM4 domain in all four GluA subunits. The receptor channel expressed from these splice variants has distinct properties, depending on which of the two modules is present. Specifically, flop-containing receptors desensitize more during glutamate application. Therefore, GluAs with flop modules express smaller steady-state currents than GluAs with flip modules. Both flip- and flop-containing GluAs are widely expressed in the brain with a few exceptions.

Typically, one finds that there is fidelity in the process of transcribing DNA into mRNA and then into protein—that is, that nucleotides present in the DNA are accurate predictors of the amino acid sequence of the translated protein. However, a novel mechanism in the neuronal nucleus was discovered that edits mRNAs post-transcriptionally, and at least three of the four GluA subunits are subjected to this process (Sommer, Kohler, Sprengel, & Seeburg, 1991). In fact, one of the sites edited is the critical Arg residue regulating Ca^{2+} permeability in the GluA2 subunit. At another edited site, Gly replaces Arg-764 in the GluA2 subunit, and this editing also takes place in GluA3 and GluA4. The Arg-to-Gly conversion at amino acid 764 produces receptors that exhibit significantly faster rates of recovery from the desensitized state. The extent to which other receptors or other protein molecules undergo this form of editing is an area rich for investigation. At a minimum, this editing mechanism produces dramatic differences in the function of GluRs.

Glutamate Receptors Do Not Conform to the Typical Four Transmembrane-Spanning Segment Structure Described for nAChRs

The field of glutamate receptor structure/function is advancing at a rapid pace fostered by the crystallization of the GluA2 receptor (Sobolevsky, Rosconi, & Gouaux, 2009) and report of the 3D structure of the native GluR determined by electron microscopy reconstructions (Nakagawa, Cheng, Ramm, Sheng, & Walz, 2005). These studies reveal the overall architecture of the tetrameric GluR complex and provide some global insights into how glutamate binding leads to channel opening. These models can be additionally refined by the significant amount of work analyzing crystal structures of the isolated GluR ligand-binding domain with and without the presence of bound agonists and antagonists (see Traynelis et al., 2010, for review).

The GluR has a large extracellular domain composed of the amino-terminal domain (ATD) important for receptor assembly and trafficking and the ligand-binding domain (LBD) that serves as the binding site for glutamate (Fig. 8.6A). These domains form a structurally unique dimer arrangement in the extracellular domain that transitions into a fourfold symmetry of the pore-forming region of the TM domains. Unlike the four TM segments of the nAChR that each completely traverses the membrane, the TM2 segment of GluRs forms a reentrant loop within the membrane (Fig. 8.6A) and enters back into the cytoplasm, similar in some ways to the pore-forming domain (P segment) of voltage-activated K^+ channels. An enlargement of this TM2 segment (Fig. 8.6B) highlights the amino acids conserved in the GluRs and further shows the positions of the critical Gln residue responsible for Ca^{2+} permeability of the receptor. Thus, it appears that glutamate receptors are highly divergent from the nAChR receptor family.

Other Non-NMDA GluRs Have Less Well-Characterized Functions

GluK1-GluK5 forms a second non-NMDA receptor subfamily (Fig. 8.2) that is activated by the agonist kainate but whose contribution to producing functionally distinct receptors is less well understood (Traynelis et al., 2010). Their overall structure is similar to that of GluA1–4, and they exhibit about 40% sequence homology; however, their agonist-binding profile and their electrophysiological properties are distinct. GluK1–GluK2 can form either homo- or heterotetramers, but GluK4 and GluK5 require coexpression with one of the GluK1–Gluk3 family members. They are generally expressed at lower levels in the brain than the GluA1–4 subtypes (Hollmann & Heinemann, 1994). GluK4 is expressed at significant concentrations in only two cell types: hippocampal CA3 and dentate granule cells. GluK5 exhibits distinct properties when combined with other GluR subunits. For example, coexpression of GluK2 and GluK5 produces functional receptors that respond to AMPA, although neither subunit itself responds to this agonist.

GluD1 and GluD2 receptors can form homotetrameric receptors, but do not seem to form heteromers with other GluRs. They are also resistant to activation by all known agonists capable of activating other members of the GluR family (Traynelis et al., 2010). Their physiological role remains poorly characterized.

NMDA Receptors Are a Family of Ligand-Gated Ion Channels That Are Also Voltage Dependent

NMDA receptors are involved in aspects of development, learning and memory, and neuronal damage due to brain injury. The particular significance of this receptor to neuronal function comes from two of its unique properties. First, the receptor exhibits associativity. For the channel to be open, the receptor must bind glutamate and the membrane in which it resides must be depolarized. This behavior is due to an Mg^{2+}-dependent block of the receptor at normal membrane resting potentials. Second, the receptor permits a significant influx of Ca^{2+}, and increases in levels of the second messenger Ca^{2+} can activate a variety of processes that alter the properties of the neuron. Excess Ca^{2+} is also toxic, and the hyperactivation of NMDA receptors is thought to contribute to a variety of neurodegenerative disorders.

The NMDA receptor binds a large number of distinct pharmacological compounds. For example, certain hallucinogenic compounds, such as phencyclidine (PCP) and dizocilpine (MK-801), are effective blockers of the ion channel associated with the NMDA receptor (Fig. 8.7). These potent antagonists require the channel to be open to gain access to their binding sites and therefore are referred to as open-channel blockers. They also become trapped when the channel closes and are difficult to wash out once bound. Antagonists for the glutamate-binding site also have been developed, and some of the most well known are AP-5 and AP-7. These and other glutamate-binding site antagonists also produce hallucinogenic effects in humans. NMDA remains a specific agonist for this receptor; however, it is about one order of magnitude less potent than L-glutamate for receptor activation. L-Glutamate is the predominant endogenous neurotransmitter that activates the NMDA receptor; however, L-aspartate can also activate the receptor, as can an endogenous dipeptide in the brain, *N*-acetylaspartylglutamate (Hollmann & Heinemann, 1994).

NMDA Receptor Subunits Show Similarity to Non-NMDA Receptor Subunits

The first cloned NMDA subunit was named NMDAR1 (now termed GluN1), and the deduced amino acid sequence indicated a protein of approximately 97 kDa, similar to other members of the GluR family. Four potential transmembrane domains were identified, and four individual subunits are thought to compose the macromolecular NMDA receptor complex. However, recall that the transmembrane organization of GluR subunits indicates that TM2 forms a reentrant loop in the membrane (Fig. 8.6), and it is assumed that

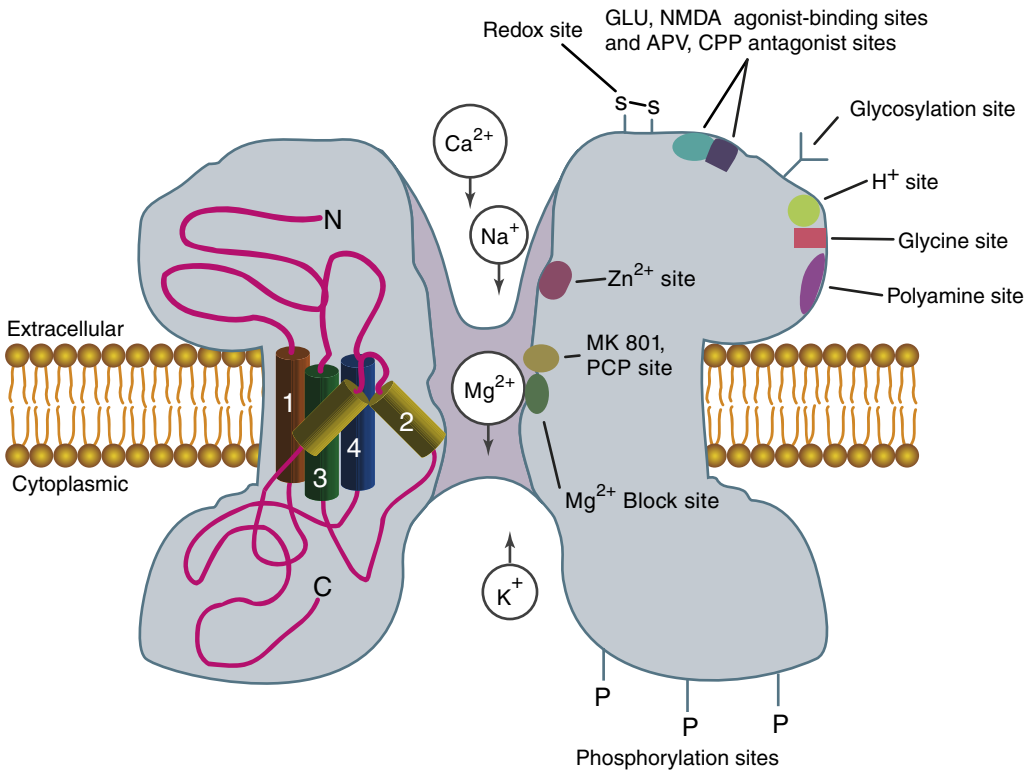

FIGURE 8.7 Diagram of an NMDA receptor highlighting binding sites for numerous agonists, antagonists, and other regulatory molecules. The location of these sites is a crude approximation for the purpose of discussion. *Adapted from Hollmann and Heinemann (1994).*

NMDA receptor subunits will also follow this structural topology (Fig. 8.7). The TM2 segment of each subunit clearly lines the pore of the NMDA receptor channel. In fact, a single Asn residue in TM2, analogous to that in the GluA2 subunit, regulates the Ca^{2+} permeability of the NMDA receptor.

Three of the best-characterized facets of the NMDA receptor were found when the GluN1 subunit was initially expressed in oocytes, although currents were unusually small. These characteristics are (1) a Mg^{2+}-dependent, voltage-sensitive ion channel block, (2) a glycine requirement for effective channel opening, and (3) Ca^{2+} permeability. However, these initial expression studies were complicated by the apparent endogenous expression of other GluN-like subunits. No glutamate-stimulated current is found when GluN1 is expressed in mammalian cells and the NMDAR is now recognized to exist in the nervous system as obligate heteromers of GluN1 mixed with other subunits (Traynelis et al., 2010).

Several other members of the NMDA receptor family have been cloned (GluN2A–2D and GluN3A and GluN3B), and their deduced primary structures are highly related to each other and to other GluRs (see Fig. 8.2). These GluN receptor subunits do not form channels when expressed singly or in combination unless they are coexpressed with GluN1. Apparently, GluN1 serves an essential role for the formation of a functional pore by which activation of NMDA receptors permits the flow of ions. The native NMDA receptor is thought to be composed of two GluN1 subunits and either two GluN2 subunits or a combination of GluN2 and GluN3 subunits. The GluN1 or GluN3 subunits provide the glycine-binding site for the receptor, while the GluN2 subunits contain the glutamate binding sites (Traynelis et al., 2010). The C-terminal domains of GluN2A–GluN2D are quite large relative to the GluN1 C-terminus and appear to play roles in altering channel properties and in determining the subcellular localization of the receptors. All the NMDAR subunits have an Asn residue at the critical point in the TM2 domain essential for producing Ca^{2+} permeability. This Asn residue also appears to form at least part of the binding site for Mg^{2+}, indicating that the sites for Mg^{2+} binding and Ca^{2+} permeation overlap.

The distribution of GluN2 subunits generally is more restricted than the homogeneous distribution of GluN1, with the exception of GluN2A, which is expressed throughout the nervous system. GluN2C is restricted mostly to cerebellar granule cells, whereas 2B and 2D exhibit broader distributions. As noted, the large size of the C terminus of the GluN2 subunit suggests a potential role in association with other proteins, possibly to target or restrict specific NMDA receptor types to areas of the neuron (see below). Mechanisms related to receptor targeting now are becoming understood and will clearly play major roles in determining the efficacy of synaptic transmission.

Additional NMDA Receptor Diversity Occurs through RNA Splicing

At least eight splice variants now have been identified for the GluRN1 subunit and these variants produce differences, ranging from subtle to significant, in the properties of the expressed receptor (Hollmann & Heinemann, 1994; Traynelis et al., 2010). For example, GluN1 receptors lacking a particular N-terminal insert due to alternative splicing exhibit enhanced blockade by protons and exhibit responses that are potentiated by Zn^{2+} in micromolar concentrations. Zn^{2+} classically has been described as an NMDA receptor antagonist that significantly blocks its activation. Clearly, the particular splice variant incorporated into the receptor complex affects the types of physiological response generated. Spermine, a polyamine found in neurons and in the extracellular space, also slightly increases the amplitude of NMDA responses, and this modulatory effect also appears to be associated with a particular splice variant. The physiologic role of spermine in regulating NMDA receptors remains unclear.

NMDA Receptors Exhibit Complex Channel Properties

The biophysical properties of the NMDA receptor are complex. Single-channel conductance has a main level of 50 pS; however, subconductances are evident, and different subunit combinations and splice variants produce channels with distinct single-channel properties. A binding site for the Ca^{2+}-binding protein calmodulin also has been identified on the GluN1 subunit. Binding of Ca^{2+}–calmodulin to NMDA receptors produces a fourfold decrease in open-channel probability. Ca^{2+} influx through the NMDA receptor could induce calmodulin binding and lead to an immediate short-term feedback inhibition, decreasing ion flow through the receptor.

Glutamate Receptors Cluster at Synapses

Glutamate receptors are concentrated at excitatory synapses through interactions with underlying scaffolding molecules (Fig. 8.8). These scaffolding molecules and a host of other structural and signalling proteins form an electron dense structure at excitatory synapses called the postsynaptic density (PSD). One of the best known of these scaffolds is PSD95, a multidomain protein enriched at excitatory synapses that helps organize receptors and signalling molecules. Through one of its multiple PDZ domains, PSD95 binds directly to the

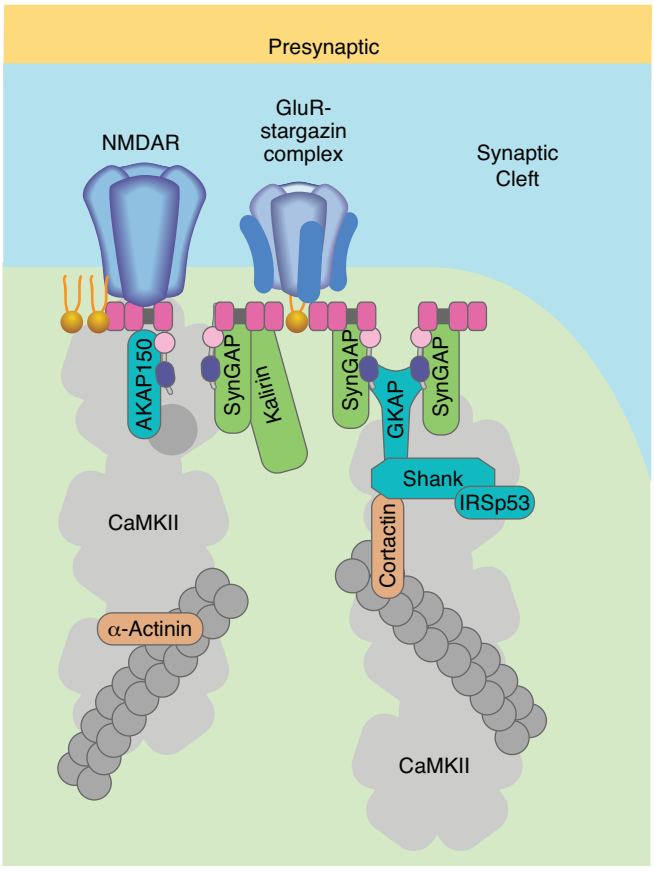

FIGURE 8.8 Diagram of glutamate receptor clustering at an excitatory synapse. The NMDA receptor interacts directly with PSD-95 through binding to one of PSD-95's three PDZ domains (the PDZ domains of PSD-95 are shown as pink squares). The AMPAR is associated with a protein called stargazin and stargazin interacts with one of the PDZ domains of PSD-95. Only a few of the many other signaling and scaffolding proteins at excitatory synapses are shown. AKAP150 is A-kinase anchoring protein of 150 kDa that binds to protein kinase A and other proteins, SynGAP is an abundant synaptic associated Ras GTP-ase activating protein that interacts with PSD-95, GKAP is a guanylate kinase associated protein that interacts with PSD-95, CaMKII is an abundant Ca^{2+}/calmodulin-activated protein kinase that interacts directly with the NMDAR. CaMKII also interacts with itself and with α-actinin, which is an actin-binding protein. This web of protein-protein interactions forms the electron dense structures called the postsynaptic densities visible in electon micrographs of excitatory synapses. *Adapted from Sheng and Hoogenraad (2007).*

cytoplasmic domain of GluN2 subunits and anchors them tightly to the PSD (Sheng & Hoogenraad, 2007). In fact, biochemically isolated PSDs stripped of the overlying membrane retain GluNs indicating the interaction is mediated by tight binding. A number of other PSD enriched proteins have been identified to bind to the C-terminal domain of GluN receptor subunits, including the Ca^{2+}/calmodulin-activated protein kinase CaMKII (Fig. 8.8).

GluA receptors do not interact directly with PSD-95, and their relative concentration in the PSD is dynamic. The up- and down-regulation of GluA receptor number in the postsynaptic membrane alters the efficiency of synaptic transmission and provides a mechanism for the expression of plasticity at excitatory synapses. One accessory protein factor important for receptor trafficking is the protein stargazin that was recently discovered as a structural component of isolated GluA receptors. Stargazin is one member of a family of proteins called TARPs for transmembrane AMPA receptor regulatory proteins that are important for the maturation and targeting of GluA receptors to excitatory synapses (Fig. 8.8). TARPs bind tightly to GluA receptors and they can be identified as additional protein density in electron microscopic reconstructions of isolated GluA receptors (Nakagawa et al., 2005). This situation is analogous in most respects to that described for rapsyn binding to the nAChR (Fig. 8.5). However, TARPs are themselves membrane-spanning proteins, having four predicted TM domains. TARPs also have a domain that interacts with PSD-95 (or other PDZ containing proteins), and it is this interaction that leads to the association of GluA receptors with PSDs. TARPs also affect the maturation and channel properties of GluA receptors in addition to their role in synaptic targeting. Interestingly, TARP binding decreases when glutamate binds to the receptor suggesting interplay exists between receptor use and TARP mediated localization. There are other well-documented proteins that interact with the C-terminal domain of GluA receptor subunits, some in a subtype specific manner. This list includes GRIP/ABP, PICK-1, NSF, and SAP-97, and these proteins have likewise been implicated in the maturation and trafficking of GluA receptors. It is also well documented that specific residues in the C-terminal domain of GluA receptors are phosphorylated and phosphorylation regulates channel properties and surface expression (Traynelis et al., 2010). These post-translational modifications and interactions with other proteins must work in concert for the proper localization and stability of non-NMDA receptors at synapses.

Summary

A general model for ionotropic receptors has emerged mainly from analyses of the nAChR. Ionotropic receptors are large membrane-bound complexes generally composed of five subunits. The subunits each have four transmembrane domains, and the amino acids in TM2 form the lining of the pore. Transmitter binding induces rapid conformational changes that are translated into an increase in the diameter of the pore, permitting ion influx. Cation or anion selectivity is obtained through the coordination of specific negatively or positively charged amino acids at strategic locations in the receptor pore. Glutamate receptors are structurally distinct from

the nAChR family of receptors and a major advancement in defining these differences came from the successful crystallization of the GluR2 receptor. This and previous results showed that the TM2 domain of glutamate receptors forms a hairpin instead of traversing the membrane completely, causing the remainder of the receptor to adopt a different subunit topology than that described for the nAChR family. Glutamate receptors are also composed of four, not five, subunits. These differences are perhaps not surprising given that the nAChR family and the glutamate receptor family have arisen from two different ancestral genes.

G-PROTEIN COUPLED RECEPTORS

The number of members in the G-protein coupled receptor family is enormous, with over 800 identified from sequencing of the human genome. Historically, the term *metabotropic* was used to describe the fact that intracellular metabolites are produced when these receptors bind ligand. However, there are now clearly documented cases where the activation of "metabotropic" receptors does not produce alterations in metabolites but instead produces their effects by interacting with G-proteins that directly alter the behavior of ion channels. Thus, these receptors are now referred to as G-protein-coupled receptors (GPCRs). Currently, the GPCR family can be divided into three subfamilies on the basis of their structures: (1) the rhodopsin-adrenergic receptor subfamily (class A), (2) the secretin-vasoactive intestinal peptide receptor subfamily (class B), and (3) the metabotropic glutamate receptor subfamily (class C).

When a GPCR is activated, it couples to a G-protein initiating the exchange of GDP for GTP, activating the G-protein (Fig. 8.1B). Activated G-proteins then couple to downstream effectors to alter the activity of other intracellular enzymes or ion channels. Many of the G-protein target enzymes produce diffusible second messengers that stimulate further downstream biochemical processes, including the activation of protein kinases (see Chapter 9). Time is required for each of these coupling events, and the effects of GPCR activation are typically slower in onset than those observed following the activation of ionotropic receptors. Because there is a lifetime associated with each intermediate, the effects produced by GPCR activation are also longer in duration than those produced by the activation of ionotropic receptors. Most small neurotransmitters, such as ACh, glutamate, 5-HT, and GABA, can bind to and activate both ionotropic and GPCRs. Thus, each of these transmitters can induce both fast responses (milliseconds), such as typical excitatory or inhibitory postsynaptic potentials, and slow-onset and longer duration responses (from tenths of seconds to, potentially, hours). These effects span a broad range of time domains providing the nervous system with a rich source for temporal information processing that is subject to constant modification.

GPCR Structure Conforms to a General Model

A GPCR typically consists of a single polypeptide with a generally conserved structure; however, there are now clear examples where functional GPCRs are composed of dimers. The receptor subunits contain seven helical segments that wrap back and forth through the membrane (Fig. 8.9). GPCRs are homologous to rhodopsin, and detailed structural information on rhodopsin was originally used to provide a framework for describing other GPCR structures. However, there are now crystal structures available for the human adenosine (A2a) receptor, the human D3 receptor, the human β2 adrenoreceptor, and the avian β1 adrenoreceptor that provide important comparisons to describe the unique and conserved features of GPCR structure.

The most conserved feature of GPCRs is the seven membrane-spanning segments; however, other generalities can be made about their structure. The N terminus of the receptor extends into the extracellular space, whereas the C terminus resides within the cytoplasm (Fig. 8.9A). Each of the seven TM domains between N and C termini consists of approximately 24 mostly hydrophobic amino acids. These seven domains associate together to form an oblong ring within the plasma membrane (Fig. 8.9B). Between each transmembrane domain is a loop of amino acids of various sizes. The loops connecting TM1 and TM2, TM3 and TM4, and TM5 and TM6 are intracellular and are labeled i1, i2, and i3, respectively, whereas those between TM2 and TM3, TM4 and TM5, and TM6 and TM7 are extracellular and are labeled e1, e2, and e3, respectively (see Fig. 8.9A).

The Neurotransmitter-Binding Site is Buried in the Core of the Receptor

The neurotransmitter-binding site for class A GPCRs resides within a pocket formed in the center of the seven membrane-spanning segments (Fig. 8.9). In the βAR, this pocket resides approximately 11 Å into the hydrophobic core of the receptor, placing the ligand-binding site within the plasma membrane lipid bilayer (Kobilka, 1992; Rosenbaum, Rasmuseen & Kobilka, 2009). Strategically positioned charged and polar residues in the membrane-spanning segments point inward into a central pocket that forms the binding site for the ligand. For example, Asn residues in the second and third segments, two Ser residues in the fifth segment, and a Phe residue in the sixth segment provide major contact

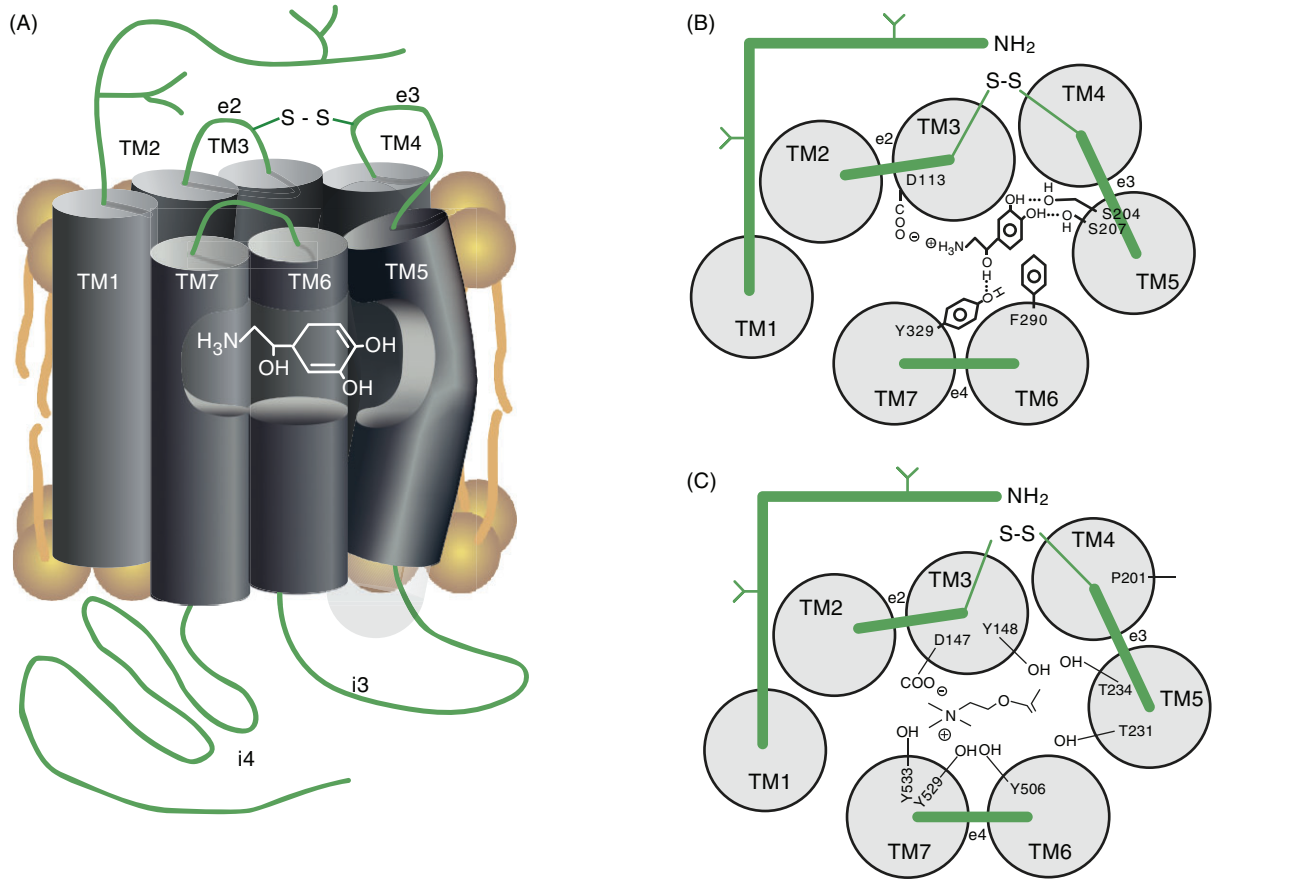

FIGURE 8.9 (A) Diagram showing the approximate position of the catecholamine-binding site in the βAR. The transmitter-binding site is formed by amino acids whose side chains extend into the center of the ring produced by the seven transmembrane domains (TM1–TM7). Note that the binding site exists at a position that places it within the plane of the lipid bilayer. (B) A view looking down on a model of the βAR identifying residues important for ligand binding. The seven transmembrane domains are represented as gray circles labeled TM1 though TM7. Amino acids composing the extracellular domains are represented as green bars labeled e1 through e4. The disulfide bond (–S–S–) that links e2 to e3 is also shown. Each of the specific residues indicated makes stabilizing contact with the transmitter. (C) A view looking down on a model of the mAChR identifying residues important for ligand binding. Stabilizing contacts, mainly through hydroxyl groups (-OH), are made with the transmitter on four of the seven transmembrane domains. The chemical nature of the transmitter (i.e., epinephrine versus Ach) determines the type of amino acids necessary to produce stable interactions in the receptor-binding site (compare B and C). *Adapted from Strosberg (1990).*

points in the βAR-binding site for the transmitter (Fig. 8.9B; Kobilka, 1992). Replacing the Asp in TM3 with a Glu reduced transmitter binding by more than 100-fold, and replacement with a less conserved amino acid, such as Ser, reduces binding by more than 10,000-fold. Two Ser residues in TM5 are also essential for efficient transmitter binding and receptor activation, as is an Asp residue in TM2 and a Phe residue in TM6. In total, the two Asp, the two Ser, and the Phe residues are highly conserved in all receptors that bind catecholamines. Variations in the amino acids at these five positions appear to provide specificity between the binding of different transmitters to the individual GPCRs.

The neurotransmitter-binding site of mAChRs, like that of the β2AR, has been investigated in great detail (Fig. 8.9C). The Asp residue in TM3 is also critical for ACh binding to mAChRs. Mutagenesis studies indicate important roles for Tyr and Thr residues in TM3, TM5, TM6, and TM7 in contributing to the ligand-binding site for ACh. Interestingly, many of these mutations do not affect antagonist binding, indicating that distinct sets of amino acids participate in binding agonists and antagonists. When the transmembrane domains are examined from a side view (Fig. 8.9A), the key amino acids implicated in agonist binding lie at about the same level within the core of the receptor structure, buried approximately 10–15 Å from the surface of the plasma membrane. An additional amino acid identified as essential for agonist binding of the mAChR is a Pro residue in TM4 (P201 in Fig. 8.9C). This residue is also highly conserved among GPCRs, and structural predictions suggest that it affects ligand binding not by interacting with agonist directly but by stabilizing a conformation essential for high-affinity binding. Structural predictions

also place this Pro residue in the same plane as the Asp, Tyr, and Thr residues that form the ligand-binding site of the mAChR.

Transmitter Binding Causes a Conformational Change in the Receptor and Activation of G-Proteins

Proposed models for GPCR activation assume that the receptor can isomerize spontaneously between inactive and active states although there is significant evidence of additional intermediate states along this pathway. Agonist binding stabilizes the active conformation and shifts the equilibrium toward the active form, and G-protein activation ensues. In the absence of agonist, the inactive state of GPCRs is favored, and little G-protein activation occurs. This kinetic model indicates that agonist binding is not necessary for the receptor to undergo transition into the active state; instead, it stabilizes the activated state of the receptor. This model is supported by observations of both spontaneously arising and engineered mutants of the βAR and αAR that can express constitutive activity in the absence of agonist. The mutants stabilize the active conformation of the molecule in a state more similar to the agonist-bound form of the receptor, leading to productive interactions with G proteins. Stabilization of intermediate states by pharmacological agents can explain how certain drugs produce full agonist, partial agonist, neutral antagonist or inverse agonist behavior (Rosenbaum et al., 2009).

The Third Intracellular Loop Forms a Major Determinant for G-Protein Coupling

Extensive studies using site-directed mutagenesis and the production of chimeric molecules have revealed the domains and amino acids essential for G-protein coupling to GPCRs. Receptor domains within the second (i2) and third (i3) intracellular loops (Fig. 8.9) appear largely responsible for determining the specificity and efficiency of coupling for adrenergic and muscarinic cholinergic receptors and are the likely sites for G-protein coupling of the entire GPCR family. In particular, the 12 amino acids of the N-terminal region of the third intracellular loop significantly affect the specificity of G-protein coupling. Other regions in the C terminus of the third intracellular loop and the N-terminal region of the C-terminal tail appear to be more important for determining the efficiency of G-protein coupling than for determining its specificity (Kobilka, 1992). The third intracellular loop varies enormously in size among the different G-protein-coupled receptors, ranging from 29 amino acids in the substance P receptor to 242 amino acids in the mAChR (Strader, Fong, Tota, Underwood, & Dixon, 1994). The intracellular loop connecting TM5 and TM6 is the main point of receptor coupling to G-proteins, and ligand binding to amino acids in TM5 and TM6 may be responsible for triggering the G-protein–receptor interaction by transmitting a conformational change to the third intracellular loop.

Specific Amino Acids Are Involved in Transducing Transmitter Binding into G-Protein Coupling

Residues associated with transmitting the conformational change induced by ligand binding to the activation of G-proteins have been investigated with the use of mAChRs. These studies revealed that an Asp residue in TM2 is important for the receptor activation of G-proteins, and altering the Asp by site-directed mutagenesis has a major negative effect on G-protein–receptor activation. A Thr residue in TM5 (T231 in Fig. 8.9C) and a Tyr residue in TM6 (Y506 in Fig. 8.9C) are also essential. Because these residues are connected by i3, they are assumed to play fundamental roles in transmitting the conformational change induced by ligand binding to the area of i3 essential for G-protein coupling and activation. When mutated, a Pro residue on TM7 (part of a conserved AsnProXXTyr motif) produces a major impairment in the ability of the TM3 segment to induce G-protein coupling. The specifics of these earlier mutagenesis studies have largely been confirmed by comparison of different crystallized forms of the GPCRs and the term "rotamer toggle switch" is used to capture the conformational transition from the inactive to active conformations. There is also a highly conserved sequence AspGluArgTyr in TM3 and a Glu reside in TM6 that forms a series of interactions termed the "ionic lock" that help stabilize the inactive conformation (Rosenbaum et al., 2009). Disruption of this interaction is thought to be an important step in inducing the active conformation capable of productive G-protein interactions.

As mentioned earlier, GPCRs are often single polypeptides; however, they are clearly separable into distinct functional domains. For example, β2AR can be physically split, with the use of molecular techniques, into two fragments: one fragment containing TM1–TM5 and the other containing TM6 and TM7. In isolation, neither of these fragments can produce a functional receptor; however, when coexpressed in the same cell, functional β2ARs that can bind ligand and activate G-proteins are produced. This remarkable experiment indicates that physical connection in the primary sequence is not essential for producing functional β2ARs and also emphasizes the contribution of domains in the separate fragments (TM1–TM5 and TM6 and TM7) to both ligand binding and G-protein coupling.

GPCRs Also Exist as Homo- or Hetero-oligomers

The observation that GPCRs can be physically split through genetic engineering, but produced functional channels when recombined, provided the first hint that full-length GPCRs might also oligomerize with each other into functional molecules. A test of this hypothesis was accomplished by making chimeric receptors composed of TM1–5 of the α2-AR and TM6 and 7 of the m3 muscarinic receptors and vice versa. When either of these chimeric molecules was expressed in isolation, neither formed a functional receptor. However, when coexpressed, receptors were formed that bind both muscarinic and adrenergic ligands and ligand binding led to functional activation of downstream effectors. Through domain swapping, the ligand-binding sites for both receptor ligands were reconstituted by oligomerization of the two chimeric receptors into one bifunctional chimeric dimer. It is now clear that oligomerization of GPCRs into homo- or hetero dimers is adding a new layer of complexity and diversity to the study of these receptors. Important functional consequences could relate to alterations in (1) ligand binding, (2) efficiency and specificity of coupling to downstream effectors, (3) subcellular localization, and (4) receptor desensitization. The evolving and apparently widespread nature of direct receptor–receptor interactions leads one to believe that our current understanding of GPCRs and their biological impact will be undergoing continual modifications for many years to come.

G-Protein Coupling Increases Affinity of the Receptor for Neurotransmitter

The affinity of a GPCR for agonist increases when the receptor is coupled to the G-protein. This positive feedback effectively increases the lifetime of the agonist-bound form of the receptor by decreasing the dissociation rate of the agonist. An excellent demonstration of this effect comes from studies using engineered βAR receptors that are constitutively active in their ability to couple to G-proteins. These mutant receptors show a significantly increased affinity for agonists. When the G-protein dissociates, the agonist-binding affinity of the receptor returns to its original state. Changes induced by ligand binding apparently stabilize the receptor in a conformation with both higher affinity for ligand and higher affinity for coupling to G-proteins.

Specificity and Potency of G-Protein Activation Are Determined by Several Factors

GPCRs associate with G-proteins to transduce ligand binding into intracellular effects. This coupling step can lead to diverse responses, depending on the type of G-protein and the type of effector enzyme present. Ligand binding to a single subtype of GPCR can activate multiple G-protein-coupled pathways. For example, activated α2ARs have been shown to couple to as many as four different G-proteins in the same cell (Strader et al., 1994). Some of the specificity for G-protein activation can be determined by the specific conformations assumed by the receptor, and a single receptor can assume multiple conformations. For example, α2ARs can isomerize into at least two states. One state interacts with a G-protein that couples to phospholipase C, and a second state interacts with G-proteins that couple to both phospholipase C and phospholipase A_2. Thus, a single GPCR can produce a diversity of responses, making it difficult to assign specific biological effects to individual receptor subtypes in all settings.

Activated GPCRs are free to couple to many G-protein molecules, permitting a significant amplification of the initial transmitter-binding event. This catalytic mechanism is referred to as "collision coupling," whereby a transient association between the activated receptor and the G-protein is sufficient to produce the exchange of GDP for GTP, activating the G-protein. For example, because adenylyl cyclase appears to be tightly coupled to the G-protein, the rate-limiting step in the production of cAMP is the number of successful collisions between the receptor and the G-protein. A constant GTPase activity hydrolyzes GTP, bringing the G-protein and therefore the adenylyl cyclase back to the basal state. The apparent maximal rate is achieved when all the G-protein–cyclase complexes have become activated or, more accurately, when the rate of formation is maximal with respect to the rate of GTP hydrolysis. Additionally, the important process of receptor desensitization can also regulate the number of receptors capable of productive G-protein interactions.

Receptor Desensitization is a Built-in Mechanism for Decreasing the Cellular Response to Transmitter

Desensitization is an important process whereby cells can decrease their sensitivity to a particular stimulus to prevent saturation of the system (Kobilka, 1992; Rosenbaum et al., 2009). For GPCRs, desensitization is defined as an increase in the concentration of agonist required to produce half-maximal stimulation of, for example, adenylyl cyclase. In practical terms, desensitization of receptors produces less response for a constant amount of transmitter.

There are two known mechanisms for desensitization. One mechanism is a decrease in response brought

about by the covalent modifications produced by receptor phosphorylation and is quite rapid (seconds to minutes). The other mechanism is the physical removal of receptors from the plasma membrane (through a mechanism of receptor-mediated endocytosis) and tends to require greater periods of time (minutes to hours). The latter process can be either reversible, where receptors are sequestered but are recycled to the plasma membrane or irreversible, where the receptors are removed from the cell through degradation (Fig. 8.10).

The Rapid Phase of GPCR Desensitization is Mediated by Receptor Phosphorylation

Desensitization of the βAR appears to involve at least three protein kinases: PKA, PKC, and a G-protein receptor kinase (GRK). Phosphorylation of ARs by PKA does not require that the agonist be bound to the receptor and appears to be a general mechanism by which the cell can reduce the effectiveness of all receptors, independent of whether they are in the agonist-bound or unbound state. This process is also referred to as heterologous desensitization because the receptor does not require bound-agonist. PKA and PKC phosphorylate sites on the third intracellular loop and possibly the C-terminal cytoplasmic domain. Phosphorylation of these sites interferes with the ability of the receptor to couple to G-proteins, thus producing the desensitization.

GRKs can also phosphorylate GPCRs and lead to receptor desensitization. Six members of the GRK family of kinases have been identified: rhodopsin kinase (GRK1), βARK (GRK2), and GRK3 through GRK6 (Huang & Tesmer, 2011; Premont, Inglese, & Lefkowitz, 1995). GRK2 is a Ser and Thr specific protein kinase initially identified by its capacity to phosphorylate the βAR. GRK2 phosphorylates only the agonist-bound form of the receptor, usually when agonist concentrations reach the micromolar level, as typically found in the synaptic cleft. This process is referred to as homologous desensitization because the regulation is specific for those receptor molecules that are in the transmitter-bound state. Phosphorylation of βAR by GRK2 does not interfere with coupling to G-proteins directly. Instead, an additional protein, arrestin, binds the GRK2-phosphorylated form of the receptor, thus blocking receptor–G-protein coupling (Fig. 8.10). This process is analogous to the desensitization of the light-sensitive receptor molecule rhodopsin produced by GRK1 phosphorylation and the binding of arrestin. Phosphorylation sites on βAR for GRK2 reside on the C-terminal cytoplasmic domain and are distinct from those phosphorylated by PKA.

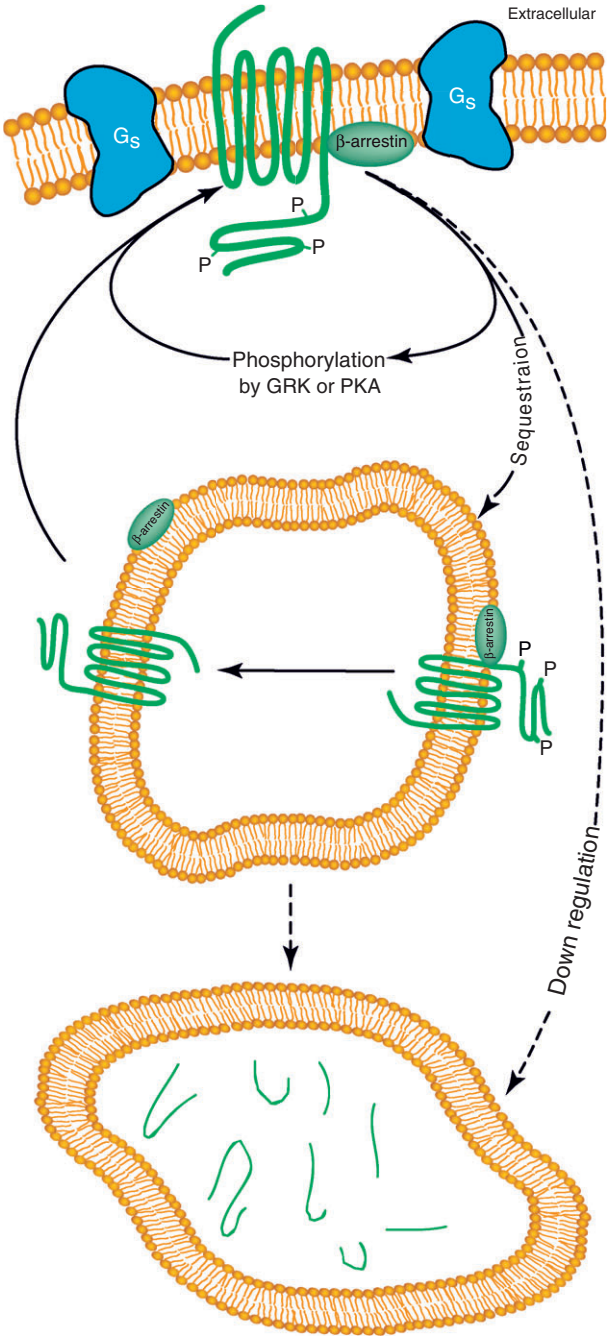

FIGURE 8.10 Intracellular pathways associated with desensitization of GPCRs. GPCRs are phosphorylated (noted with P) on their intracellular domains by PKA, GRK, and other protein kinases. The phosphorylated form of the receptor can be removed from the cell surface by a process called sequestration with the help of the adapter protein β-arrestin; thus fewer binding sites remain on the cell surface for transmitter interactions. In intracellular compartments, the receptor can be dephosphorylated and returned to the plasma membrane in its basal state. Alternatively, phosphorylated receptors can be degraded (down regulated) by targeting to a lysosomal organelle. Degradation requires replenishment of the receptor pool through new protein synthesis. *Adapted from Kobilka (1992).*

The cycle of homologous desensitization starts with the activation of a GPCR, which induces activation of G-proteins and dissociation of the $\beta\gamma$ subunit complex from α subunits. At least one role for the $\beta\gamma$ complex appears to be to bind to GRKs, which leads to their recruitment to the membrane in the area of the locally activated G-protein–receptor complex. The recruited GRK is then activated, leading to phosphorylation of the agonist-bound receptor and subsequent binding of arrestin. Arrestin binds to the same domains on the receptor necessary for coupling to G-proteins, thus terminating the actions of the activated receptor (Fig. 8.10). The ensuing process of sequestration follows GPCR phosphorylation and arrestin binding.

Desensitization Can Also Be Produced by Loss of Receptors from the Cell Surface

Desensitization of GPCRs is also produced by removal of the receptor from the cell surface. This process can be either reversible (sequestration, or internalization) or irreversible (down regulation). Sequestration is the term used to describe the rapid (within minutes) but reversible endocytosis of receptors from the cell surface after agonist application (Fig. 8.10). Neither G-protein coupling nor receptor phosphorylation appears to be essential for this process, but phosphorylation by GRKs clearly enhances the rate of sequestration. The binding of arrestin to the phosphorylated receptor also enhances sequestration (Ferguson et al., 1996; Huang & Tesmer, 2011). Thus, arrestin binding appears to promote not only rapid desensitization by disrupting the receptor–G-protein interaction but also receptor sequestration. Receptor cycling through intracellular organelles is an important trafficking mechanism that leads to an enhanced rate of dephosphorylation of the phosphorylated receptor, returning it to the cell surface in its basal state (Fig. 8.10).

Down regulation occurs more slowly than sequestration and is irreversible (Fig. 8.10). The early phase (within 4h) may involve both a PKA-dependent and a PKA-independent process. This early phase of down regulation is apparently due to receptor degradation after endocytotic removal from the plasma membrane. The later phases (>14h) of down regulation appear to be further mediated by a reduction in receptor biosynthesis through a decrease in the stability of the receptor mRNA and a decreased transcription rate.

Other Post-translational Modifications Are Required for Efficient GPCR Function

Like many proteins expressed on the cell surface, GPCRs are glycosylated, and the N-terminal extracellular domain is the site of carbohydrate attachment. Glycosylation does not appear to be essential to the production of a functional ligand-binding pocket (Strader et al., 1994), although prevention of glycosylation may decrease membrane insertion and alter intracellular trafficking of the β2AR.

Another important structural feature of most GPCRs is the disulfide bond formed between two Cys residues present on the extracellular loops (e2 and e3; Fig. 8.9). This disulfide bond stabilizes a restricted conformation of the mature receptor by covalently linking the two extracellular domains, and this conformation favors ligand binding. Disruption of this disulfide bond significantly decreases agonist binding (Kobilka, 1992). A third Cys residue, in the C-terminal domain of GPCRs (in i4; Fig. 8.9A), serves as a point for covalent attachment of a fatty acid (often palmitate). Fatty acid attachment stabilizes interactions between the C-terminal domain of a GPCR and the membrane.

GPCRs All Exhibit Similar Structures

The family of GPCRs exhibits structural similarities that permit the construction of "trees" describing the degree of their evolutionary kinship (Fig. 8.11). Some remarkable relations become evident in such an analysis. For example, the D1 and D5 subtypes of DA receptors are related more closely to the AR than to the D2, D3, and D4 DA receptors. The similarities and differences among GPCR families are highlighted in the remainder of this chapter and their evolutionary relatedness to each other can be seen in Figure 8.11.

Muscarinic ACh Receptors

Muscarine is a naturally occurring plant alkaloid that binds to muscarinic subtypes of the AChRs to activate them. mAChRs play a dominant role in mediating the actions of ACh in the brain, indirectly producing both excitation and inhibition through binding to a family of unique GPCRs. mAChRs are found both presynaptically and postsynaptically, and, ultimately, their main neuronal effects appear to be mediated through alterations in the properties of ion channels. Presynaptic mAChRs take part in important feedback loops that regulate ACh release. ACh released from the presynaptic terminal can bind to mAChRs on the same nerve ending, thus activating enzymatic processes that modulate subsequent neurotransmitter release. This modulation is typically an inhibition; however, activation of m5AChRs produces an enhancement in subsequent release. These autoreceptors are an important regulatory mechanism for the short-term (milliseconds to seconds) modulation of neurotransmitter release.

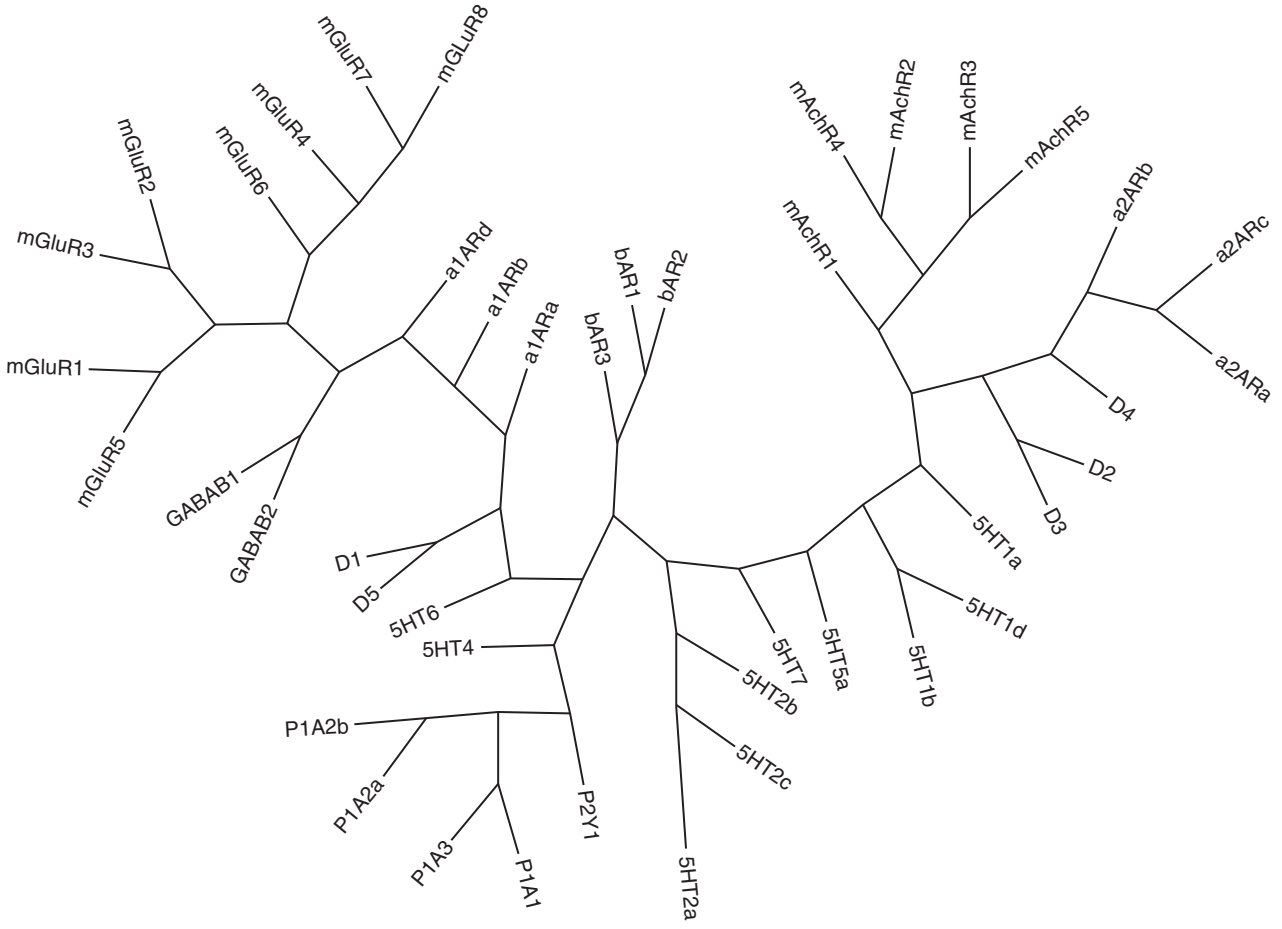

FIGURE 8.11 Evolutionary relationship of the GPCR family. The tree was constructed by aligning the protein sequences from each receptor family with the ClustalW program. Based on the alignment, the phylogenetic relationship was inferred with the maximum parsimony method and the tree was constructed using the Phylogeny Inference Package v 3.6 (distributed by J. Felsenstein, Department of Genome Sciences, University of Washington, Seattle.) Dr. Yin Liu (Department of Neurobiology and Anatomy, University of Texas Health Science Center-Houston, Houston, TX) kindly provided the phylogenetic tree and figure.

The family of mAChRs now includes five members (m1–m5), ranging from 55 to 70 kDa, and each of the five subtypes exhibits the typical architecture of seven TM domains. Much of the diversity in this family of receptors resides in the third intracellular loop (i3) responsible for the specificity of coupling to G-proteins. The m1, m3, and m5 mAChRs couple predominantly to G-proteins that activate the enzyme phospholipase C. m2 and m4 receptors (which are more highly related to each other than other family members; Fig. 8.11) couple to G-proteins that inhibit adenylyl cyclase, as well as to G-proteins that regulate K^+ and Ca^{2+} channels directly. As is the case for other GPCRs, the domain near the N terminus of i3 is important for the specificity of G-protein coupling. This domain is conserved in m1, m3, and m5 AChRs, but is unique in m2 and m4. Several other important residues also have been identified for G-protein coupling. A particular Asp residue near the N-terminus of the second intracellular loop (i2) is important for G-protein coupling, as are residues residing in the C-terminal region of the i3 loop.

Major mAChRs found in the brain are m1, m3, and m4, and each is distributed diffusely. The m2 subtype is the heart isoform and is not highly expressed in other organs. Genes for m4 and m5 lack introns, whereas those encoding m1, m2, and m3 contain introns, although little is known concerning alternatively spliced products of these receptors. Atropine is the most widely utilized antagonist for mAChR and binds to most subtypes, as does *N*-methylscopolamine. The antagonist pirenzipine appears to be relatively specific for the m1 mAChR, and other antagonists, such as AF-DX116 and hexahydrosiladifenidol, appear to be more selective for m2 and m3 subtypes.

Adrenergic Receptors

The catecholamines epinephrine (adrenaline) and norepinephrine (noradrenaline) produce their effects by

binding to and activating adrenergic receptors. Interestingly, epinephrine and norepinephrine can both bind to the same adrenergic receptor. Adrenergic receptors are currently separated into three families: α1, α2, and β (Fig. 8.11). Each of the α1 and α2 families is further subdivided into three subclasses. Similarly, the β family also contains three subclasses (β1, β2, and β3; Fig. 8.11). The main adrenergic receptors in the brain are the α1 and β1 subtypes. α2ARs have diverse roles, but the function that is best characterized (in both central and peripheral nervous tissue) is their role as autoreceptors. Different AR subtypes bind to G-proteins that can alter the activity of phospholipase C, Ca^{2+} channels, and, probably the best studied, adenylyl cyclase. For example, activation of α2ARs produces inhibition of adenylyl cyclase, whereas all βARs activate the cyclase.

Only a few agonists or antagonists cleanly distinguish the AR subtypes. One of them, isoproterenol, is an agonist that appears to be highly specific for βARs. Propranolol is the best-known antagonist for βARs, and phentolamine is a good antagonist for α receptors but binds weakly at βARs. The genomic organization of the different AR subtypes is unusual. Like many G-protein-coupled GPCRs, β1 and β2ARs are encoded by genes lacking introns. β3ARs, which have a role in lipolysis, are encoded by an intron-containing gene, as are αARs, providing an opportunity for alternative splicing as a means of introducing functional heterogeneity into the receptor.

Dopamine Receptors

Some 80% of the DA in the brain is localized to the corpus striatum, which receives major input from the substantia nigra and takes part in coordinating motor movements and other important information processing functions. DA is also found diffusely throughout the cortex, where its specific functions remain less well understood, but certainly play roles in higher cognitive functions. Many of the prescribed neuroleptic drugs exert their effects by blocking DA binding, and imbalances in the DA system have long been associated with neuropsychiatric disorders.

DA receptors are found both pre- and postsynaptically, and their structure is homologous to that of the receptors for other catecholamines (Civelli, Bunzow, & Grandy, 1993). Five subtypes of DA receptors can be grouped into two main classes: D1-like and D2-like receptors that are evolutionarily quite distinct (Fig. 8.11). D1-like receptors include D1 and D5, whereas D2-like receptors include D2, D3, and D4. The main distinction between these two classes is that D1-like receptors activate adenylyl cyclase through interactions with G_s, whereas D2-like receptors inhibit adenylyl cyclase and other effector molecules by interacting with G_i/G_o. D1-like receptors are also slightly larger in molecular mass than D2-like receptors. An additional point of interest is that D5 receptors selectively associate with $GABA_A$ receptors, impacting their function and vice versa (Liu et al., 2000). The deduced amino acid sequence for the entire family ranges from 387 amino acids (D4) to 477 amino acids (D5). Main structural differences between D1-like and D2-like receptors are that the intracellular loop between the sixth and the seventh transmembrane segments is larger in D2-like receptors, and D2-like receptors have smaller C-terminal intracellular segments.

D1-like receptors, like βARs, are transcribed from intronless genes. Conversely, all D2-like receptors contain introns, thus providing for possibilities of alternatively spliced products. Post-translational modifications include glycosylation at one or more sites, disulfide bonding of the two Cys residues in e2 and e3, and acylation of the Cys residue in the C-terminal tail (analogous to the β2AR). The DA-binding site includes two Ser residues in TM5 and an Asp residue in TM3, analogous to the βAR. The recent crystallization of the D3 receptor (Chien et al., 2010) supports the importance of these amino acid interactions with ligand, confirms the similarity to the β2AR, and provides the potential for future subtype specific drug design.

Because of the presumed role of DA in neuropsychiatric disorders, enormous effort has been put into developing pharmacological tools for manipulating this system. DA receptors bind bromocriptine, lisuride, clozapine, melperone, fluperlapine, and haloperidol. Because these drugs do not show great specificity for receptor subtypes, their usefulness for dissecting effects specifically related to binding to one or another DA receptor subtype is limited. However, their role in the treatment of human neuropsychiatric disorders is enormous (see Chapter 41).

Purinergic Receptors

Purinergic receptors bind to ATP or other nucleotide analogs and to its breakdown product adenosine. Although ATP is a common constituent found within synaptic vesicles, adenosine is not and is therefore not considered a "classic" neurotransmitter. However, the multitude of receptors that are activated by adenosine indicates that this molecule has important modulatory effects on the nervous system. Situations of high metabolic activity that consume ATP and situations of insufficient ATP-regenerating capacity can lead to the accumulation of adenosine. Because adenosine is permeable to membranes and can diffuse into and out of cells, a feedback loop is established in which adenosine can serve as a local diffusible signal that communicates the metabolic status of the neuron to surrounding cells and vice versa (Junger, 2011; Linden, 1994). In addition, all mammalian cells express extracellular ectonucleotidases that rapidly metabolize nucleotides into adenosine

providing an additional extracellular source of transmitter for the activation of adenosine receptors.

The original nomenclature describing purinergic receptors defined adenosine as binding to P1 receptors and ATP as binding to P2 receptors. Families of both P1 and P2 receptors have since been described, and adenosine receptors are now identified as A-type purinergic receptors, consisting of P1A1, P1A2a, P1A2b, and P1A3. ATP receptors are designated as P type and consist of P2X and P2Y subtypes (Junger, 2011). Recall that P2X subtypes are ionotropic receptors (see earlier discussion).

A-type receptors (P1A) exhibit the classic arrangement of seven transmembrane-spanning segments but are typically shorter than most GPCRs, ranging in size between 35 and 46 kDa. The ligand-binding site of A-type receptors is unique in that the ligand, adenosine, has no inherent charged moieties at physiological pH. A-type receptors appear to utilize His residues as their points of contact with adenosine, and, in particular, a His residue in TM7 is essential because its mutation eliminates agonist binding. Other His residues in TM6 and TM7 are conserved in all A-type receptors and may serve as other points of contact with agonists. A1 receptors are highly expressed in the brain, and their activation down regulates adenylyl cyclase and increases phospholipase C activity. The A2a and A2b receptors are not as highly expressed in nervous tissue and are associated with the stimulation of adenylyl cyclase and phospholipase C, respectively. The A3 subtype exhibits a unique pharmacological profile in that binding of xanthine derivatives (caffeine falls in this class of molecules), which blocks the action of adenosine competitively, is much weaker than for A1 or A2 receptors. Very low levels of the A3 receptor are found in brain and peripheral nervous tissue. The A3 receptor appears to be coupled to the activation of phospholipase C.

The P-type receptors, P2Y1–P2Y7, are also typical G-protein-linked GPCRs, mostly localized to the periphery. However, direct effects of ATP have been detected in neurons, and often the response is biphasic, an early excitatory effect followed, with its breakdown to adenosine, by a secondary inhibitory effect. Interestingly, P-type receptors exhibit a higher degree of homology to peptide-binding receptors than they do to A-type purinergic receptors. As in A-type receptors, P-type receptors have a His residue in the third transmembrane domain and presumably bind to nucleotides using a similar constellation of amino acids as other members of the class A GPCRs.

Serotonin Receptors

Cell bodies containing serotonin (5-HT) are found in the raphe nucleus in the brain stem and in nerve endings distributed diffusely throughout the brain. 5-HT has been implicated in sleep, modulation of circadian rhythms, eating, and arousal. 5-HT also has hormone-like effects when released in the bloodstream, regulating smooth muscle contraction and affecting platelet-aggregating and immune systems.

5-HT receptors are classified into seven subtypes, 5-HT1 to 5-HT7 (Fig. 8.11), with a further subdivision within subtypes. Recall that the 5-HT3 receptor is ionotropic (see earlier discussion). The other 5-HT receptors exhibit the typical seven transmembrane-spanning segments and all couple to G-proteins to exert their effects. For example, 5-HT1a, 1b, 1d, and 4, 5, 6, and 7 either activate or inhibit adenylyl cyclase. 5-HT1c and 5-HT2 receptors preferentially stimulate activation of phospholipase C to produce increased intracellular levels of diacylglycerol and inositol 1,4,5-trisphosphate.

5-HT receptors can also be grossly distributed into two groups on the basis of their gene structures. Both 5-HT1c and 5-HT2 are derived from genes that contain multiple introns. In contrast, similar to the βAR family, 5-HT1 is coded by a gene lacking introns. Interestingly, 5-HT1a is more closely related ancestrally to the D2 receptor family than it is to other membranes of the 5-HT receptor family that are separated quite far apart on the evolutionary tree (Fig. 8.11).

Glutamate GPCRs

GPCRs that bind glutamate (metabotropic glutamate receptors (mGluRs)) are similar in general structure in having seven transmembrane-spanning segments to other GPCRs; however, they are divergent enough to be placed in a separate evolutionary-derived receptor family (Fig. 8.11; Hollmann & Heinemann, 1994; Nakanishi, 1994; Niswender & Conn, 2010). In fact, sequence homology between the mGluR family and other GPCRs is minimal except for the $GABA_B$ receptor (Fig. 8.11) and these two receptor families along with Ca^{2+}-sensing and taste receptors are now grouped together as class C GPCRs. The mGluR family is heterogeneous in size, ranging from 854 to 1179 amino acids. Both the N-terminal and the C-terminal domains are unusually large for G-protein-coupled receptors. The binding site for glutamate resides in the large N-terminal extracellular domain and several crystal structures of this domain in different states have been obtained. The binding site is called the Venus Fly trap Domain (VFD) to anecdotally capture the structural transition of the open to closed nature of the domain when bound to glutamate. Recall that in Class A GPCRs, the ligand-binding pocket sits within the TM domains of the receptor. Additionally, mGluRs exist as functional dimers in the membrane in contrast to the single subunit forms of most GPCRs (Kunishima et al., 2000; Niswender & Conn, 2010).

Because of this dimer structure, the mGluRs can exist in states with either one or two molecules of glutamate bound. Maximal activity requires that two glutamate molecules are bound, but there remains some controversy about whether a single molecule of glutamate can activate the receptor. The second intracellular loop (i2), as opposed to the third intracellular loop in class A GPCRs, along with the large C-terminal domain are thought to be the major determinants responsible for G-protein coupling. The C-terminal domain also serves as the site for interactions with other intracellular scaffolding and regulatory molecules. These significant structural distinctions support the idea that mGluRs evolved separately from other GPCRs.

Currently, eight different mGluRs can be subdivided into three groups on the basis of sequence homologies (Fig. 8.11) and their capacity to couple to specific enzyme systems. Group I includes mGluR1 and mGluR5, and these receptors are found predominantly postsynaptic and activate G-proteins that stimulate phospholipase C or adenylyl cyclase. Group II includes mGluR2 and mGluR3 that are found pre- and postsynaptic, inhibit adenylyl cyclase, inhibit Ca^{2+}-channels, and activate K^+-channels. Group III includes mGluR4–mGluR8 and produce functional effects similar to Group II mGluRs. mGluR6 is unique and is found only in the retina, where it stimulates the enzyme cGMP phosphodiesterase.

Group I mGluRs are selectively activated by the agonist (S)-3,5-dihydroxyphenylglycine [(S)-3,5-DHPG)]. Group II mGluRs are selectively activated by (2S,2′R,3′R)-2-(2′,3′)-Dicarboxycyclopropyl)glycine DCG-IV and (2R,4R)-4-Aminopyrrolidine-2,4-dicarboxylate (2R,4R-APDC) and group II mGluRs are selectively activated by L-(+)-2-Amino-4-phosphonobutyric acid (L-AP4). Numerous other pharmacological compounds have also been developed that can selectively activate members within some of these mGluR classes.

mGluRs are widespread in the nervous system and are found both pre- and postsynaptically on neurons and are also abundant on glia. Generalizations about the specific functions of each class or subtype are difficult. Presynaptically, they serve as autoreceptors and appear to participate in the inhibition of neurotransmitter release. Their postsynaptic roles appear to be quite varied and depend on the specific G-protein to which they are coupled. mGluR1 activation has been implicated in long-term synaptic plasticity at many sites in the brain, including long-term potentiation in the hippocampus and long-term depression in the cerebellum (see Chapter 47).

$GABA_B$ Receptor

$GABA_B$ receptors are found throughout the nervous system, where they are sometimes colocalized with ionotropic $GABA_A$ receptors. $GABA_B$ receptors are present both pre- and postsynaptically. Presynaptically, they appear to mediate inhibition of neurotransmitter release through an autoreceptor-like mechanism by activating K^+ conductances and diminishing Ca^{2+} conductances. In addition, $GABA_B$ receptors may affect K^+ channels through a direct physical coupling to the K^+ channel, not mediated through a G-protein intermediate. Postsynaptically, $GABA_B$ receptor activation produces a characteristic slow hyperpolarization (termed the slow inhibitory postsynaptic potential) through the activation of a K^+ conductance. This effect appears to be through a pertussis toxin-sensitive G-protein that inhibits adenylyl cyclase. The initial cloning of the $GABA_B$ receptor was made possible by the development of the high-affinity, high-specificity antagonist CGP64213. This antagonist is several orders of magnitude more potent at inhibiting $GABA_B$ receptor function than the more widely known antagonist saclofen. Baclofen, an analog of saclofen, remains a common agonist for activating $GABA_B$ receptors.

Cloning of the $GABA_B$ receptor ($GABA_BR1$) revealed that it has high sequence homology to the family of glutamate GPCRs and is also a member of the class C GPCRs that shows little similarity to other GPCRs (Fig. 8.11). The large N-terminal extracellular domain of the $GABA_B$ receptor is the presumed site of GABA binding. With the exception of this large extracellular domain, the $GABA_B$ receptor structure is typical of the GPCR family, exhibiting seven TM domains. Functional $GABA_B$ receptors exist as obligate dimers in the membrane. Expression of the $GABA_B1$ subunit does not produce functional receptors, but when coexpressed with the $GABA_B2$ subunit, receptors that are indistinguishable functionally and pharmacologically from those in brain were produced. GABA binds to the $GABA_B1$ subunit to activate the receptor and the $GABA_B2$ subunit is responsible for coupling to G-proteins (Kniazeff, Prezeau, Rondard, Pin, & Goudet, 2011). As noted earlier, GPCRs can interact with themselves and other receptors. It is well to keep in mind that these types of direct receptor interactions may be more widespread than currently appreciated.

Peptide Receptors

Neuropeptide receptors form an immense family and make up the majority of Class B GPCRs. Because of their diversity, they cannot be covered in detail in this chapter. Despite this diversity, however, none of the receptors that bind peptides appears to be ionotropic (coupled directly to the opening of ion channels). Neuropeptide receptors exert their effects either through the typical pathway of activation of G-proteins or through the activation of an associated tyrosine kinase activity.

Summary

GPCRs are typically single polypeptides composed of seven TM-spanning segments. The binding site for neurotransmitter in Class A GPCRs is located within the core of the circular structure formed by these TM segments. Transmitter binding produces conformational changes in the receptor that expose parts of the i3 region, among others, for binding to G-proteins that activate additional downstream enzymes or other effectors. G-protein binding increases the affinity of the receptor for transmitter. Desensitization is common among GPCRs and leads to a decreased response of the receptor to neurotransmitter by several distinct mechanisms. Class C GPCRs are structurally distinct from the other classes. They have large N-terminal extracellular domains that form the binding site for neurotransmitter. Additionally, functional class C GPCRs appear to function as homo- or heterodimers in the membrane, but otherwise couple to G-proteins in a similar manner to the rest of the GPCR family.

CHAPTER

9

Intracellular Signaling

SIGNALING THROUGH G-PROTEIN-LINKED RECEPTORS

Signal transduction through G-protein-linked receptors requires three membrane-bound components: (1) a cell surface receptor that determines to which signal the cell can respond; (2) a G protein on the intracellular side of the membrane that is stimulated by the activated receptor; and (3) either an effector enzyme that changes the level of a second messenger or an effector channel that changes ionic fluxes in the cell in response to the activated G protein. The human genome encodes for more than 800 receptors for catecholamines, odorants, neuropeptides, and light that couple to one or more of the 16 identified G proteins. These, in turn, regulate one or more of more than two dozen different effector channels and enzymes. The key feature of this information flow is the ability of G proteins to detect the presence of activated receptors and to amplify the signal by altering the activity of appropriate effector enzymes and channels. A nervous system with information flow by fast transmission alone would be capable of stereotyped or reflex responses. Modulation of this transmission and changes in other cellular functions by G-protein-linked systems and by receptor-tyrosine kinase-linked systems enables an orchestrated response. The large diversity of signaling molecules and their intracellular targets offer nearly unlimited flexibility of response over a broad time scale and with high amplification.

G proteins are GTP-binding proteins that couple the activation of seven-helix receptors by neurotransmitters at the cell surface to changes in the activity of effector enzymes and effector channels. A common effector enzyme is adenylate cyclase, which synthesizes cyclic AMP (cAMP)—an intracellular surrogate for the neurotransmitter, the first messenger. Phospholipase C (PLC), another effector enzyme, generates diacylglycerol (DAG) and inositol 1, 4, 5-trisphosphate (IP_3), the latter of which releases intracellular stores of Ca^{2+}. Information from an activated receptor flows to the second messengers that typically activate protein kinases, which modify a host of cellular functions. Ca^{2+}, cAMP, and DAG have in common the ability to activate protein kinases with broad substrate specificities. They phosphorylate key intracellular proteins, ion channels, enzymes, and transcription factors taking part in diverse cellular biological processes. The activities of protein kinases and phosphatases are in balance, constituting a highly regulated process, as revealed by the phosphorylation state of these targets of the signal transduction process. In addition to regulating protein kinases, second messengers such as cAMP, cyclic GMP (cGMP), Ca^{2+}, and arachidonic acid can directly gate, or modulate, ion channels. G proteins can also couple directly to ion channels without the interception of second messengers or protein kinases. In these diverse ways, a neurotransmitter outside the cell can modulate essentially every aspect of cell physiology and encode the history of cell stimuli in the form of altered activity and expression of its cellular constituents. An overview of G-protein signaling to protein kinases is presented in Fig. 9.1.

Receptors Catalyze the Conversion of G Proteins into the Active GTP-Bound State

G proteins undergo a molecular switch between two interconvertible states that are used to "turn on" or "turn off" downstream signaling. G proteins taking part in signal transduction utilize a regulatory motif that is seen in other GTPases engaged in protein synthesis and in intracellular vesicular traffic. G proteins are switched on by stimulated receptors, and they switch themselves off after a time delay. G proteins are inactive when GDP is bound and are active when GTP is bound. The sole function of seven-helix receptors in activating

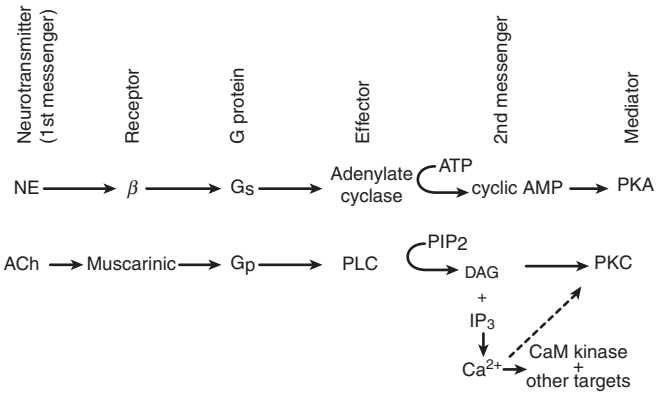

FIGURE 9.1 Overview of G-protein signaling to protein kinases. Norepinephrine (NE) and acetylcholine (ACh) can stimulate certain receptors that couple through distinct G proteins to different effectors, which results in increased synthesis of second messengers and activation of protein kinases (PKA and PKC). PLC, phospholipase C; PIP_2, phosphatidylinositol bisphosphate; DAG, diacylglycerol; CaM, Ca^{2+}-calmodulin dependent; IP_3, inositol 1, 4, 5-triphosphate.

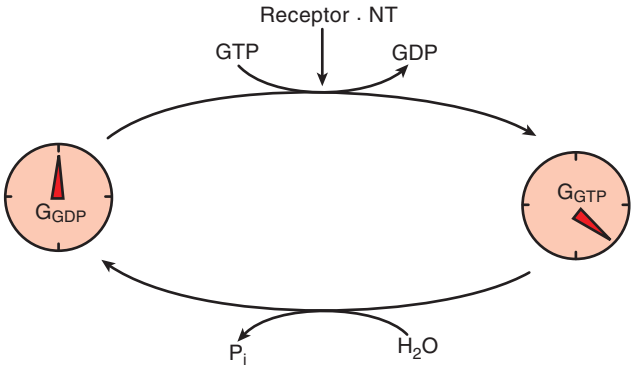

FIGURE 9.2 GTPase activity of G proteins serves as a timer and amplifier. Receptors activated by neurotransmitters (NT) initiate the GTPase timing mechanism of G proteins by displacement of GDP by GTP. Neurotransmitters thus convert G-GDP ("turned-off state") to G-GTP (time-limited "turned-on" state).

G proteins is to catalyze an exchange of GTP for GDP. This is a temporary switch because G proteins are designed with a GTPase activity that hydrolyzes the bound GTP and converts the G protein back into the GDP-bound, or inactive, state. Thus, a G protein must continuously sample the state of activation of the receptor, and it transmits downstream information only while the neuron or glial cell is exposed to neurotransmitter. The GTPase activity of G proteins thus serves both as a regulatable timer and as an amplifier (Fig. 9.2).

The G-Protein Cycle

G proteins are trimeric structures composed of two functional units: (1) an α subunit (39–52 kDa) that

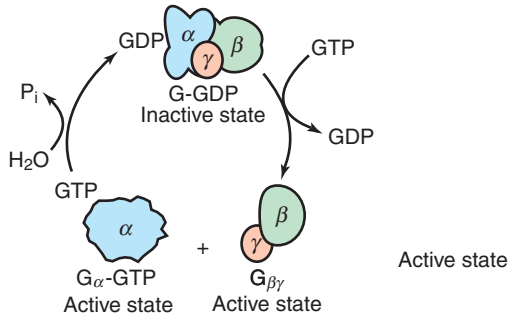

FIGURE 9.3 Interconversion, catalyzed by excited receptors, of G-protein subunits between inactive and active states. Displacement of GDP with GTP dissociates the inactive heterotrimeric G protein, generating α-GTP and $\beta\gamma$, both of which can interact with their respective effectors and activate them. The system converts into the inactive state after GTP has been hydrolyzed and the subunits have reassociated. *From Stryer (1995). Used with permission of W. H. Freeman and Company.*

catalyzes GTPase activity and (2) a $\beta\gamma$ dimer (35 and 8 kDa, respectively) that interacts tightly with the α subunit when bound to GDP (Stryer & Bourne, 1986; Birnbaumer, 2007). The role of the three subunits in the G-protein cycle is depicted in Figures 9.3 and 9.4. In the basal state, GDP is bound tightly to the α subunit, which is associated with the $\beta\gamma$ pair to form an inactive G protein. In addition to blocking interaction of the α subunit with its effector, the $\beta\gamma$ pair increases the affinity of the α subunit for activated receptors. Binding of the neurotransmitter to the receptor produces a conformational change that positions previously buried residues that promote increased affinity of the receptors for the inactive G protein. A given receptor can interact with only one or a limited number of G proteins, and the α subunit generates most of this specificity. Coupling with the activated receptor reduces the affinity of the α subunit for GDP, facilitating its dissociation and replacement with GTP. Thus, the receptor effectively catalyzes an exchange of GTP for GDP. GTP-GDP exchange is inherently very slow and ensures that very little of the G protein is in the on state under basal conditions. The level of G protein in the "on" state can increase from being 1% to being more than 50% of all G protein (Stryer & Bourne, 1986).

Information Flow through G-Protein Subunits

One of the more tense and public debates in signal transduction has been the question of whether the α subunit alone conveys information that specifies which effector is activated or whether the $\beta\gamma$ pair can also interact with effectors. One of the contestants even paid for a vanity license plate proclaiming "α not $\beta\gamma$." This notion was eventually changed because of the finding that $\beta\gamma$ can directly activate certain K^+ channels. It is now apparent that α and $\beta\gamma$ subunits can both modify effector

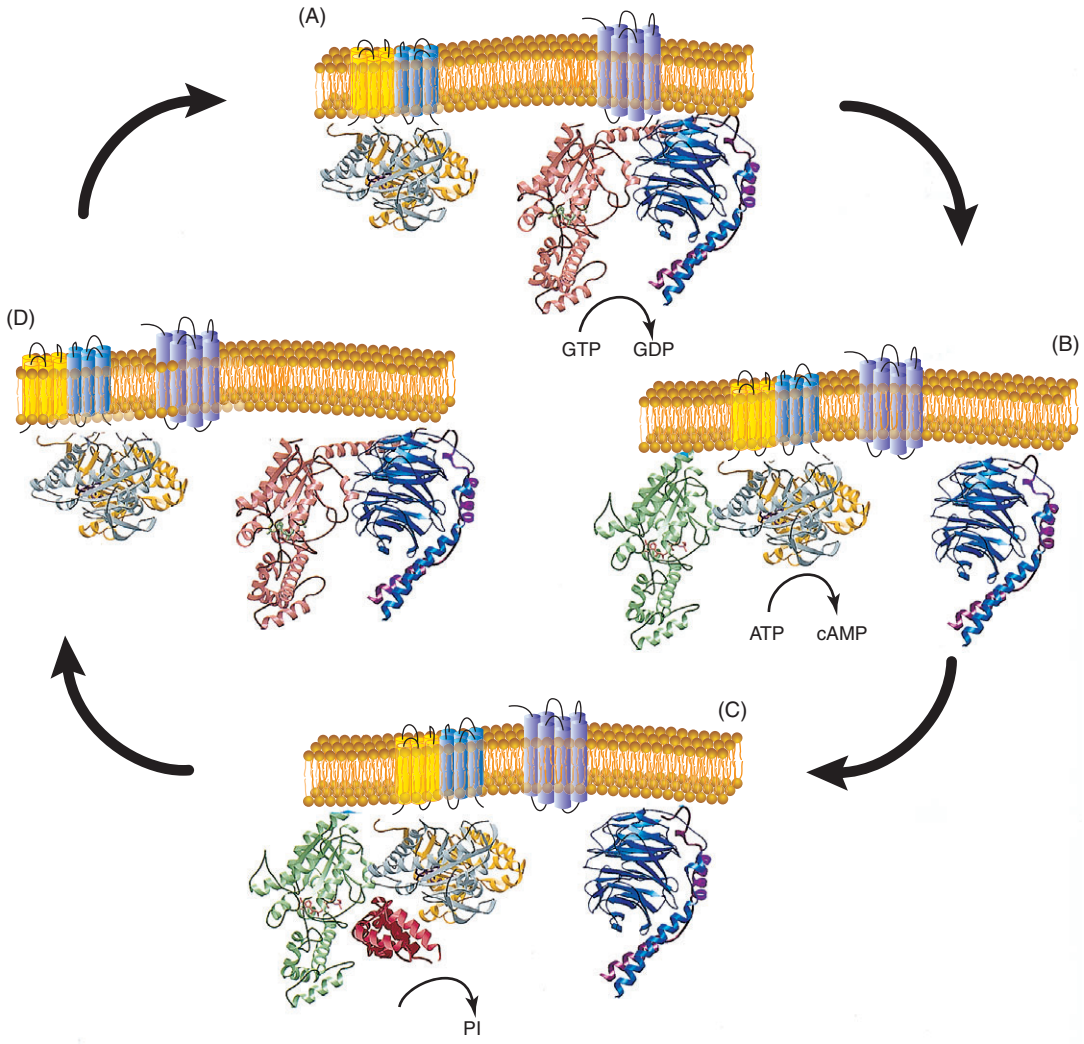

FIGURE 9.4 (A) G proteins are held in an inactive state because of very high affinity binding of GDP to their α subunits. When activated by agonist, membrane-bound seven helical receptors (Fig. 9.4 right, glowing magenta) interact with heterotrimeric G proteins (α, amber; β, teal; γ, burgundy) and stimulate dissociation of GDP. This permits GTP to bind to and activate α, which then dissociates from the high-affinity dimer of β and γ subunits. (B) Both activated (GTP-bound) α (lime) and $\beta\gamma$ are capable of interacting with downstream effectors. Figure 9.4 shows the interaction of GTP-α_s with adenylate cyclase (catalytic domains are mustard and ash). Adenylate cyclase then catalyzes the synthesis of the second messenger cyclic AMP (cAMP) from ATP. (C) Signaling is terminated when α hydrolyzes its bound GTP to GDP. In some signaling systems, GTP hydrolysis is stimulated by GTPase-activating proteins or GAPs (cranberry) that bind to α and stablize the transition state for GTP hydrolysis. (D) Hydrolysis of GTP permits GDP-α to dissociate from its effector and associate again with $\beta\gamma$. The heterotrimeric G protein is then ready for another signaling cycle if an activated receptor is present. This figure is based on the original work of Mark Wall and John Tesmer.

enzymes, but the historic association of G-protein function with α has persisted for the purpose of nomenclature, with G_s and α_s referring to the G protein and its corresponding α subunit, which stimulates adenylate cyclase. The α subunits may act either independently or in concert with $\beta\gamma$ (Clapham & Neer, 1993). Furthermore, β and γ subunits in a $\beta\gamma$ pair can combine in many different ways. Other legacy terms include G_i, G_p, and G_o used for G-protein activities that inhibited adenylate cyclase, stimulated phospholipase, or were presumed to have other effects, respectively.

Effector Enzymes, Channels, and Transporters Decode Receptor-Mediated Cell Stimulation in the Cell Interior

The function of the trimeric G proteins is to decode information about the concentration of neurotransmitters bound to appropriate receptors on the cell surface and convert this information into a change in the activity of enzymes and channels that mediate the effects of the neurotransmitter. The known effector functions of α include both stimulation and inhibition of adenylate

cyclases that is sensitive to cholera toxin and pertussis toxin, respectively. In addition, it modulates activation of cGMP phosphodiesterase, PLC, and regulation of Na^+/K^+ exchange, PI3K, RhoGEF and rasGAP. The effector functions of $\beta\gamma$ dimers include inhibition of many adenylate cyclases and co-stimulation of others. In addition, they regulate stimulation of phospholipase Cβ, K^+ and Ca^{2+} channels, phospholipase A_2, phosphatidylinositol-3-kinase, PKD and dynamin in vesicle budding.

Response Specificity in G-Protein Signaling

How can a neurotransmitter produce a specific response if G-protein coupling has the potential for such a diversity of effectors? A given neuron has only a subset of receptors, G proteins, and effectors, thereby limiting possible signaling pathways. Transducin, for example, is confined to the visual system, where the predominant effector is the cGMP phosphodiesterase and not adenylate cyclase. Signal specificity is further refined by selective affinities between cognate sets of receptors, G proteins, and effector(s), and by spatial compartmentalization, such as at nerve terminals, where co-localization effects privileged signaling from a given receptor to a limited set of effectors. Furthermore, the intrinsic GTPase activity of G proteins can be modulated by GTPase-activating proteins (GAPs) that terminate its active state more quickly and selectively affect signal output.

Fine-Tuning of cAMP by Adenylate Cyclases

The level of cAMP is highly regulated due to a balance between synthesis by adenylate cyclases and degradation by cAMP phosphodiesterases (PDEs). Each of these enzymes can be regulated and manipulated independently. Adenylate cyclase was the first G-protein effector to be identified, and now a group of related adenylate cyclases are known to be regulated differentially by both α and $\beta\gamma$ subunits (Taussig & Gilman, 1995). G proteins can both activate and inhibit adenylate cyclases either synergistically or antagonistically.

Adenylate cyclases are large proteins of approximately 120 kDa. They consist of a tandem repeat of the same structural motif—a short cytoplasmic region followed by six putative transmembrane segments and then a highly conserved catalytic domain of approximately 35 kDa on the cytoplasmic side that bind ATP and catalyze its conversion into cAMP. Some isoforms are activated by calmodulin, a Ca^{2+}-binding protein that activates many enzymes after it binds Ca^{2+}.

Differential Regulation of Adenylate Cyclase Isoforms

All adenylate cyclase isoforms are stimulated by G_s through its α_s subunit. Known isoforms can be divided into four groups on the basis of additional regulatory properties (Fig. 9.5). Group I (AC1, 3, 8) possesses a calmodulin-binding domain and is activated by Ca^{2+}-calmodulin. Group II (AC2, 4, 7) is weakly responsive to direct interaction with α_s or $\beta\gamma$ but is highly activated when both are present. As described later, this synergistic effect enables this cyclase to function as a coincidence detector. Group III cyclases (AC5, 6) are negatively regulated by inhibitory G proteins, whereas Group IV (AC9) has a forskolin-insensitive cyclase.

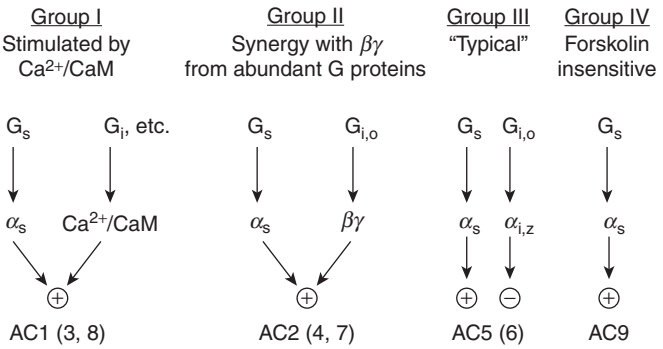

FIGURE 9.5 Isoforms of adenylate cyclase (AC). All isoforms are stimulated by α_s but differ in the degree of interaction with Ca^{2+}-calmodulin and with $\beta\gamma$ derived from inhibitory G proteins. Not shown is the ability of excess $\beta\gamma$ to complex with α_s and inhibit Group I and Group III adenylate cyclases. *Updated from Taussig and Gilman (1995).*

INHIBITION OF ADENYLATE CYCLASES

Adenylate cyclases are also subject to several forms of inhibitory control. First, activation of all adenylate cyclases can be antagonized by $\beta\gamma$ released from abundant G proteins, such as G_i, G_o, and G_z. Released $\beta\gamma$ complexes with α_s-GTP and shift the equilibrium toward an inactive trimer by mass action. Second, either α or $\beta\gamma$ subunits derived from G_i, G_o, or G_z can directly inhibit group I cyclases, and the α subunit from G_i or G_z can inhibit Group III cyclases. The level of G_s in particular is low; thus, a_s derived from G_s is sufficient to activate adenylate cyclases, but the $\beta\gamma$ derived from it is insufficient to directly inhibit or activate adenylate cyclases. This explains the apparent paradox that receptors that couple to G_s produce effects only through a_s, whereas receptors that couple to G_i produce effects through both α_i and $\beta\gamma$. Additional inhibitory regulation of some groups is also effected by CaM kinases and by calcium.

RECEPTORS COUPLING TO ADENYLATE CYCLASE

Dozens of neurotransmitters and neuropeptides work through cAMP as a second messenger and by G protein-linked activation or inhibition of adenylate cyclase. Among the neurotransmitters that increase cAMP are the amines norepinephrine, epinephrine, dopamine, serotonin, and histamine and the neuropeptides vasointestinal peptide (VIP) and somatostatin. In the olfactory system, a special form of G-protein α subunit, termed

α_{olf}, serves the same function as α_s and couples several hundred seven-helix receptors to AC3 adenylate cyclase in the neuroepithelium.

ADENYLATE CYCLASES AS COINCIDENCE DETECTORS

Adenylate cyclases can integrate concurrent stimulation of neurons by two or more neurotransmitters (Bourne & Nicoll, 1993). AC1 adenylate cyclase is stimulated by neurotransmitters that couple to G_s and by neurotransmitters that elevate intracellular Ca^{2+}. This adenylate cyclase can convert the depolarization of neurons into an increase in cAMP. Its role in associative forms of learning may be related to its ability to link cAMP-based and Ca^{2+}-based signals. Stimulation of AC2 adenylate cyclase by α_s is conditional on the presence of $\beta\gamma$ derived from an abundant G protein—that is, other than G_s, thus enabling the cyclase to serve as a coincidence detector. Thus, activation of a second receptor, presumably coupled to the abundant G_i and G_o, is needed to provide the $\beta\gamma$.

Sources of Second Messengers: Phospholipids

Two phospholipids—phosphatidylinositol 4,5-bisphosphate (PIP_2) and phosphatidylcholine (PC)—are primary precursors for a G-protein-based second-messenger system. Three second-messengers—diacylglycerol, arachidonic acid and its metabolites, and elevated Ca^{2+}—are ultimately produced. A single step converts inert phospholipid precursors into lipid messengers. DAG action is primarily mediated by protein kinase C (PKC) (Tanaka & Nishizuka, 1994). The elevation of Ca^{2+} levels is accomplished by the regulated entry of Ca^{2+} from a concentrated pool sequestered in the endoplasmic reticulum or from outside the cell. Ca^{2+} has many direct cellular targets but mediates most of its effects through Ca^{2+}/calmodulin. One class of calmodulin-dependent enzymes is a family of protein kinases that enable Ca^{2+} signals to regulate a large number of cellular processes by phosphorylation (Wayman et al., 2008).

GENERATION OF DAG AND IP_3 FROM G_q AND G_i COUPLED TO PLCβ

The phosphatidylinositide-signaling pathway is just as prominent in neuronal signaling as the cAMP pathway and is similar to it in overall design (Berridge, 2009). Stimulation of a large number of neurotransmitters and hormones [including acetylcholine (Ml, M3), serotonin ($5HT_2$, $5HT_{1C}$), norepinephrine (α_{1A}, α_{1B}), glutamate (metabotropic), neurotensin, neuropeptide Y, and substance P] is coupled to the activation of a phosphatidylinositide-specific PLC.

Phosphatidylinositol (PI) is composed of a diacylglycerol backbone with myoinositol attached to the *sn*-3 hydroxyl by a phosphodiester bond (Fig. 9.6). The *six* positions of the inositol are not equivalent: the 1 position is attached by a phosphate to the DAG moiety. PI is phosphorylated by PI kinases at the 4 position and then at the 5 position to form PIP_2. In response to the appropriate G-protein coupling, PLC hydrolyzes the bond between the *sn*-3 hydroxyl of the DAG backbone and the phosphoinositol to produce two second messengers: DAG, a hydrophobic molecule, and IP_3, which is water soluble (Fig. 9.7). There are six classes of PLCs that hydrolyze PIP_2 (PLCβ, γ, δ, ε, ζ, and η), with a common catalytic domain structure but different regulatory properties. G proteins couple to several variants of PLCβ. PLCγ is regulated by growth factor tyrosine kinases. Less is known about regulation of the others, but PKCε can be regulated by both G proteins and small GTPases.

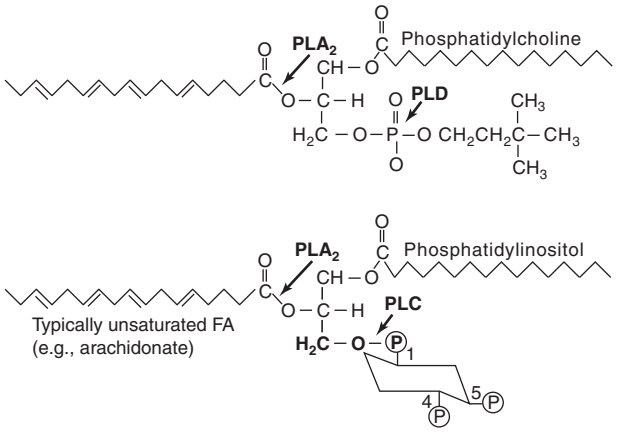

FIGURE 9.6 Structures of phosphatidylinositol and phosphatidylcholine. The sites of hydrolytic cleavage by PLC, PLD, and PLA_2 are indicated by arrows. FA, fatty acid.

PLCβ is coupled to neurotransmitters by G_i and G_q. A pertussis toxin-sensitive pathway is mediated by a number of isoforms referred to as G_q and mediated by their α_q. G_i is coupled to PLCβ via its $\beta\gamma$ rather than α subunit in a pathway that is insensitive to pertussis toxin. Receptor tyrosine kinases can regulate PLCγ by a G-protein-independent pathway involving their recruitment to the receptor and activation via phosphorylation.

DAG DERIVED FROM ACTIVATION OF PHOSPHOLIPASE D

A slower but larger increase in DAG can be generated by activation of phospholipase D (PLD), which cleaves phosphatidylcholine to produce phosphatidic acid and choline. Dephosphorylation of phosphatidic acid produces DAG. The PLD pathway may be used by some mitogens and growth factors and likely contains a variety of activation schemes that may include G proteins.

ADDITIONAL LIPID MESSENGERS

DAG is itself a source of another lipid messenger, by the action of phospholipase A_2 (PLA_2), which releases

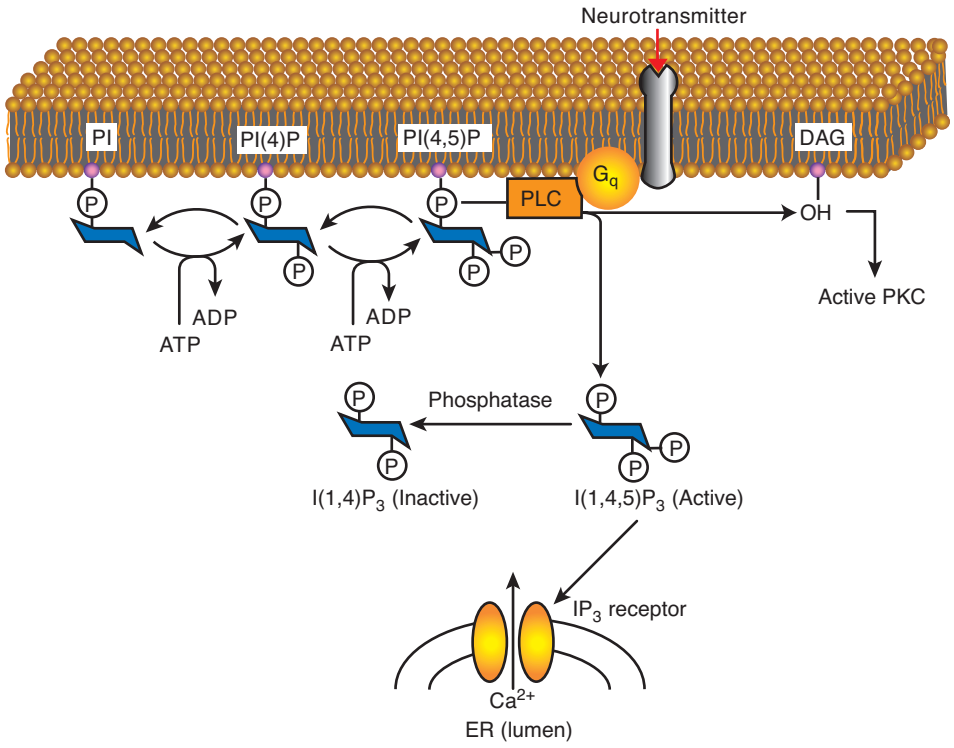

FIGURE 9.7 Schematic pathway of IP3 and DAG synthesis and action. Stimulation of receptors coupled to Gq activates PLCβ, which leads to the release of DAG and IP_3. DAG activates PKC, whereas IP_3 stimulates the IP_3 receptor in the endoplasmic reticulum (ER), leading to mobilization of intracellular Ca^{2+} stores.

the fatty acid, typically arachidonic acid, from the *sn*-2 position of the DAG backbone (Fig. 9.6). Arachidonic acid has biological activity of its own in addition to serving as a precursor for prostaglandins and leukotrienes. Arachidonic acid and other *cis*-unsaturated fatty acids can modulate K^+ channels, PLCγ, and some forms of PKC.

The phosphatidylinositides exist with modifications at the 3, 4, and 5 position to generate a family of seven lipids, [PI3P, PI4P, PI5P, PI(3,4)P2, PI(4,5)P2, PI(3,5)P2, and PI(3,4,5)P3] lipids that mediate important structural or enzymatic effects. They bind to specific protein binding domains to regulate vesicular traffic and protein kinases involved in survival and cell death. Mutations in their synthesis and metabolism have pathophysiological consequences (McCrea & De Camilli, 2009). There is evidence that another lipid, sphingomyelin, is a precursor for intracellular signals as well.

IP3, A POTENT SECOND MESSENGER THAT PRODUCES ITS EFFECTS BY MOBILIZING INTRACELLULAR Ca^{2+}

The main function of IP_3 is to stimulate the release of Ca^{2+} from intracellular stores. Ca^{2+} levels are kept low in the cytosol by its sequestration in the ER where it is complexed with low-affinity-binding proteins. The ER is the major IP_3-sensitive Ca^{2+} store in cells (Fig. 9.7) and Ca^{2+} readily flows down its concentration gradient into the cell lumen upon opening of Ca^{2+} channels in the ER.

The IP_3 receptor is a macromolecular complex that functions as an IP_3 sensor and a Ca^{2+} release channel. It has a broad tissue distribution but is highly concentrated in the cerebellum. The IP_3 receptor is a tetramer of 313-kDa subunits with a single IP_3-binding site at its N-terminal of each subunit, facing the cytoplasm. Ca^{2+} release by IP_3 is highly cooperative so that a small change in IP_3 has a large effect on Ca^{2+} release from the ER. The mouse mutants *pcd* and *nervous* have deficient levels of the IP_3 receptor and exhibit defective Ca^{2+} signaling, and a genetic knockout of the IP_3 receptor leads to motor and other deficits.

TERMINATION OF THE IP_3 SIGNAL

IP_3 is a transient signal terminated by dephosphorylation to inositol. Inactivation is initiated either by dephosphorylation to inositol 1,4-bisphosphate (Fig. 9.8) or by an initial phosphorylation to a tetrakisphosphate form that is dephosphorylated by a different pathway. Both pathways have in common an enzyme that cleaves the phosphate on the 1 position. Complete dephosphorylation yields inositol, which is recycled in the biosynthetic pathway. Recycling is important because most tissues do not contain *de novo* biosynthetic pathways for making inositol. Salvaging inositol may be particularly important

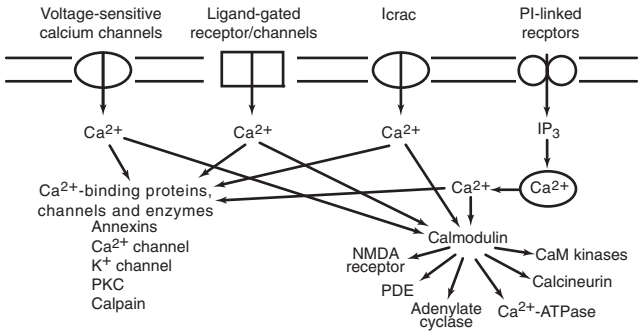

FIGURE 9.8 Multiple sources of Ca^{2+} converge on calmodulin and other Ca^{2+}-binding proteins. Cellular levels of Ca^{2+} can rise either by influx (e.g., through voltage-sensitive channels or ligand-gated channels) or by redistribution from intracellular stores triggered by IP_3. Calcium modulates dozens of cellular processes by the action of the Ca^{2+}-calmodulin complex on many enzymes, and calcium has some direct effects on enzymes such as PKC and calpain. CaM kinase, Ca^{2+}-calmodulin-dependent kinase.

when cells are actively undergoing PI turnover. It is intriguing that Li^+, the simple salt used to treat bipolar disorder, selectively inhibits the salvage of inositol by inhibiting the enzyme that dephosphorylates the 1 position and is common to the two pathways. At therapeutic doses of Li^+, the reduced salvage of inositol in cells with high phosphoinositide signaling may lead to a depletion of PIP_2 and a selective inhibition of this signaling pathway in active cells.

Calcium Ion

Calcium has a dual role as a carrier of electrical current and as a second messenger. Its effects are more diverse than those of other second messengers such as cAMP and DAG because its actions are mediated by a much larger array of proteins, including protein kinases (Carafoli and Klee, 1999). Furthermore, many signaling pathways directly or indirectly increase cytosolic Ca^{2+} concentration from 100 nM to 0.5–1.0 mM. The source of elevated Ca^{2+} can be either the ER or the extracellular space (Fig. 9.8). In addition to IP_3-mediated release, Ca^{2+} can activate its own mobilization through the ryanodine receptor on the ER. Mechanisms for Ca^{2+} influx from outside the cell include several voltage-sensitive Ca^{2+} channels and ligand-gated cation channels that are permeable to Ca^{2+} [e.g., nicotinic receptor and *N*-methyl-d-aspartate (NMDA) receptor].

DYNAMICS OF Ca^{2+} SIGNALING REVEALED BY FLUORESCENT Ca^{2+} INDICATORS

We know a great deal about the spatial and temporal regulation of Ca^{2+} signals because of the development of fluorescent Ca^{2+} indicators. A variety of fluorescent compounds selectively bind Ca^{2+} at physiological concentration ranges and rapidly change their fluorescent properties upon binding Ca^{2+} to a fairly accurate measurement of ionized Ca^{2+}.

Calmodulin-Mediated Effects of Ca^{2+}

Ca^{2+} acts as a second messenger to modulate the activity of many mediators. The predominant mediator of Ca^{2+} action is calmodulin, a ubiquitous 17-kDa calcium-binding protein. Ca^{2+} binds to calmodulin in the physiological range and converts it into an activator of many cellular targets (Cohen & Klee, 1988). Binding of Ca^{2+} to calmodulin produces a conformational change that greatly increases its affinity for more than two dozen eukaryotic enzymes that it activates, including cyclic nucleotide PDEs, adenylate cyclase, nitric oxide synthase, Ca^{2+}-ATPase, calcineurin (a phophoprotein phosphatase), and several protein kinases (Fig. 9.8). This activation of calmodulin allows neurotransmitters that change Ca^{2+} to affect dozens of cellular proteins, presumably in an orchestrated fashion.

REGULATION OF GUANYLATE CYCLASE BY NITRIC OXIDE

An important target of Ca^{2+}-calmodulin is the enzyme nitric oxide synthase (NOS). This enzyme synthesizes one of the simplest known messengers, the gas NO (Sen & Snyder, 2010). In the pathway that led to its discovery, acetylcholine stimulates the PI signaling pathway in the endothelium to increase intracellular Ca^{2+}, which activates NOS so that more NO is made. NO then diffuses radially from the endothelial cells across two cell membranes to the smooth muscle cell, where it activates guanylate cyclase to make cGMP. This in turn activates a cGMP-dependent protein kinase that phosphorylates proteins, leading to a relaxation of muscle. In 1998, Robert F. Furchgott, Louis J. Ignarro, and Ferid Murad received the Nobel Prize for their discoveries concerning nitric oxide as a signaling molecule and therapeutic mediator in the cardiovascular system.

Let us now turn to the details of the NO pathway. Nitric oxide is derived from L-arginine in a reaction catalyzed by NOS, a complex enzyme that converts L-arginine and O_2 into NO and L-citrulline. NO lasts only a few seconds in biological fluids and thus no specialized processes are needed to inactivate this particular signaling molecule. As a gas, NO is soluble in both aqueous and lipid media and can diffuse readily from its site of synthesis across the cytosol or cell membrane and affect targets in the same cell or in nearby neurons, glia, and vasculature (Sen & Snyder, 2010). NO produces a variety of effects, including relaxation of smooth muscle of the vasculature, relaxation of smooth muscle of the gut in peristalsis, and killing of foreign cells by macrophages. It was first recognized as a neuronal messenger that couples glutamate receptor stimulation to increases in cGMP. NO produced by Ca^{2+}-calmodulin-dependent

activation of NOS concentrated in cerebellar granule cells activates guanylate cyclase in nearby Purkinje cells during the induction of long-term depression in the cerebellum (see Chapter 32).

ACTIVATION OF GUANYLATE CYCLASES

Two types of guanylate cyclase, a soluble one regulated by NO and a membrane-bound enzyme regulated directly by neuropeptides, synthesize cGMP from GTP in a reaction similar to the synthesis of cAMP from ATP. NO activates the soluble enzyme by binding to the iron atom of the heme moiety. This is the basic mechanism for the regulation of soluble guanylate cyclases. A number of therapeutic muscle relaxants, such as nitroglycerin and nitroprusside, are NO donors that produce their effects by stimulating cGMP synthesis. Membrane-bound guanylate cyclases are transmembrane proteins with a binding site for neuroendocrine peptides on the extracellular side of the plasma membrane and a catalytic domain on the cytosolic side.

Cyclic GMP Phosphodiesterase, an Effector Enzyme in Vertebrate Vision

The versatility of G-protein signaling is illustrated in vertebrate phototransduction, in which a specialized G protein called transducin (G_t) is activated by light rather than by a hormone or neurotransmitter. Transducin stimulates cGMP phosphodiesterase, an effector enzyme that hydrolyzes cGMP and ultimately turns off the dark current (see Chapter 27). Nature has evolved an elegant mechanism for using photons of light to modify a hormone-like molecule, retinal, that activates a seven-helix receptor called rhodopsin. Activated rhodopsin dissociates α_t from transducin which then activates a soluble cGMP phosphodiesterase.

Rods can detect a single photon of light because the signal-to-noise ratio of the system is very low and the amplification factor in phototransduction is quite high; one rhodopsin molecule stimulated by a single photon can activate 500 transducins. Transducin remains in the "on" state long enough to activate 500 PDEs. PDE can hydrolyze about 100 cGMP molecules in the second before it is deactivated. cGMP in rods regulates a cGMP-gated cation channel, leading to additional amplification of the signal.

Modulation of Ion Channels by G Protein

Each type of neuron has a repertoire of ion channels that give it a distinct response signature, and it is not surprising that several types of mechanisms regulate these channels. Channel modulation occurs via G proteins, second messengers, and their cognate protein kinases that phosphorylate ion channels as well as by direct effects of G proteins (Greengard, 2001).

The first ion channel demonstrated to undergo regulation by G proteins was the cardiac K^+ channel that mediates slowing of the heart by acetylcholine released from the vagus nerve. When this I_{KACh} channel is examined in a membrane patch delimited by the seal of a cell-attached electrode, the addition of acetylcholine within the electrode increases the frequency of channel opening dramatically, whereas the addition of acetylcholine to the cell surface outside the seal does not. The process is therefore described as membrane delimited, with a direct interaction between the G protein (either α_i or $\beta\gamma$) and the channel.

Ca^{2+} channels are also modulated by G proteins. The central role played by Ca^{2+} in muscle contraction, in synaptic release, and in gene expression makes Ca^{2+} influx a compelling target for regulation by neurotransmitters. In the heart, where L-type Ca^{2+} channels are critical for the regulation of contractile strength, the Ca^{2+} current is enhanced by a_s formed by β-adrenergic stimulation of G_s. In contrast, N-type Ca^{2+} channels, which modulate synaptic release in nerve terminals, are often inhibited by muscarinic and α-adrenergic agents and by opiates acting at receptors coupled to G_i and G_o.

G-Protein Signaling Gives Special Advantages in Neural Transmission

The G-protein-based signaling system provides several advantages over fast transmission (Hille, 1992; Birnbaumer, 2007). These advantages include amplification of the signal, modulation of cell function over a broad temporal range, diffusion of the signal to a large cellular volume, cross talk, and coordination of diverse cell functions. The sacrifice in speed relative to signaling by ligand gated ion channels is compensated by a broad range of signaling that facilitates integration of signals by the G-protein system. A slower time frame means that cellular processes that are quite distant from the receptor can be modulated. Diffusion of second messengers such as IP_3, Ca^{2+}, and DAG can extend neurotransmission through the cell body and to the nucleus to alter gene expression and via NO to other cells. Neurotransmitters acting through G proteins can elicit a coordinated response of the cell that can modulate synaptic release, resynthesis of neurotransmitter, membrane excitability, the cytoskeleton, metabolism, and gene expression.

Summary

A major class of signaling utilizing G-protein-linked signals affords the nervous system a rich diversity of modulation, amplification, and plasticity. Signals are mediated through second messengers activating proteins that modify cellular processes and gene transcription. A key feature is the ability of G proteins to detect the presence of activated receptors and to amplify the signal

through effector enzymes and channels. Phosphorylation of key intracellular proteins, ion channels, and enzymes activates diverse, highly regulated cellular processes. The specificity of response is ensured through receptors reacting only with a limited number of G proteins. Coupling between receptor, G protein, and its effector(s), and spatial compartmentalization of the system enables specificity and localized control of signaling. Phospholipids and phosphoinositols provide substrates for second-messenger signaling for G proteins. Stimulation of release of intracellular calcium is often the mediator of the signal. Calcium itself has a dual role as a carrier of electrical current and as a second messenger. Calmodulin is a key regulator that provides complexity and enhances specificity of the signaling system. Sensitivity of the system is imparted by an extremely robust amplification system, as seen in the visual system, which can detect single photons of light.

MODULATION OF NEURONAL FUNCTION BY PROTEIN KINASES AND PHOSPHATASES

Protein phosphorylation and dephosphorylation are key processes that regulate cellular function. They play a fundamental role in mediating signal transduction initiated by neurotransmitters, neuropeptides, growth factors, hormones, and other signaling molecules (Fig. 9.9). The functional state of many proteins is modified by phosphorylation-dephosphorylation, the most ubiquitous post-translational modification in eukaryotes. More than a fifth of all proteins serve as targets for kinases and phosphatases. Phosphorylation or dephosphorylation can rapidly modify the function of enzymes, structural and regulatory proteins, receptors, and ion channels taking part in diverse processes, without a need to change the level of their expression. It can also produce long-term alterations in cellular properties by modulating transcription and translation and changing the complement of proteins expressed by cells.

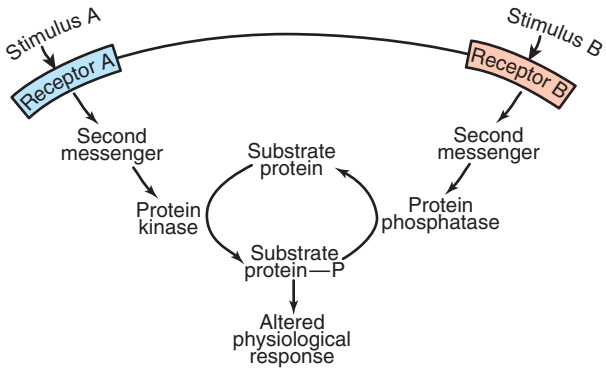

FIGURE 9.9 Regulation by protein kinases and protein phosphatases. Enzymes and other proteins serve as substrates for protein kinases and phosphoprotein phosphatases, which modify their activity and control them in a dynamic fashion. Multiple signals can be integrated at this level of protein modification. *Adapted from Svenningsson et al. (2004).*

Protein kinases catalyze the transfer of the terminal, or γ, phosphate of ATP to the hydroxyl moieties of Ser, Thr, or Tyr residues at specific sites on target proteins. Most protein kinases are either Ser/Thr kinases or Tyr kinases, with only a few designed to phosphorylate both categories of acceptor amino acids. Protein phosphatases catalyze the hydrolysis of the phosphoryl groups from phosphoserine, phosphothreonine, phosphotyrosine, or both types of phosphorylated amino acids on phosphoproteins.

The activity of protein kinases and protein phosphatases is often regulated either by a second messenger (e.g., cAMP or Ca^{2+}) or by an extracellular ligand (e.g., nerve growth factor). In general, second-messenger-regulated kinases modify Ser and Thr, whereas receptor-linked kinases modify Tyr. Among the many protein kinases and protein phosphatases in neurons, a relatively small number serve as master regulators to orchestrate neuronal function. The cAMP-dependent protein kinase (PKA) is a prototype for the known regulated Ser/Thr kinases; they are similar in overall structure and regulatory design. PKA is the predominant mediator for signaling through cAMP, the only other being a cAMP-liganded ion channel in olfaction and an exchange protein directly activated by cAMP (Epac), which modulate GDP–GTP exchange for the small GTPases Rap1 and Rap2. Epacs are activated by cAMP independent of PKA action and regulate cell adhesion, cell junction formation, and exocytosis.

In a similar fashion, the related cGMP-dependent protein kinase (PKG) mediates most of the actions of cGMP. Ca^{2+}-calmodulin-dependent protein kinase II (CaMKII) and several other kinases mediate many of the actions of stimuli that elevate intracellular Ca^{2+}. Finally, the PI signaling system increases both DAG and Ca^{2+}, which activate any of a family of protein kinases collectively called protein kinase C (PKC).

The activities of these second messenger-regulated protein kinases are countered by a relatively small number of phosphatases, exemplified by protein phosphatase 1 (PP–1), protein phosphatase 2A (PP–2A), and protein phosphatase 2B (PP–2B, or calcineurin). Phosphorylation and dephosphorylation are reversible processes, and the net activity of the two processes determines the phosphorylation state of each substrate. The Nobel Prize for Physiology and Medicine was awarded to Edwin G. Krebs and Edmund H. Fischer in 1992 for their pioneering work on the regulation of cell function by protein kinases and phosphatases.

Certain Principles are Common in Protein Phosphorylation and Dephosphorylation

Protein kinases and protein phosphatases are described either as multifunctional if they have a broad specificity and therefore modify many protein targets or as dedicated if they have a very narrow substrate specificity. Spatial positioning of kinases and their substrates in the cell further increases or decreases the likelihood of phosphorylation-dephosphorylation of a given substrate.

The amplification of signal transduction described earlier is continued during transmission of the signal by protein kinases and protein phosphatases. In some cases, the kinases are themselves subject to activation by phosphorylation in a cascade in which one activated kinase phosphorylates and activates a second, and so on, to provide amplification and a switch-like response termed ultrasensitivity.

Kinases and phosphatases integrate cellular stimuli and encode the stimuli as the steady-state level of phosphorylation of a large complement of proteins in the cell (Hunter, 1995). Distinct signal transduction pathways can converge on the same or different target substrates. In some cases, these substrates can be phosphorylated by several kinases at distinct sites. Phosphorylation can alter cellular processes over broad time scales, from milliseconds to hours and even much longer by altering gene expression.

Phosphorylation produces specific changes in the function of a target protein, such as increasing or decreasing the catalytic activity of an enzyme, conductance of an ion channel, or desensitization of a receptor. Kinases and phosphatases modulate proteins by regulating the presence of a highly charged and bulky phosphoryl moiety on Ser, Thr, or Tyr at a precise location on the substrate protein. The phosphate may elicit a conformational change or alter interaction with other proteins.

Finally, each of the three kinases exemplified here can function as a cognitive kinase—that is, a kinase capable of a molecular memory. Although the activity of each kinase requires a second messenger for initial activation, each can become persistently active and independent of its second messenger. This molecular memory potentiates the activity of these kinases and may enable them to participate in aspects of neuronal plasticity.

cAMP-Dependent Protein Kinase was the First Well-Characterized Kinase

Neurotransmitters that stimulate the synthesis of cAMP exert their intracellular effects primarily by activating PKA. The functions (and substrates) regulated by PKA include gene expression [cAMP response element-binding protein (CREB)], catecholamine synthesis (tyrosine hydroxylase), carbohydrate metabolism (phosphorylase kinase), cell morphology [microtubule-associated protein 2 (MAP–2)], postsynaptic sensitivity (AMPA receptor), and membrane conductance (K channel). Paul Greengard and Eric Kandel received the Nobel Prize for Medicine in 2000 (along with Arvid Carlsson) for their discoveries concerning signal transduction via PKA and phosphoprotein phosphatases in the nervous system. PKA is a tetrameric protein composed of two types of subunits: (1) a dimer of regulatory (R) subunits (either two RI subunits for type I PKA or two RII subunits for type II PKA) and (2) two catalytic subunits (C subunit). Two or more isoforms of the RI, RII, and C subunits have distinct tissue and developmental patterns of expression but appear to function similarly. The C subunits are 40-kDa proteins that contain the binding sites for protein substrates and ATP. The R subunits are 49-to 51-kDa proteins that contain two cAMP-binding sites. In addition, the R subunit dimer contains a region that interacts with cellular anchoring proteins that serve to localize PKA appropriately within the cell.

The binding of second messengers by PKA and the other second-messenger-regulated kinases relieves an inhibitory constraint and thus activates the enzymes (Fig. 9.10). cAMP binding leads to subunit dissociation, thereby relieving the C subunit of its inhibitory R subunits and activating the kinase. The steady-state level of cAMP determines the fraction of PKA that is in the dissociated or active form. In this way PKA decodes cAMP signals into the phosphorylation of proteins and the resultant change in various cellular processes.

PKA is a member of a large family of protein kinases that have in common a significant degree of homology in their catalytic domains and are likely derived from an ancestral gene (Fig. 9.11). This homology extends to the three-dimensional crystal structure based on x-ray

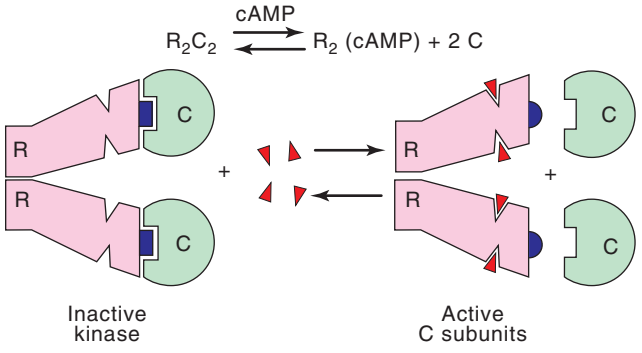

FIGURE 9.10 Activation of PKA by cAMP. An autoinhibitory segment (blue) of the regulatory subunit (R) dimer interacts with the substrate-binding domain of the catalytic (C) subunits of PKA, blocking access of substrates to their binding site. Binding of four molecules of cAMP reduces the affinity of R for C, resulting in dissociation of constitutively active C subunits.

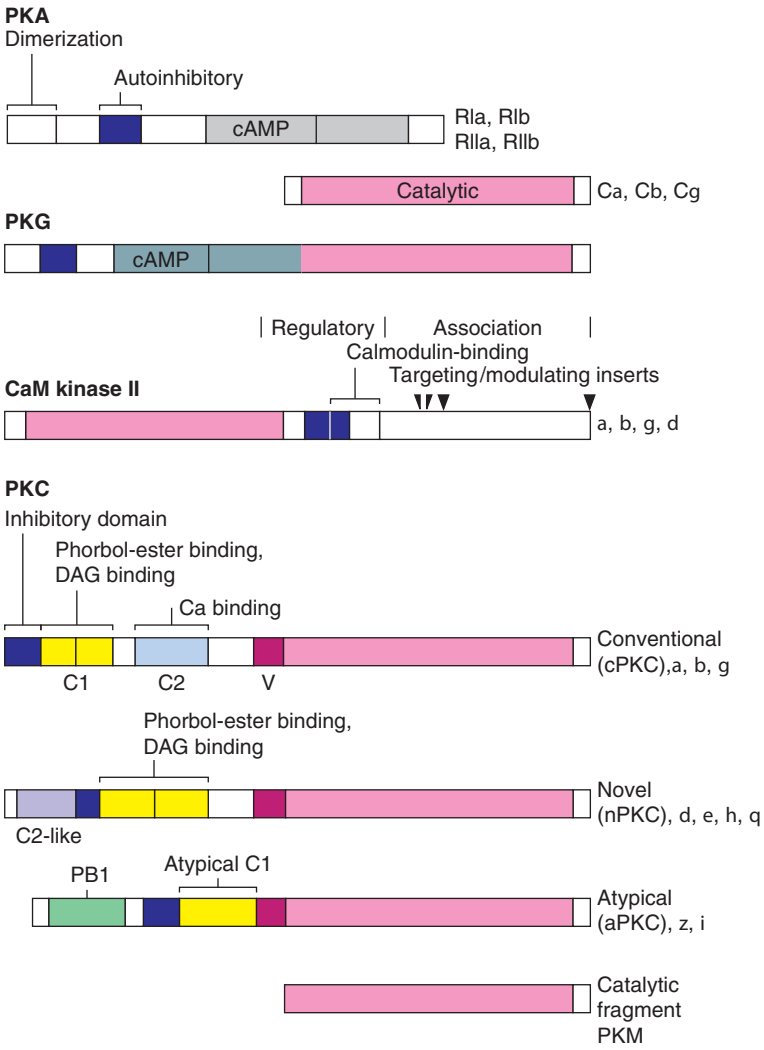

FIGURE 9.11 Domain structure of protein kinases. Protein kinases are encoded by proteins with recognizable structural sequences that encode specialized functional domains. Each of the kinases [PKA, PKG, CaMKII, and PKC] has homologous catalytic domains that are kept inactive by the presence of an autoinhibitory segment (blue lines). Regulatory domains contain sites for binding second messengers such as cAMP, cGMP, Ca^{2+}-calmodulin, DAG, and Ca^{2+}-phosphatidylserine. Alternative splicing creates additional diversity.

crystallography of PKA and other kinases. The catalytic domain may be in a subunit distinct from the regulatory domain, as in PKA, or in the same subunit, as in PKC and the CaM kinases. The crystal structure of the C subunit complexed to a segment of protein kinase inhibitor (PKI), a selective high-affinity inhibitor of PKA, reveals that the C subunit is composed of two lobes. The N-terminal lobe contains a highly conserved region that binds Mg^{2+}-ATP in a cleft between the two lobes. A larger C-terminal lobe contains the protein-substrate recognition sites and the appropriate amino acids for catalyzing transfer of the γ-phosphoryl moiety from ATP to the substrate. Inhibition by PKI is diagnostic of PKA involvement; PKI contains an autoinhibitory sequence resembling PKA substrates and is positioned in the catalytic site like a substrate, thus blocking access for substrates.

PKA phosphorylates Ser or Thr at specific sites in dozens of proteins. The sequences of amino acids at the phosphorylation sites are not identical. Each kinase has a characteristic consensus sequence that forms the basis for distinct substrate specificities.

A regulatory theme common to PKA, CaMKII, and PKC is that their second messengers activate them by displacing an inhibitory domain from the active site. In PKA, binding of the R subunit distorts the active site of the C subunit and blocks access of substrates by positioning a pseudosubstrate or inhibitory sequence in the catalytic site. Binding of cAMP to the R subunit produces a large conformation change in R that disrupts its binding to the C subunit, thus leading to dissociation of an active C subunit. CaMKII and PKC have the catalytic domain and inhibitory sequence in the same polypeptide with binding of their respective second-messengers similarly de-inhibiting the kinase by displacement of the autoinhibitory domain (Fig. 9.11).

Multifunctional CaMKII Decodes Diverse Signals That Elevate Intracellular Ca^{2+}

Most of the effects of Ca^{2+} in neurons and other cell types are mediated by calmodulin, and many of the effects of Ca^{2+}-calmodulin are mediated by protein phosphorylation-dephosphorylation (Wayman et al., 2008). The Ca^{2+}-signaling system contains a family of Ca^{2+}-calmodulin-dependent protein kinases with broad substrate specificity, including CaM kinases I, II, and IV; of these, CaMKII is the best characterized. CaMKII phosphorylates tyrosine hydroxylase, MAP-2, synapsin I, calcium channels, Ca^{2+}-ATPase, transcription factors, and glutamate receptors and thereby regulates synthesis of catecholamines, cytoskeletal function, synaptic release in response to high-frequency stimuli, calcium currents, calcium homeostasis, gene expression, and synaptic plasticity, respectively. This kinase is found in every tissue but is particularly enriched in neurons. It is found in the cytosol, in the nucleus, in association with cytoskeletal elements, and in postsynaptic thickening termed the postsynaptic density found in asymmetric synapses. It is a large multimeric enzyme, consisting of 12 subunits derived from four homologous genes (α, β, γ, and δ) that encode different isoforms of the kinase that range from 54 to 72 kDa per subunit.

The catalytic, regulatory, and targeting domains of CaMKII are all contained within a single polypeptide (Fig. 9.11). Following the catalytic domain on the N-terminal half of each isoform is the regulatory domain, which contains an autoinhibitory domain with an overlapping calmodulin-binding sequence. The C-terminal end contains an association domain that allows 12 subunits (two rings of six catalytic domains each) to assemble into a multimer, as well as targeting sequences that direct the kinase to distinct intracellular sites (Chao et al., 2011).

Regulation of the kinase by autophosphorylation is a critical feature of CaMKII. The kinase is inactive in the basal state because an autoinhibitory segment distorts the active site and sterically blocks access to its substrates. Binding of Ca^{2+}-calmodulin to the calmodulin-binding domain of the kinase displaces the autoinhibitory domain from the catalytic site, thus activating the kinase by enabling ATP and protein substrates to bind. Displacement of this domain also exposes a binding site for anchoring proteins that the activated kinase can bind. If the kinase is activated, it can autophosphorylate Thr-286 (in α-CaMKII). Phosphorylation disables the autoinhibitory segment by preventing it from reblocking the active site after calmodulin dissociates and thereby locks the kinase in a partially active state that is independent, or autonomous, of Ca^{2+}-calmodulin and can anchor to additional targets. Autophosphorylation prolongs the active state of the kinase, a potentiation that led to its description as a cognitive kinase.

CaMKII is targeted to distinct cellular compartments. Differences between the four genes encoding CaMKII and between the two or more isoforms that are encoded by each gene by apparent alternative splicing reside primarily in a variable region at the start of the association domain (Fig. 9.11). In some isoforms, this region contains an additional sequence that targets those isoforms to the nucleus. The major neuronal isoform, α-CaMKII, is largely cytosolic but is also found associated with postsynaptic densities and synaptic vesicles. Targeting to the NMDA type glutamate receptor occurs only after calmodulin activates the kinase and exposes a binding site. The kinase also serves as a scaffold for binding of other proteins, including the recruitment of the ubiquitin proteasome to dendritic spines.

Protein Kinase C is the Principal Target of the PI Signaling System

Protein kinase C is a collective name for members of a relatively diverse family of protein kinases most closely associated with the PI-signaling system. PKC is a multifunctional Ser/Thr kinase capable of modulating many cellular processes, including exocytosis and endocytosis of neurotransmitter vesicles, neuronal plasticity, gene expression, regulation of cell growth and cell cycle, ion channels, and receptors. The role of DAG generated during PI signaling was unclear until its link to PKC was established. Many PKC isoforms also require an acidic phospholipid such as phosphatidylserine for appropriate activation. The kinase is also of interest because it is the target of a class of tumor promoters called phorbol esters. They activate PKC by simulating the action of DAG, bypassing the normal receptor-based pathway, and inappropriately stimulating cell growth.

We now understand that the PKC family of kinases is diverse in structure and regulatory properties (Newton, 2010). PKC is monomeric (78–90 kDa) with catalytic, regulatory, and targeting domains all on one polypeptide (Fig. 9.11). The conventional isoforms (or cPKC), have all of the following domains:

- an autoinhibitory or pseudosubstrate sequence
- C1, a cysteine-rich domain that binds DAG and phorbol esters
- C2, a region necessary for Ca^{2+} sensitivity and for binding to phosphatidylserine and to anchoring proteins
- V, a variable protease-sensitive hinge
- the catalytic domain.

Another class of isoforms, termed novel PKCs (nPKC), lacks a true C2 domain and is therefore not Ca^{2+} sensitive. Another class is considered atypical (aPKC) because it lacks C2 and the first of two cysteine-rich domains that

are necessary for DAG (or phorbol ester) sensitivity. This class is neither Ca^{2+} nor DAG sensitive but has a PB1 domain involved in protein interaction. Not included is a family of closely related kinases termed PKN.

Activation of PKC is best understood for the conventional isoforms. Generation of DAG resulting from stimulation of the PI-signaling pathway increases the affinity of cPKC isoforms for Ca^{2+} and phosphatidylserine. DAG, or specifically its *sn*-1,2-diacylglycerol isomer, is derived only from PI turnover, and it is the only isomer effective in activating PKC. Cell stimulation results in the translocation of cPKC from a variety of sites to the membrane or cytoskeletal elements where it interacts with PS-Ca^{2+}-DAG at the membrane. Binding of the second messengers to the regulatory domain disrupts the nearby autoinhibitory domain, leading to a reversible activation of PKC by deinhibition. Translocation is not restricted to the plasma membrane. Upon activation some PKC isoforms reversibly translocate to intracellular sites enriched with anchoring proteins, termed receptors for activated C kinase (RACK).

Prolonged activation of PKC can be produced by the addition of phorbol esters, which simulate activation by DAG but remain in the cell until they are washed out. In a matter of hours to days, such persistent activation by phorbol esters leads to a degradation of PKC. This phenomenon is sometimes used experimentally to produce a PKC-depleted cell (at least for phorbol ester-binding isoforms) and thereafter to test for a loss of putative PKC functions.

Spatial Localization Regulates Protein Kinases and Phosphatases

Protein kinases and protein phosphatases are often positioned spatially near their substrates or they translocate to their substrates upon activation to improve speed and specificity in response to neurotransmitter stimulation. For example, A Kinase Anchoring Protein 79 (AKAP79) while first identified with PKA binding, also has binding site for PKC and calcineurin (Logue & Scott, 2010). Another example of a signaling complex is the protein termed yotiao, which binds to the NMDA type glutamate receptor and serves as an anchor for both PKA and a phosphatase (PP–1).

The use of anchoring proteins has several consequences. First, rate of phosphorylation and specificity are enhanced when kinases or phosphatases are concentrated near intended substrates. Second, it increases the signal-to-noise ratio for substrates that are not near anchoring proteins by reducing basal state phosphorylation. For example, PKA is anchored on the Golgi away from the nucleus so that phosphorylation in the basal state or even after a brief stimulus produces little phosphorylation of nuclear proteins. Prolonged stimuli, however, enable some C subunits to diffuse passively through nuclear pores and regulate gene expression. Termination of the nuclear action of C subunits is aided by PKI, which acts to inhibit and export it back out of the nucleus. Third, anchoring can enable significant phosphorylation of nearby substrates at basal cAMP, such as a Ca^{2+} channel phosphorylated when its phosphorylation site is exposed during depolarization.

The Cognitive Kinases

The ability of three major Ser/Thr kinases (PKA, CaMKII, and PKC) in brain to initiate or maintain synaptic changes that underlie learning and memory may require that they themselves undergo some form of persistent change in activity. Both their functional and molecular properties led to their description as cognitive kinases.

cAMP-Dependent Protein Kinase

A role for PKA as a cognitive kinase can be seen in long-term facilitation of the gill-withdrawal reflex in *Aplysia* and in long-term potentiation in the rodent hippocampus. In motor neuron cultures, repeated or prolonged exposure to serotonin or cAMP leads to long-term facilitation because PKA becomes persistently active despite the fact that cAMP is no longer elevated (Chain et al., 1999). During such activation there is a preferential degradation and decrease in the inhibitory RII subunits and thus a slight excess of C subunits that remain persistently active because of insufficient RII subunits. The C subunit then enters the nucleus and induces expression of one protein that facilitates further proteolysis of RII. In this interesting process, a molecular memory of appropriate stimulation by serotonin is encoded by a persistence of PKA activity that is regenerative.

Ca^{2+}-Calmodulin-Dependent Protein Kinase

CaMKII has features of a cognitive kinase because it has a molecular memory based on autophosphorylation and it phosphorylates proteins that modulate synaptic plasticity (Lisman, Schulman, & Cline, 2002). The biochemical properties of CaMKII suggest mechanisms by which appropriate stimulus frequencies can generate an autonomous enzyme (Fig. 9.12). At low stimulus frequency, the time between stimuli is sufficient for calmodulin to dissociate and the kinase to be dephosphorylated, and the same submaximal activation will occur with each stimulus. At higher frequencies, however, some subunits will remain autophosphorylated and bound to calmodulin so successive stimuli will result in more calmodulin bound per holoenzyme, which will make autophosphorylation more probable because it requires two active proximate neighboring subunits. The enzyme is therefore able to decode

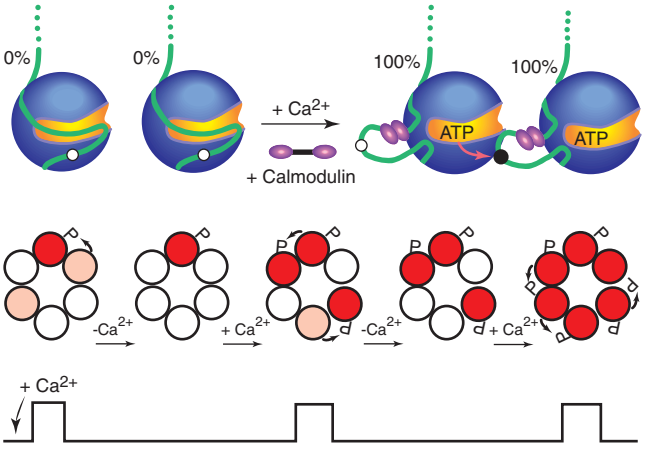

FIGURE 9.12 Frequency-dependent activation of CaMKII. Autophosphorylation occurs when both neighboring subunits in a holoenzyme are bound to calmodulin. At a high frequency of stimulation (rapid Ca^{2+} spikes), the interspike interval is too short to allow significant dephosphorylation or dissociation of calmodulin, thereby increasing the probability of autophosphorylation with each successive spike. In a simplified CaMKII with only one ring of six subunits, calmodulin-bound subunits are shown in pink and autophosphorylated subunits with trapped calmodulin are shown in red. *Adapted from Hudmon and Schulman (2002).*

the frequency of cellular stimulation and translate this into a prolonged activated state.

CaMKII phosphorylates a number of substrates that affect synaptic strength. Inhibition of CaMKII in hippocampal slices or just elimination of its autophosphorylation by an α-CaMKII mouse knock-in in which the critical Thr was replaced by Ala blocks autonomy and the induction of long-term potentiation. These mice are deficient in learning spatial navigational cues, one of the functions of the rodent hippocampus. The basis for its role involves a net shift of AMPA receptors to the synapse that may be mediated by phosphorylation of both GluA1 receptors and their accessory protein(s), leading to a greater postsynaptic response (Lisman, Schulman, & Cline, 2002; Opazo et al., 2010). The autophosphorylated kinase also serves as a scaffold to recruit the ubiquitin proteasome to synaptic sites that enable dynamic changes at the synapse.

Protein Kinase C

PKC can also be converted into a form that is independent, or autonomous, of its second messenger and can be described as a cognitive kinase. During the persistent phase of long-term potentiation, some of the inhibitory domain of some PKC molecules is proteolytically removed, thus converting it to a constitutively active kinase termed protein kinase M (PKM). PKCζ can also be transcribed from an internal promoter to produce PKM, whose translation in dendrites is unblocked during LTP and whose activity then disables the translational block, an interesting form of molecular memory (Sacktor, 2011). PKC (and PKM) substrates associated with long-term potentiation include NMDA and AMPA receptors.

Protein Tyrosine Kinases Take Part in Cell Growth and Differentiation

Protein kinases that phosphorylate tyrosine residues are usually associated with the regulation of cell growth and differentiation. Signal transduction by protein tyrosine kinases often includes a cascade of kinases phosphorylating other kinases, eventually activating Ser/Thr kinases, which carry out the intended modification of a cellular process. There are both receptor tyrosine kinases, activated by the binding of extracellular growth factors such as nerve growth factor and epidermal growth factor, and soluble ones, activated indirectly by extracellular ligands such as c-Src (Lemmon & Schlessinger, 2010).

Protein Phosphatases Undo What Kinases Create

Protein phosphatases in neuronal signaling are categorized as either phosphoserine-phosphothreonine phosphatases (PSPs) or phosphotyrosine phosphatases (PTPs) (Hunter, 1995; Mansuy & Shenolikar, 2006). The enzymes catalyze the hydrolysis of the ester bond of the phosphorylated amino acids to release inorganic phosphate and the unphosphorylated protein. A limited number of multifunctional PSPs account for most of such phosphatase activity in cells. They are categorized based on their domain structure, inhibitor sensitivity, and catalytic mechanism (Table 9.1). There are three families of protein serine/threonine phosphatases, designated as phosphoprotein phosphatases (PP-1, -2B (calcineurin), -2A, -4, -6, -5, -7), metal-dependent phosphatases (PP2C), and aspartate-based phosphatases (FCP and SCP). Protein phosphatase 2B (PP-2B, or calcineurin) responds directly to a second messenger, Ca^{2+}. The specificity of PP-1 and PP-2A is particularly broad in isolation, but both their protein substrates and cellular localization are refined by interaction with many regulatory and scaffold proteins. Phosphotyrosine phosphatases constitute a distinct and larger class of phosphatases, including PTPs with dual specificity for both phosphotyrosines and phosphoserine-phosphothreonines. PTPs are either soluble enzymes or membrane proteins with variable extracellular domains that enable regulation by extracellular binding of either soluble or membrane-bound signals.

Structure and Regulation of PP-1 and Calcineurin

PP-1 and calcineurin are the best characterized phosphatases with regard to both structure and regulation.

TABLE 9.1 Categories of Protein Phosphatases[a]

Phosphatase	Characteristic	Other Inhibitors
PP-1	Sensitive to phospho-inhibitor-1, phospho-DARPP-32, and inhibitor-2	Weakly sensitive to okadaic acid
PP-2B (calcineurin)	Ca^{2+}/calmodulin-dependent	FK506, cyclosporin
PP-2A	Highly abundant	Highly sensitive to okadaic acid
PP-4/PP-6	Nuclear	Highly sensitive to okadaic acid
PP-5	Nuclear	Mildly sensitive to okadaic acid
PP-7	Nuclear	Mildly sensitive to okadaic acid
PP-2C	Requires metal (Mg^{2+}/Mn^{2+})	EDTA
FCP/SCP[b]	Aspartic acid-based catalysis	
Receptor PTPs[c]	Plasma membrane	Vanadate
Nonreceptor PTPs	Various cellular compartments	Vanadate
Dual specificity PTPs	Nuclear (e.g., cdc25A/B/C and VH family)	Vanadate

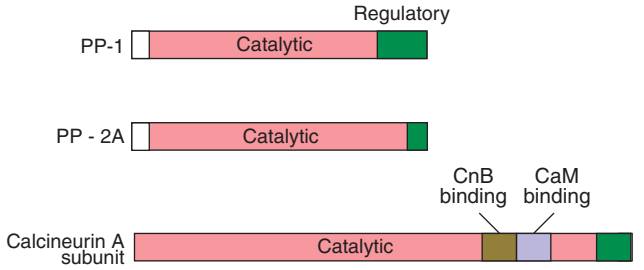

FIGURE 9.13 Domain structure of the catalytic subunits of some Ser/Thr phosphatases. The three major phosphoprotein phosphatases, PP-1, PP-2A, and calcineurin, have homologous catalytic domains but differ in their regulatory properties.

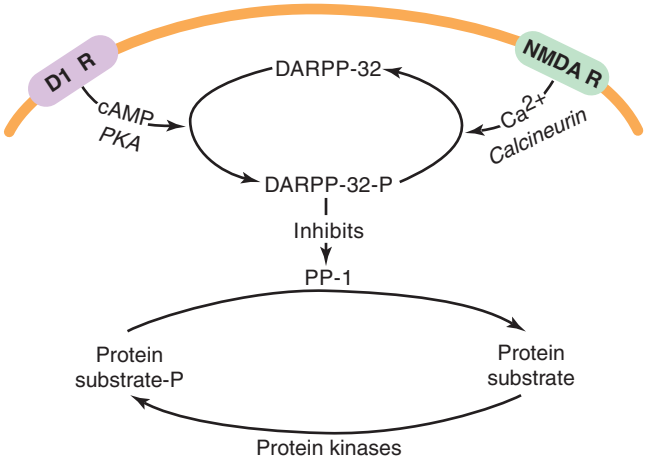

FIGURE 9.14 Cross talk between kinases and phosphatases. The state of phosphorylation of protein substrates is regulated dynamically by protein kinases and phosphatases. In the striatum, for example, dopamine stimulates PKA, which converts DARPP-32 into an effective inhibitor of PP-1. This increases the steady-state level of phosphorylation of a hypothetical substrate subject to phosphorylation by a variety of protein kinases. This action can be countered by NMDA receptor stimulation by another stimulus that increases intracellular Ca^{2+} and activates calcineurin. PP-1 is deinhibited and dephosphorylates the phosphorylated substrate when calcineurin deactives DARPP-32-P. *Adapted from Svenningsson et al. (2004).*

The domain structures of the catalytic subunits of PP-1 and calcineurin are depicted in Figure 9.13. PP-1 is a protein of 35–38 kDa; most of the sequence forms the catalytic domain, and its C-terminal is the site of regulatory phosphorylation. The catalytic domains of PP-1, PP-2A, and calcineurin are highly homologous.

PP-1 and PP-2A are normally complexed in cells with specific targeting or regulatory subunits. Targeting of PP-1 can be modulated by phosphorylation of its targets. As PP-1 dissociates from targeting subunits, it becomes susceptible to inhibition by inhibitor-2.

Inhibition of PP-1 by two other inhibitors, inhibitor-1 and its homologue DARPP-32 (dopamine and cAMP-regulated phosphoprotein; M_r 32,000), is conditional on their phosphorylation by either PKA or PKG (Fig. 9.14). Because the substrates for PKA and PP-1 overlap to a great extent, the rate and extent of phosphorylation of such substrates are enhanced by the ability of PKA to catalyze their phosphorylation while blocking their dephosphorylation via PP-1. Inhibitor-1, DARPP-32, and inhibitor-2 are all selective for PP-1. Highly selective inhibitors capable of penetrating the cell membrane are available for these phosphatases. Okadaic acid, a natural product of marine dinoflagellates, is a tumor promoter but, unlike phorbol esters, it acts on PP-2A and PP-1 rather than on PKC.

PROTEIN PHOSPHATASE 1

The x-ray structure of the catalytic subunit of PP-1 bound to the toxin microcystin, a cyclic peptide inhibitor,

reveals PP-1 to be a compact ellipsoid with hydrophobic and acidic surfaces forming a cleft for binding substrates. PP-1 is a metalloenzyme requiring two metals in the active site that likely take part in electrostatic interactions with the phosphate on substrates that aid in catalyzing the hydrolytic reaction. Substrate binding is blocked when phospho-inhibitor-1 or microcrystin LR binds to this surface.

CALCINEURIN (PP-2B)

Calcineurin is a Ca^{2+}-calmodulin-dependent phosphatase that is highly enriched in the brain. It is a heterodimer with a 60-kDa subunit (CnA) that contains an N-terminal catalytic domain similar to PP-1 and a C-terminal regulatory domain that includes an autoinhibitory segment, a calmodulin-binding domain, and a binding site for the 19-kDa regulatory B subunit (CnB). CnB is a calmodulin-like Ca^{2+}-binding protein that binds to a hinge region of CnA. Some activation of calcineurin is attained by binding of Ca^{2+} to CnB. Stronger activation is obtained by the binding of Ca^{2+}-camodulin. Additional regulation may be accorded by interaction of its hinge region with cyclophilin and FKBP (FK506-binding protein), proteins that bind the immunosuppressive agents cyclosporin and FK506, respectively.

The Ca^{2+}-calmodulin sensitivities of calcineurin and CaMKII are quite different. Weak or low-frequency stimuli may selectively activate calcineurin, whereas strong or high-frequency stimuli activate CaMKII and calcineurin. This difference may play a role in the bidirectional control of synaptic strength (depression vs. potentiation) by low- and high-frequency stimulation.

Protein Kinases, Protein Phosphatases, and Their Substrates are Integrated Networks

Cross talk between protein kinases and protein phosphatases is critical to their ability to integrate inputs into neurons. Such cross talk is exemplified by the interaction of cAMP and Ca^{2+} signals through PKA and calcineurin, respectively. The medium spiny neurons in the neostriatum receive cortical inputs from glutamatergic neurons that are excitatory and nigral inputs by dopaminergic neurons that inhibit them. A possible signal transduction scheme for this regulation is shown in Figure 9.14. The key to regulation is the bidirectional control of DARPP-32 phosphorylation (Svenningsson et al., 2004). Glutamate activates calcineurin by increasing intracellular Ca^{2+}, leading to the dephosphorylation and inactivation of phospho-DARPP-32. This releases inhibition of PP-1, which can then dephosphorylate a variety of substrates, including Na^+, K^+-ATPase, and lead to membrane depolarization. This is countered by dopamine, which stimulates cAMP formation and activation of PKA, which then converts DARPP-32 into its phosphorylated (i.e., PP-1 inhibitory) state. There are many other receptors and signaling integrated by these pathways. For example, adenosine, serotonin, and VIP act through their cognate receptors to elevate cAMP, similarly to dopamine at D1 receptors, while opiates can signal to inhibit the action of dopamine at D1 and adenosine at A2A receptors. Although PKA and calcineurin are acting in an antagonistic manner, they are not doing it by phosphorylating and dephosphorylating the ATPase. By their actions upstream, at the level of DARPP-32, the regulation of numerous target enzymes (e.g., Ca^{2+} channels and Na^+ channels) in addition to the ATPase can be coordinated.

Studying Cellular Processes Controlled by Phosphorylation-Dephosphorylation

Major goals of signal transduction research are to delineate pathways by which signals such as neurotransmitters transduce their signals to modify cellular processes. This is often the start of a process to identify targets for therapeutic intervention in disease. Cellular and biochemical assays can often identify the entire signaling pathway, from stimulation of receptor, to generation of a second-messenger activation of a kinase or phosphatase, change in the phosphorylation state of the substrate, and an ultimate change in its functional state. Such investigations utilize a variety of pharmacological inhibitors or activators of the signaling molecules complemented by genetic approaches that utilize transfection of activated forms of the kinases or phosphatases in question, siRNAs, transgenic animals, and mice with individual signaling components knocked out.

Summary

The morphology of a cell is determined by protein constituents. Its function is regulated by the phosphorylation or dephosphorylation of the proteins. Phosphorylation modifies the function of regulatory proteins subsequent to their genetic expression. The activities of the protein kinases and protein phosphatases are typically regulated by second messengers and extracellular ligands. Kinases and phosphatases integrate and encode stimulation of a large group of cellular receptors. The number of possible effects is almost limitless and enables the tuning of cellular processes over a broad time scale. Most of the effects of Ca^{2+} in cells are mediated by calmodulin, which in turn mediates changes in protein phosphorylation-dephosphorylation. The phosphoinositol signaling system is mediated through PKC, which modulates many cellular processes

from exocytosis to gene expression. All three classes of enzymes discussed have been described as cognitive kinases because they are capable of sustaining their activated states after their second-messenger stimuli have returned to basal levels. PKA has been implicated in learning and memory in *Aplysia* and in hippocampus, where it is involved in long-term potentiation. Protein phosphatases play an equally important role in neuronal signaling by dephosphorylating proteins. Cross talk between protein kinases and protein phosphatases is key to their ability to integrate inputs into neurons.

INTRACELLULAR SIGNALING AFFECTS NUCLEAR GENE EXPRESSION

For all living cells, regulation of gene expression by intracellular signals is a fundamental mechanism of development, homeostasis, and adaptation to the environment. Protein phosphorylation and regulation of gene expression by intracellular signals are the most important mechanisms underlying the remarkable degree of plasticity exhibited by neurons. Alterations in gene expression underlie many forms of long-term changes in neural functioning, with a time course that ranges from hours to many years. Signaling can also regulate translation of mRNA, including translation that is localized to dendrites and synaptic spines, as well as protein degradation that facilitates dynamic regulation of cell function and shape.

Interactions of Specific DNA Sequences with Regulatory Proteins Control Both Basal and Signal-Regulated Transcription

Information contained within DNA must be expressed through other molecules: RNA and proteins. The human genome contains approximately 25,000 genes that encode structural RNAs or protein-coding messenger RNAs (mRNAs). Regulated gene expression conferred by the nucleotide sequence of the DNA itself is called *cis* regulation because the control regions are linked physically on the DNA to regions that can potentially be transcribed. The *cis* regulatory sequences function by serving as high-affinity binding sites for regulatory proteins called transcription factors.

The transcription of specific genes into mRNA is carried out by a complex enzyme called RNA polymerase II. Roger Kornberg won the Nobel Prize in Chemistry in 2006 for his studies on the molecular basis for eukaryotic transcription. Transcription is often divided into three steps: initiation of RNA synthesis, RNA chain elongation, and chain termination. Extracellular signals, such as neurotransmitters, hormones, drugs, and growth factors generally control the transcription initiation step.

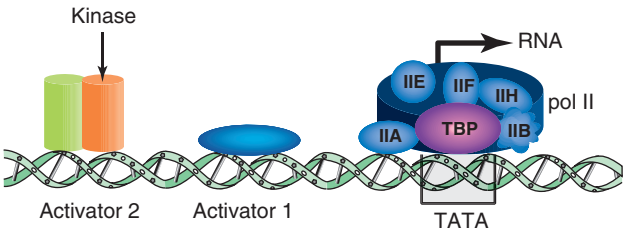

FIGURE 9.15 Schematic of a generalized RNA polymerase II promoter showing three separate *cis*-regulatory elements along a stretch of DNA. These elements are two hypothetical activator protein-binding sites and the TATA element. The TATA element is shown binding the TATA-binding protein (TBP). Multiple general transcription factors (IIA, IIB, etc.) and RNA polymerase II (pol II) associate with TBP. Each transcription factor comprises multiple individual proteins complexed together. This basal transcription apparatus recruits RNA polymerase II into the complex and also forms the substrate for interactions with the activator proteins binding to the activator elements shown. Activator 2 is shown to be a substrate for a protein kinase.

Transcription initiation requires two critical processes: (1) positioning of RNA polymerase II at the correct start site of the gene to be transcribed and (2) controlling the efficiency of initiations to produce the appropriate transcriptional rate for the circumstances of the cell (Tjian & Maniatis 1994). The *cis*-regulatory elements that set the transcription start sites of genes are called the basal promoter. Other *cis*-regulatory elements tether additional activator and represser proteins to the DNA to regulate the overall transcriptional rate (Fig. 9.15).

Sequence-Specific Transcription Factors

The promoters for RNA polymerase II transcribed genes contain a distinct basal promoter element on which a basal transcription complex is assembled. The basal promoter of most of these genes contains a sequence called a TATA box that is rich in the nucleotides adenine (A) and thymine (T) located between 25 and 30 bases upstream of the transcription start site.

To achieve significant levels of transcription, this multiprotein assembly requires help from sequence-specific transcriptional activators that recognize and bind distinct *cis*-regulatory elements. Functional *cis*-regulatory elements are generally 7–12 bp in length and structured as a palindrome, each of which is a specific binding site for one or more transcription factors. Each gene has a particular combination of *cis*-regulatory elements, the nature, number, and spatial arrangement of which determine the gene's unique pattern of expression, including the cell types in which it is expressed, the times during development in which it is expressed, and the level at which it is expressed in adults both basally and in response to physiological signals (Tjian & Maniatis, 1994).

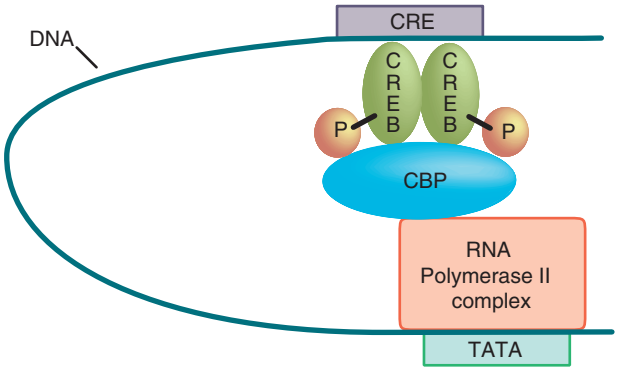

FIGURE 9.16 Looping of DNA permits activator (or represser) proteins binding at a distance to interact with the basal transcription apparatus. The basal transcription apparatus is shown as a single box (pol II complex) bound at the TATA element. The activator protein (CREB) is shown as having been phosphorylated. On phosphorylation, many activators, such as CREB, are able to recruit adaptor proteins that mediate between the activator and the basal transcription apparatus. An adaptor protein that binds phosphorylated CREB is called a CREB-binding protein (CBP).

Many transcription factors are active only as dimers or higher order complexes formed via a multimerization domain. Both partners in a dimer commonly contribute jointly to both the DNA-binding domain and the activation domain. Dimerization can be a mechanism of either positive or negative control of transcription. The effects of sequence-specific transcriptional activator and represser factors are frequently mediated by adapter proteins (Fig. 9.16). In many cases, these adapter proteins are enzymes, such as histone acyl transferases and deacetylases, with the ability to modify the structure of the proteins associated with the DNA and modulate transcription (Fig. 9.16).

A Significant Consequence of Intracellular Signaling is the Regulation of Transcription

Intracellular signals play a major role in the regulation of gene expression—for example, via nuclear translocation and/or phosphorylation of activator proteins. Signal-directed change in location or conformation of these proteins permits information obtained by the cell from its different signaling systems to regulate gene expression appropriate to the status of the cell.

Transcriptional Regulation by Intracellular Signals

Extracellular control of transcription requires a translocation step by which the signal is transmitted through the cytoplasm to the nucleus. Some transcription factors are themselves translocated to the nucleus. For example, the transcription factor NF-κB is retained in the cytoplasm by its binding protein IκB, which masks the NF-κB nuclear localization signal. Signal-regulated phosphorylation of IκB by PKC and other protein kinases leads to dissociation of NF-κB, permitting it to enter the nucleus. Other transcription factors must be directly phosphorylated or dephosphorylated to bind DNA. In many cytokine-signaling pathways, plasma membrane receptor tyrosine phosphorylation of transcription factors known as signal transducers and activators of transcription (STATs) permits their multimerization, which in turn permits both nuclear translocation and construction of an effective DNA-binding site within the multimer. Yet other transcription factors, such as CREB (Fig. 9.16), are already bound to their cognate *cis*-regulatory elements and become able to activate transcription after phosphorylation by a kinase that translocates to the nucleus.

Role of cAMP and Ca^{2+} in the Activation Pathways of Transcription

The cAMP second-messenger pathway regulates expression of a large number of genes via cAMP response elements (CREs) with the consensus palindromic sequence of TGACGTCA. Phosphorylation of CRE-bound CREB on its Ser-133 by activated PKA that translocates to the nucleus recruits the adapter protein CBP. This, in turn, interacts with the basal transcription complex and modifies histones to enhance the efficiency of transcription. CREB also serves to illustrate the convergence of signaling pathways (Fig. 9.17). CREB Ser-133 phosphorylation is not only mediated by PKA but also by CaMKII and CaMKIV and by RSK2, a kinase activated in growth factor pathways, including Ras and MAP kinase (Sakamoto, Karelina & Obrietan, 2011).

CREB illustrates yet another important principle of transcriptional regulation: CREB is a member of a family of related proteins. Many transcription factors are members of families; this permits complex forms of positive and negative regulation. CREB is closely related to other proteins called activating transcription factors (ATFs) and CRE modulators (CREMs). The dimerization domain used by CREB-ATF proteins and several other families of transcription factors is called a leucine zipper. The dimerization motif is an α helix in which every seventh residue is a leucine; based on the periodicity of α helices, the leucines line up along one face of the helix two turns apart. Dimerization juxtaposes the adjacent basic, DNA binding, regions of each of the partners. This combination of motifs is why this superfamily of proteins is referred to as basic leucine zipper proteins (bZIPs).

AP-1 Transcription Factors

Activator protein 1 (AP-1) is another family of bZIP transcription factors that play a central role in the regulation of neural gene expression by extracellular signals. The AP-1 family comprises multiple proteins that bind as heterodimers (and a few as homodimers) to the DNA sequence TGACTCA. While the AP-1 sequence

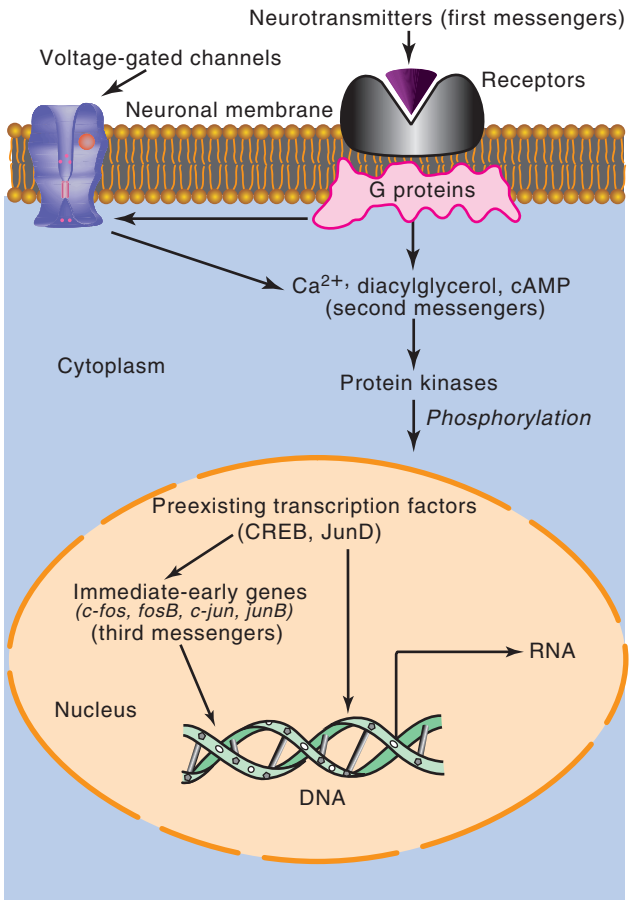

FIGURE 9.17 Signal transduction to the nucleus. In this schematic, activation of a neurotransmitter receptor activates cellular signals (G proteins and second-messenger systems). These signals, in turn, regulate the activation of protein kinases, which translocate to the nucleus. Within the nucleus, protein kinases can activate genes regulated by constitutively synthesized transcription factors. A subset of these genes encodes additional transcription factors (third messengers), which can then activate multiple downstream genes.

differs from the CRE sequence (TGACGTCA) by only a single base, this one-base difference strongly biases protein binding away from the CREB family of proteins. AP-1 sequences confer responsiveness to the PKC pathway. AP-1 proteins generally bind DNA as heterodimers composed of one member each of two different families of related bZIP proteins, the Fos family (c-Fos, Fra-1, Fra-2, and FosB) and the Jun family (c-Jun, JunB, and JunD) providing for a multiplicity of regulatory control.

Cellular Immediate-Early Genes

Genes that are activated transcriptionally by synaptic activity, drugs, and growth factors have often been classified roughly into two groups. Genes, such as the c-*fos* gene itself, that are activated rapidly (within minutes), transiently, and without requiring new protein synthesis are often described as cellular immediate-early genes (IEGs). Genes that are induced or repressed more slowly (within hours) and are dependent on new protein synthesis have been described as late-response genes. Several IEGs have been used as cellular markers of neural activation because they are markedly induced by depolarization (the critical signal being Ca^{2+} entry) and second-messenger and growth factor pathways, permitting novel approaches to functional neuroanatomy.

The protein products of those cellular IEGs that function as transcription factors bind to *cis*-regulatory elements contained within a subset of late-response genes to activate or repress them (Fig. 9.17). In sum, neural genes that are regulated by extracellular signals are activated or repressed with varying time courses by reversible phosphorylation of constitutively synthesized transcription factors and by newly synthesized transcription factors, some of which are regulated as IEGs.

*Activation of the c-*fos *Gene*

The c-*fos* gene is activated rapidly by neurotransmitters or drugs that stimulate the cAMP pathway or Ca^{2+} elevation. Both pathways produce phosphorylation of transcription factor CREB. The c-*fos* gene contains three binding sites for CREB. The c-*fos* gene can also be induced by the Ras/MAP kinase pathway, which is activated by a number of growth factors. For example, neurotrophins, such as nerve growth factor (NGF), bind a family of receptor tyrosine kinases (Trks); NGF interacts with Trk A, which activates Ras. Ras then acts through a cascade of protein kinases. Cross talk between neurotransmitter and growth factor–signaling pathways has been documented with increasing frequency and likely plays an important role in the precise tuning of neural plasticity to diverse environmental stimuli.

Regulation of c-Jun

Expression of most of the proteins of the Fos and Jun families that constitute transcription factor AP-1 and the binding of AP-1 proteins to DNA is regulated by extracellular signals. Phosphorylation and activation of c-Jun can result from the action of Jun N-terminal kinase (JNK). JNK is a member of the mitogen activated protein kinase (MAPK) family of protein kinases. JNK has also been shown to be activated by neurotransmitters, including glutamate. Thus, AP-1–mediated transcription within the nervous system requires multiple steps, beginning with the activation of genes encoding AP-1 proteins.

Cytokines as Inducers of Gene Expression in the Nervous System

With regard to function, the boundary between trophic, or growth, factors and cytokines in the nervous system has become increasingly arbitrary. However,

cell-signaling mechanisms offer a useful means of distinction. Growth factors, such as neurotrophins (e.g., nerve growth factor, brain-derived neurotrophic factor, and neurotrophin 3), epidermal growth factor (EGF), and fibroblast growth factor (FGF), act through receptor protein tyrosine kinases, whereas cytokines, such as leukemia inhibitory factor (LIF), ciliary neurotrophic factor (CNTF), and interleukin-6 (IL-6), act through nonreceptor protein tyrosine kinases.

LIF, CNTF, and IL-6 subserve a wide array of overlapping functions inside and outside the nervous system, including hematopoietic and immunologic functions outside the nervous system and regulation of neuronal survival, differentiation, and, in certain circumstances, plasticity within the nervous system. Their receptors contain a common signal-transducing subunit, gp130. Receptors for these cytokines consist of a signal-transducing β component, which includes gp130, and interacts with nonreceptor protein tyrosine kinases (PTKs) of the Janus kinase (Jak) family (e.g., Jak1, Jak2, and Tyk2). Some cytokine receptors interact only with a single Jak PTK, whereas others interact with multiple Jak PTKs.

Signal transduction to the nucleus includes tyrosine phosphorylation by the Jak PTKs of one or more of the STAT proteins mentioned earlier. Upon phosphorylation, STAT proteins form dimers through the association of SH2 domains, an important type of protein interaction domain. Dimerization is thought to trigger translocation to the nucleus, where STATs bind their cognate cytokine response elements. Different STATs become activated by different cytokine receptors, not because of differential use of Jak PTKs but because of specific coupling of certain STATs to certain receptors. Thus, for example, the IL-6 receptor preferentially activates STAT1 and STAT3; the CNTF receptor preferentially activates STAT3. Cytokine response elements, to which STATs bind, have now been identified within many neural genes, including vasoactive intestinal polypeptide and several other neuropeptide genes.

Steroid Hormone Receptors

The differentiation of many cell types in the brain is established by exposure to steroids. Steroid hormones, including glucocorticoids, sex steroids, mineralocorticoids, retinoids, thyroid hormone, and vitamin D, are small lipid-soluble ligands that can diffuse across cell membranes. They act on their receptors within the cell cytoplasm in marked distinction to the other types of intercellular signals described herein. Another unique feature of steroid hormones is that their receptors are themselves transcription factors. Each has a transcriptional-activation domain at its amino terminus, a DNA-binding domain, and a hormone-binding domain at its carboxy terminus. DNA-binding domains recognize specific palindromic DNA sequences, steroid hormone response elements, within the regulatory regions of specific genes.

After having been bound by hormone, activated steroid hormone receptors translocate into the nucleus, where they bind to their cognate response elements. Such binding then increases or decreases the rate at which these target genes are transcribed, depending on the precise nature and DNA sequence context of the element.

Summary

The formation of long-term memories requires changes in gene expression and new protein synthesis. It is at transcription initiation that extracellular signals such as neurotransmitters, hormones, drugs, and growth factors exert their most significant control. The transcription is modulated by transcription factors that recruit the RNA polymerases to the DNA. For example, the critical nuclear translocation step in the activation of transcription factor CREB involves the catalytic subunit of PKA, which can phosphorylate CREB on entering the nucleus. In addition, increasing evidence indicates that at least some forms of long-term memory require new gene expression.

Genes that encode the transcription factors themselves may respond quickly or slowly. These genes have been coined third messengers in signal transduction cascades. Cross talk between neurotransmitter and growth factor-signaling pathways is likely to play an important role in the precise tuning of neuronal plasticity to diverse environmental stimuli.

The active, mature transcription complex is a remarkable architectural assembly of RNA polymerase II, transcription factors, and adaptors assembled at the basal promoter. Cells can exert exquisite control of the genes being transcribed in a variety of situations—for example, to govern appropriate entry or exit from the cell cycle, to maintain appropriate cellular identity, and to respond appropriately to extracellular signals.

Transcription can be regulated by many different extracellular signals modulated by a large array of signaling pathways (many including reversible phosphorylation) and a complex array of typically dimeric transcription factors. In this chapter, regulation has been illustrated by only a few of the families of transcription factors. Those chosen appear to play important roles in the nervous system and illustrate many of the basic principles of gene regulation.

Postsynaptic Potentials and Synaptic Integration

The study of synaptic transmission in the central nervous system (CNS) provides an opportunity to learn more about the diversity and richness of mechanisms underlying this process and to learn how some of the fundamental signaling properties of the nervous system, such as action potentials and synaptic potentials, work together to process information and generate behavior.

Postsynaptic potentials (PSPs) in the CNS can be divided into two broad classes on the basis of mechanisms and, generally, duration of these potentials. One class is based on the direct binding of a transmitter molecule(s) with a receptor-channel complex; these receptors are ionotropic. The structure of these receptors is discussed in detail in Chapter 8. The resulting PSPs are generally short-lasting and thus sometimes are called fast PSPs; they have also been referred to as "classical" because they were the first synaptic potentials to be recorded in the CNS (Eccles, 1964; Spencer, 1977). The duration of a typical fast PSP is about 20 ms.

The other class of PSPs is based on the indirect effect of a transmitter molecule(s) binding with a receptor. The receptors that produce these PSPs are metabotropic. As discussed in Chapter 8, the receptors activate G proteins (G-protein-coupled receptors; GPCRs) that affect the channel either directly or through additional steps in which the level of a second messenger is altered. The changes in membrane potential produced by metabotropic receptors can be long-lasting and therefore are called slow PSPs. The mechanisms for fast PSPs mediated by ionotropic receptors are considered first.

IONOTROPIC RECEPTORS: MEDIATORS OF FAST EXCITATORY AND INHIBITORY SYNAPTIC POTENTIALS

The Stretch Reflex Is Useful to Examine the Properties and Functional Consequences of Ionotropic PSPs

The stretch reflex, one of the simpler behaviors mediated by the central nervous system, is a useful example with which to examine the properties and functional consequences of ionotropic PSPs. The tap of a neurologist's hammer to a ligament elicits a reflex extension of the leg, as illustrated in Figure 10.1. The brief stretch of the ligament is transmitted to the extensor muscle and is detected by specific receptors in the muscle and ligament (Chapter 28). Action potentials initiated in the stretch receptors are propagated to the spinal cord by afferent fibers (Chapter 28). The receptors are specialized regions of sensory neurons with somata located in the dorsal root ganglia just outside the spinal column. Axons of the afferents enter the spinal cord and make excitatory synaptic connections with at least two types of postsynaptic neurons. First, a synaptic connection is made to the extensor motor neuron. As the result of its synaptic activation, the motor neuron fires action potentials that propagate out of the spinal cord and ultimately invade the terminal regions of the motor axon at neuromuscular junctions. There, acetylcholine (ACh) is released, nicotinic ACh receptors are activated, an end plate potential

© 2013 Elsevier Inc. All rights reserved.

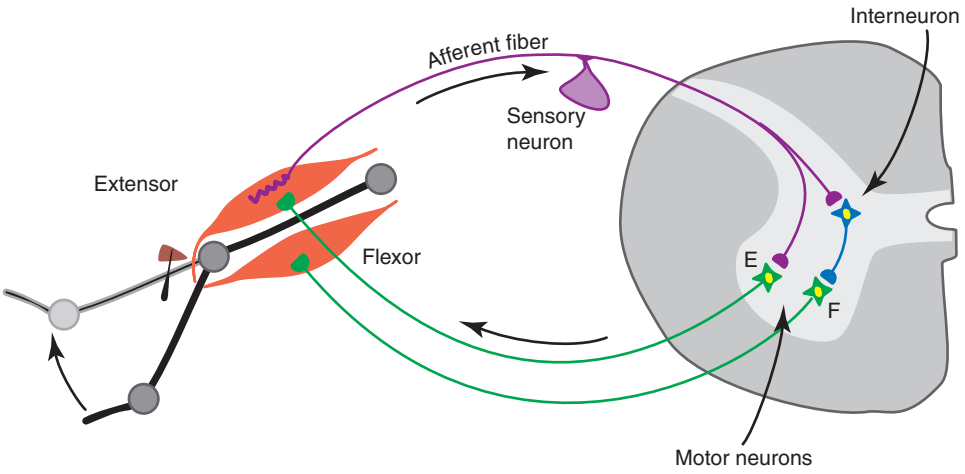

FIGURE 10.1 Features of the vertebrate stretch reflex. Stretch of an extensor muscle leads to the initiation of action potentials in the afferent terminals of specialized stretch receptors. The action potentials propagate to the spinal cord through afferent fibers (sensory neurons). The afferents make excitatory connections with extensor motor neurons (E). Action potentials initiated in the extensor motor neurons propagate to the periphery and lead to the activation and subsequent contraction of the extensor muscle. The afferent fibers also activate interneurons that inhibit the flexor motor neurons (F).

(EPP) is produced, an action potential is initiated in the muscle cell, and the muscle cell is contracted, producing the reflex extension of the leg. Second, a synaptic connection is made to another group of neurons called interneurons (nerve cells interposed between one type of neuron and another). The particular interneurons activated by the afferents are inhibitory interneurons because activation of these interneurons leads to the release of a chemical transmitter substance that inhibits the flexor motor neuron. This inhibition tends to prevent an uncoordinated (counteracting) movement (i.e., flexion) from occurring. The reflex system illustrated in Figure 10.1 also is known as the monosynaptic stretch reflex because this reflex is mediated by a single ("mono") excitatory synapse in the central nervous system. Spinal reflexes are described in greater detail in Chapter 28. Box 10.1 on optogenetics describes new techniques that can identify neuronal circuits.

Figure 10.2 illustrates procedures that can be used to experimentally examine some of the components of synaptic transmission in the reflex pathway for the stretch reflex. Intracellular recordings are made from one of the sensory neurons, the extensor and flexor motor neurons, and an inhibitory interneuron. Normally, the sensory neuron is activated by stretch to the muscle, but this step can be bypassed by simply injecting a pulse of depolarizing current of sufficient magnitude into the sensory neuron to elicit an action potential. The action potential in the sensory neuron leads to a potential change in the motor neuron known as an excitatory postsynaptic potential (EPSP; Fig. 10.2).

Mechanisms responsible for fast EPSPs mediated by ionotropic receptors in the CNS are fairly well known. Moreover, the ionic mechanisms for EPSPs in the CNS are essentially identical with the ionic mechanisms at the skeletal neuromuscular junction. Specifically, the transmitter substance released from the presynaptic terminal (Chapters 7 and 8) diffuses across the synaptic cleft, binds to specific receptor sites on the postsynaptic membrane (Chapter 8), and leads to a simultaneous increase in permeability to Na^+ and K^+, which makes the membrane potential move toward a value of about 0 mV. However, the processes of synaptic transmission at the sensory neuron–motor neuron synapse and the motor neuron–skeletal muscle synapse differ in two fundamental ways: in the transmitter used and in the amplitude of the EPSP. The transmitter substance at the neuromuscular junction is ACh, whereas that released by the sensory neurons is an amino acid, probably glutamate. Indeed, glutamate is the most common transmitter that mediates excitatory actions in the CNS. The amplitude of the postsynaptic potential at the neuromuscular junction is about 50 mV; consequently, each PSP depolarizes the postsynaptic cell beyond threshold so there is a one-to-one relation between an action potential in the spinal motor neuron and an action potential in the skeletal muscle cell. Indeed, the EPSP must depolarize the muscle cell by only about 30 mV to initiate an action potential, allowing a safety factor of about 20 mV. In contrast, the EPSP in a spinal motor neuron produced by an action potential in an afferent fiber has an amplitude of only about 1 mV. The mechanisms by which these small PSPs can trigger an action potential in the postsynaptic neuron are discussed in a later section of this chapter and in Chapter 11.

BOX 10.1

OPTOGENETICS

The brain's complexity is evident in its hundreds (at least) of neuronal cell types, each with different cellular morphologies, gene expression profiles, patterns of synaptic connectivity, and electrophysiological properties. Understanding how neural activity underlies the sophisticated computations and behavior produced by a brain—and how it is impaired in disease states—requires the ability to dissect the brain's complexity with the appropriate level of precision. The advent of optogenetics (light-activated genetically encoded proteins to manipulate cellular function) enables the nervous system to be dissected at an unparalleled level of specificity. This technology has ushered in a new era of neuroscience research, shedding light on aspects of brain function that less than a decade ago were wholly inaccessible.

One of the most powerful optogenetic technologies is the expanding set of single-component optogenetic tools developed from naturally occurring microbial rhodopsins. Like the rhodopsin underlying vision in the retina, the microbial rhodopsins are trans-membrane proteins which bind to the light-sensitive molecule retinal. Retinal undergoes a significant conformational change in the presence of light, which in turn catalyzes conformational changes in rhodopsin. Unlike rhodopsin in the eye, which is a G-protein-coupled receptor, many microbial rhodopsins are channels or pumps. The significance of this fact for neuroscience is that a single opsin protein (along with its bound organic co-factor retinal) fluxes ions in response to light, enabling the required functionality to be encoded in a single gene (i.e., a single-component tool).

The diverse optogenetic toolbox now enables powerful experimental control over neural activity. Channelrhodopsin-2 (ChR2) which is naturally found in the green algae *Chlamydomonas reinhardtii* was the first single-component optogenetic tool to be expressed in neurons, and exemplifies optogenetic capabilities. ChR2 is a non-selective cation channel that opens within microseconds following brief exposure to blue light (~470 nm). When expressed in neurons and activated by light, the flux of positive ions into the cell rapidly and reliably produces an action potential. Thus, using ChR2, an experimenter can elicit a particular desired pattern of neural firing simply by delivering the corresponding pattern of light. Such high-fidelity and temporally precise control over the neural code is unprecedented. A diverse set of optogenetic tools with complementary capabilities have arisen from multiple lines of research, including from genomic searches for novel naturally occuring microbial opsins, experimentation with chimeric proteins constructed from multiple rhodopsins, and rationally designed mutations of specific amino acids in wildtype (WT) rhodopsins. Today a wide variety of optogenetic tools exist which are faster, more reliable, more potent, and more light sensitive than WT ChR2 (e.g., ChR2-H134R, ChETA, C1V1); some of these new tools can even produce stable, long-lasting depolarizing currents for up to tens of minutes after a single brief light flash, and can be precisely activated or inactivated with different wavelengths of light (e.g., SFO, SSFO). Rhodopsins have also been produced that are sensitive to different wavelengths of light (e.g., blue, green, red), enabling simultaneous independent optogenetic control of different neural populations (e.g., VChR1, C1V1). Microbial opsins which hyperpolarize cells and inhibit action potentials such as the chloride pump halorhodopsin (NpHR) found in the halobacterium *Natronomonas pharaonis* have been discovered and methodically enhanced, thus enabling bi-directional control of neural activity (e.g., eNpHR3.0, eArch). Finally, there are tools which enable the optical control of intracellular signaling through G-protein-mediated molecular cascades (optoXRs). Given how rapidly these tools have been described and elaborated upon by a number of productive laboratories, the growing capabilities of optogenetic proteins will likely continue to expand.

It is important to remember that the power of optogenetics is limited by the degree to which these proteins can be selectively expressed and activated in specific neuronal cell types *in vitro* and *in vivo*. However, since the opsins are genetically encoded proteins, scientists have an arsenal of gene therapy and molecular biology techniques available to achieve selective expression in neural tissues. These include *in vitro* cell culture transfection, *in utero* electroporation, knock-in, knock-out and transgenic animals, promoter/enhancer manipulations, viral vectors, and inducible expression tools such as those involving Cre recombinase, many of which can be used in combination. Experiments *in vitro* can involve light delivery from mercury arc lamps, lasers, or light-emitting diodes (LEDs), and 2-photon optogenetic activation of neurons has also been achieved. In addition, both anesthetized and awake animals can be optogenetically manipulated; for *in vivo* stimulation laser light is typically delivered through <1 mm optical fibers, which are stereotaxically targeted to specific brain regions. Using these various gene therapy and optical approaches, neuroscientists have used optogenetic technologies in a variety of tissues and awake behaving organisms, including *Caenorhabditis elegans*, *Drosophila*, zebrafish, mouse, rat, macaque monkey *in vivo*, and *in vitro* human tissue. The era of optogenetic neuroscience research has already made a significant

BOX 10.1 (*cont'd*)

impact, but as the development and application of optogenetics continues additional merits of this technology are likely to be realized.

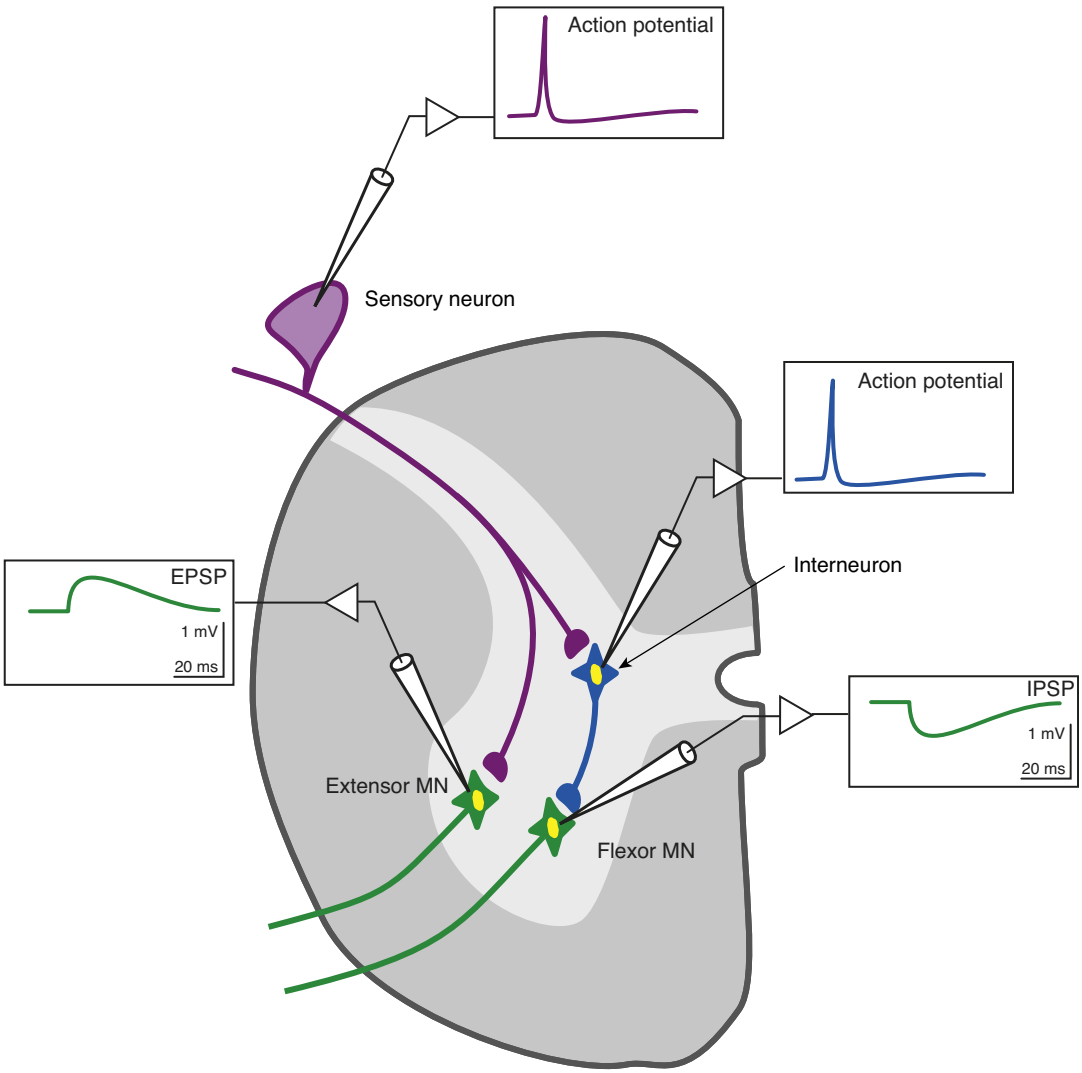

FIGURE 10.2 Excitatory (EPSP) and inhibitory (IPSP) postsynaptic potentials in spinal motor neurons. Idealized intracellular recordings from a sensory neuron, interneuron, and extensor and flexor motor neurons (MNs). An action potential in the sensory neuron produces a depolarizing response (an EPSP) in the extensor motor neuron. An action potential in the interneuron produces a hyperpolarizing response (an IPSP) in the flexor motor neuron.

Macroscopic Properties of PSPs Are Determined by the Nature of Gating and Ion-Permeation Properties of Single Channels

Patch-Clamp Techniques

Patch-clamp techniques (Hamill, Marty, Neher, Sakmann, & Sigworth, 1981), with which current flowing through single isolated receptors can be measured directly, can be sources of insight into both the ionic mechanisms and the molecular properties of PSPs mediated by ionotropic receptors. This approach was pioneered by Erwin Neher and Bert Sakman in the 1970s and led to their being awarded the Nobel Prize in Physiology or Medicine in 1991.

Figure 10.3A illustrates an idealized experimental arrangement of an "outside-out" patch recording of a single ionotropic receptor. The patch pipette contains a solution with an ionic composition similar to that of the cytoplasm, whereas the solution exposed to the outer surface of the membrane has a composition similar to that of normal extracellular fluid. The electrical potential across the patch, and hence the transmembrane potential (V_m), is controlled by the patch-clamp amplifier. The extracellular (outside) fluid is considered "ground." Transmitter can be delivered by applying pressure to a miniature pipette filled with an agonist (in this case, ACh), and the current (I_m) flowing across the patch of membrane is measured by the patch-clamp amplifier (Fig. 10.3). Pressure in the pipette that contains ACh can be continuous, allowing a constant stream of ACh to contact the membrane, or can be applied as a short pulse to allow a precisely timed and discrete amount of ACh to contact the membrane. The types of recordings obtained from such an experiment are illustrated in the traces in Figure 10.3. In the absence of ACh, no current flows through the channel (Fig. 10.3A). When ACh is applied continuously, current flows across the membrane (through the channel), but the current does not flow continuously; instead, small step-like changes in current are observed (Fig. 10.3B). These changes represent the probabilistic (random) opening and closing of the channel.

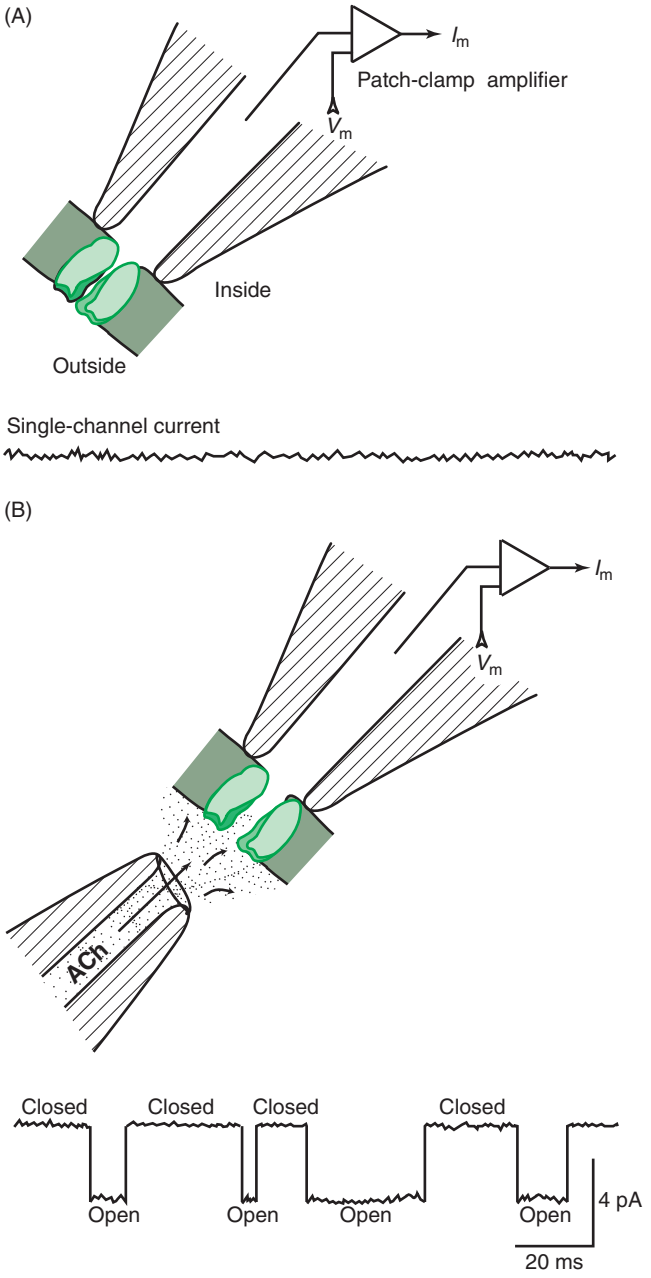

FIGURE 10.3 Single-channel recording of ionotropic receptors and their properties. (A) Experimental arrangement for studying properties of ionotropic receptors. (B) Idealized single-channel currents in response to application of ACh.

Channel Openings and Closings

As a result of the type of patch-recording techniques heretofore described, three general conclusions about the properties of ligand-gated channels can be drawn. First, ACh, as well as other transmitters that activate ionotropic receptors, causes the opening of individual ionic channels (for a channel to open, usually two molecules of transmitter must bind to the receptor). Second, when a ligand-gated channel opens, it does so in an all-or-none fashion. Increasing the concentration of transmitter in the ejection microelectrode does not increase the permeability (conductance) of the channel; it increases its probability (P) of being open. Third, the ionic current flowing through a single channel in its open state is extremely small (e.g., 10^{-12} A); as a result, current flowing through any single channel makes only a small contribution to the normal postsynaptic potential. Physiologically, when a larger region of the postsynaptic membrane, and thus more than one channel, is exposed to a released transmitter, the net conductance

of the membrane increases due to the increased probability that a larger population of channels will be open at the same time. The normal PSP, measured with standard intracellular recording techniques (e.g., Fig. 10.2), is then proportional to the sum of the currents that flow through these many individual open channels. The properties of voltage-sensitive channels (see Chapter 5) are similar in that they, too, open in all-or-none fashion, and, as a result, the net effect on the cell is due to the summation of currents flowing through many individual open ion channels. The two types of channels differ, however, in that one is opened by a chemical agent, whereas the other is opened by changes in membrane potential.

Statistical Analysis of Channel Gating and Kinetics of the PSP

The experiment illustrated in Figure 10.3B was performed with continuous exposure to ACh. Under such conditions, the channels open and close repeatedly. When ACh is applied by a brief pressure pulse to more accurately mimic the transient release from the presynaptic terminal, the transmitter commonly causes only a single opening of the channel before it diffuses away. A set of data similar to that shown in Figure 10.4A would be obtained if an ensemble of these openings were collected and aligned with the start of each opening. Each individual trace represents the response to each successive "puff" of ACh. Note that, among the responses, the duration of the opening of the channel varies considerably—from very short (less than 1 ms) to more than 5 ms. Moreover, channel openings are independent events. The duration of any one channel opening does not have any relation to the duration of a previous opening. Figure 10.4B illustrates a plot that is obtained by adding 1000 of these individual responses. Such an addition roughly simulates the conditions under which a transmitter released from a presynaptic terminal leads to the near simultaneous activation of many single channels in the postsynaptic membrane. (Note that the addition of 1000 channels would produce a synaptic current equal to about 4 nA.) This simulation is valid given the assumption that the statistical properties of a single channel over time are the same as the statistical properties of the ensemble at one instant of time (i.e., an ergodic process). The ensemble average can be fit with an exponential function with a decay time constant of 2.7 ms. An additional observation (discussed later) is that the value of the time constant is equal to the mean duration of the channel openings. The curve in Figure 10.4B is an indication of the probability that a channel will remain open for various times, with a high probability for short times and a low probability for long times.

The ensemble average of single-channel currents (Fig. 10.4B) roughly accounts for the time course of the

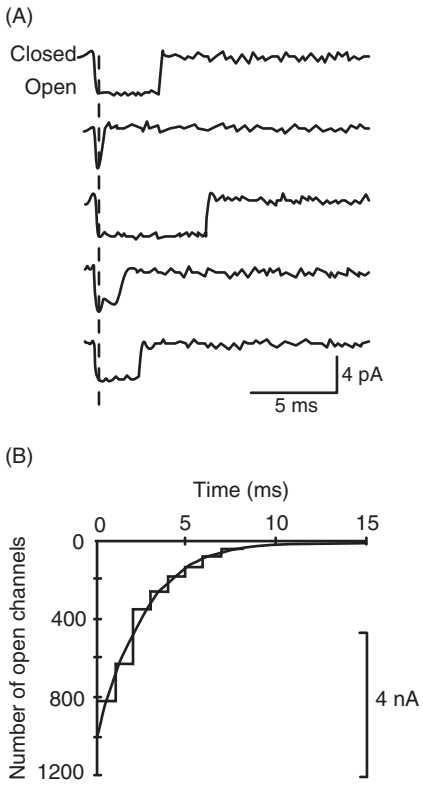

FIGURE 10.4 Determination of the shape of the postsynaptic response from single-channel currents. (A) Each trace represents the response of a single channel to a repetitively applied puff of transmitter. Traces are aligned with the beginning of the channel opening (dashed line). (B) The addition of 1000 of the individual responses. If a current equal to 4 pA were generated by the opening of a single channel, then a 4-nA current would be generated by 1000 channels opening at the same time. Data are fitted with an exponential function having a time constant equal to 1/a (see text). *Reprinted with permission from Sakmann (1992). American Association for the Advancement of Science, © 1992 The Nobel Foundation.*

EPSP. However, note that the time course of the aggregate synaptic current can be somewhat faster than that of the excitatory postsynaptic potential in Figure 10.2. This difference is due to charging of the membrane capacitance by a rapidly changing synaptic current. Because the single-channel currents were recorded with the membrane voltage clamped, the capacitive current $[I_c = C_m * (dV/dt)]$ is zero. In contrast, for the recording of the postsynaptic potential in Figure 10.2, the membrane was not voltage clamped, and therefore as the voltage changes (i.e., dV/dt), some of the synaptic current charges the membrane capacitance (see Eq. 10.7).

Analytical expressions that describe the shape of the ensemble average of the open lifetimes and the mean open lifetime can be derived by considering that single-channel opening and closing is a stochastic process (Johnston & Wu, 1995; Sakmann, 1992). Relations are formalized to describe the likelihood (probability)

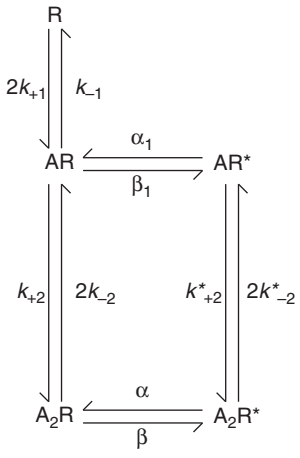
of a channel being in a certain state. Consider the following two-state reaction scheme:

$$C \underset{\alpha}{\overset{\beta}{\rightleftharpoons}} O$$

In this scheme, α represents the rate constant for channel closing and β the rate constant for channel opening. The scheme can be simplified further if we consider a case in which the channel has been opened by the agonist and the agonist is removed instantaneously. A channel so opened (at time 0) will then close after a certain random time (Fig. 10.4). It can be shown that the mean open time = $1/\alpha$ (Johnston & Wu, 1995; Sakmann, 1992).

Gating Properties of Ligand-Gated Channels

Although statistical analysis can be a valuable source of insight into the statistical nature of the gating process and the molecular determinants of the macroscopic postsynaptic potential, the description in the preceding section is a simplification of the actual processes. Specifically, a more complete description must include the kinetics of receptor binding and unbinding and the determinants of the channel opening, as well as the fact that channels display rapid transitions between open and closed states during a single agonist receptor occupancy. Thus, the open states illustrated in Figures 10.3B and 10.4A represent the period of a burst of extremely rapid openings and closings. If the bursts of rapid channel openings and closings are thought of, and behave functionally, as a single continuous channel opening, the formalism developed in the preceding section is a reasonable approximation for many ligand-gated channels. Nevertheless, a more complex reaction scheme is necessary to quantitatively explain available data. Such a scheme would include the following states,



where R represents the receptor, A the agonist, and the α, β, and k values the forward and reverse rate constants for the various reactions. A_2R^* represents a channel opened as a result of the binding of two agonist molecules. The asterisk indicates an open channel. Note that the lower part of the reaction scheme is equivalent to the one developed earlier; that is,

$$C \underset{\alpha}{\overset{\beta}{\rightleftharpoons}} O$$

With the use of probability theory, equations describing transitions between the states can be determined. The approach is identical to that used in the simplified two-state scheme. However, the mathematics and analytical expressions are more complex. For some receptors, additional states must be represented. For example, as described in Chapter 8, some ligand-gated channels exhibit a process of desensitization in which continued exposure to a ligand results in channel closure.

Null (Reversal) Potential and Slope of I-V Relations

What ions are responsible for the synaptic current that produces the EPSP? Early studies of the ionic mechanisms underlying the EPSP at the skeletal neuromuscular junction yielded important information. Specifically, voltage-clamp and ion-substitution experiments indicated that the binding of transmitter to receptors on the postsynaptic membrane led to a simultaneous increase in Na^+ and K^+ permeability that depolarized the cell toward a value of about 0 mV (Fatt & Katz, 1951; Takeuchi & Takeuchi, 1960). These findings are applicable to the EPSP in a spinal motor neuron produced by an action potential in an afferent fiber and have been confirmed and extended at the single-channel level.

Figure 10.5 illustrates the type of experiment in which the analysis of single-channel currents can be a source of insight into the ionic mechanisms of EPSPs. A transmitter is delivered to the patch while the membrane potential is varied systematically (Fig. 10.5A). In the upper trace, the patch potential is −40 mV. The ejection of transmitter produces a sequence of channel openings and closings, the amplitudes of which are constant for each opening (i.e., about 4 pA). Now consider the case in which the transmitter is applied when the potential across the patch is −20 mV. The frequency of the responses, as well as the mean open lifetimes, is about the same as when the potential was at −40 mV, but now the amplitude of the single-channel currents is decreased uniformly. Even more interesting, when the patch is depolarized artificially to a value of about 0 mV, an identical puff of transmitter produces no current in the patch. If the patch potential is depolarized to a value of about 20 mV and the puff is delivered again, openings are again observed, but the flow of current through the channel is reversed in sign; a series of

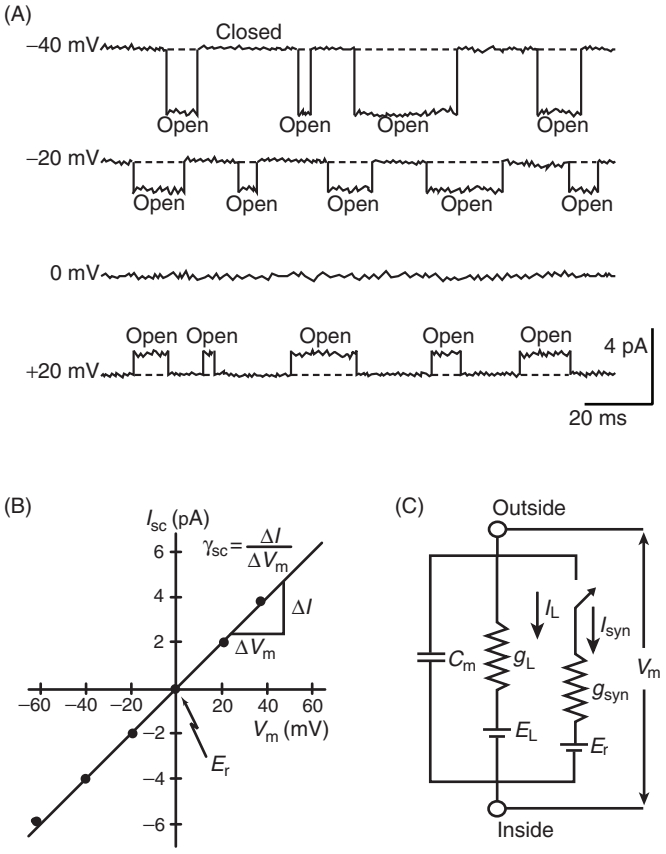


FIGURE 10.5 Voltage dependence of the current flowing through single channels. (A) Idealized recording of an ionotropic receptor in the continuous presence of agonist. (B) I–V relation of the channel in A. (C) Equivalent electrical circuit of a membrane containing that channel. γ_{SC}, single-channel conductance; I_L, leakage current; I_{SC}, single-channel current; g_L, leakage conductance; g_{syn}, macroscopic synaptic conductance; E_L, leakage battery; E_r, reversal potential.

upward deflections indicate outward single-channel currents. In summary, there are downward deflections (inward currents) when the membrane potential is at −40 mV, no deflections (currents) when the membrane is at 0 mV, and upward deflections (outward currents) when the membrane potential is moved to 20 mV.

The simple explanation for these results is that no matter what the membrane potential, the effect of the transmitter binding with receptors is to produce a permeability change that tends to move the membrane potential toward 0 mV. If the membrane potential is more negative than 0 mV, an inward current is recorded. If the membrane potential is more positive than 0mV, an outward current is recorded. If the membrane potential is at 0 mV, there is no deflection because the membrane potential is already at 0 mV. At 0 mV, the channels are opening and closing as they always do in response to the agonist, but there is no net movement of ions through them. This 0-mV level is known as the synaptic null potential or reversal potential because it is the potential at which the sign of the synaptic current reverses. The fact that the experimentally determined reversal potential equals the calculated value obtained by using the Goldman-Hodgkin-Katz (GHK) equation (Chapter 5) provides strong support for the theory that the EPSP is due to the opening of channels that have equal permeabilities to Na^+ and K^+. Ion-substitution experiments also confirm this theory. Thus, when the concentration of Na^+ or K^+ in the extracellular fluid is altered, the value of the reversal potential shifts in a way predicted by the GHK equation. (Some other cations, such as Ca^{2+}, also permeate these channels, but their permeability is low compared with that of Na^+ and K^+.)

Different families of ionotropic receptors have different reversal potentials because each has unique ion selectivity. In addition, it should now be clear that the sign of the synaptic action (excitatory or inhibitory) depends on the value of the reversal potential relative to the resting potential. If the reversal potential of an ionotropic receptor channel is more positive than the resting potential, opening of that channel will lead to depolarization (i.e., an EPSP). In contrast, if the reversal potential of an ionotropic receptor channel is more negative than the resting potential, opening of that channel will lead to hyperpolarization; that is, an inhibitory postsynaptic potential (IPSP), which is the topic of a later section in this chapter.

Plotting the average peak value of single-channel currents (I_{sc}) versus the membrane potential (transpatch potential) at which they are recorded (Fig. 10.5B) can be a source of quantitative insight into the properties of the ionotropic receptor channel. Note that the current-voltage (*I-V*) relation is linear; it has a slope, the value of which is the single-channel conductance, and an intercept at 0 mV. This linear relation can be put in the form of Ohm's law ($I = G * \Delta V$). Thus,

$$I_{sc} = \gamma_{sc} * (V_m - E_r), \tag{10.1}$$

where γ_{sc} is the single-channel conductance and E_r is the reversal potential (here, 0 mV).

Summation of Single-Channel Currents

We now know that the sign of a synaptic action can be predicted by knowledge of the relation between the resting potential (V_m) and the reversal potential (E_r), but how can the precise amplitude be determined? The answer to this question lies in understanding the relation between synaptic conductance and extra synaptic conductances. These interactions can be rather complex (see Chapter 11), but some initial understanding can be obtained by analyzing an electrical equivalent circuit for these two major conductance branches. We first need to move from a consideration of single-channel conductances and currents to that of

macroscopic conductances and currents. The postsynaptic membrane contains thousands of any one type of ionotropic receptor, and each of these receptors could be activated by transmitter released by a single action potential in a presynaptic neuron. Because conductances in parallel add, the total conductance change produced by their simultaneous activation would be

$$g_{syn} = \gamma_{sc} P * N, \tag{10.2}$$

where γ_{sc}, as before, is the single-channel conductance, P is the probability of opening of a single channel (controlled by the ligand), and N is the total number of ligand-gated channels in the postsynaptic membrane. The macroscopic postsynaptic current produced by the transmitter released by a single presynaptic action potential can then be described by

$$I_{syn} = g_{syn} * (V_m - E_r). \tag{10.3}$$

Equation 10.3 can be represented physically by a voltage (V_m) measured across a circuit consisting of a resistor (g_{syn}) in series with a battery (E_r). An equivalent circuit of a membrane containing such a conductance is illustrated in Figure 10.5C. Also included in this circuit are a membrane capacitance (C_m), a resistor representing the leakage conductance (g_L), and a battery (E_L) representing the leakage potential. (Voltage-dependent Na^+, Ca^{2+}, and K^+ channels that contribute to the generation of the action potential have been omitted for simplification.)

The simple circuit allows the simulation and further analysis of the genesis of the PSP. Closure of the switch simulates the opening of the channels by transmitter released from some presynaptic neuron (i.e., a change in P of Eq. (10.2) from 0 to 1). When the switch is open (i.e., no agonist is present and the ligand-gated channels are closed), the membrane potential (V_m) is equal to the value of the leakage battery (E_L). Closure of the switch (i.e., the agonist opens the channels) tends to polarize the membrane potential toward the value of the battery (E_r) in series with the synaptic conductance. Although the effect of the channel openings is to depolarize the postsynaptic cell *toward* E_r (0 mV), this value is never achieved because ligand-gated receptors are only a small fraction of the ion channels in the membrane. Other channels (such as the leakage channels, which are not affected by the transmitters) tend to hold the membrane potential at E_L and prevent the membrane potential from reaching the 0-mV level. In terms of the equivalent electrical circuit (Fig. 10.5C), g_L is much greater than g_{syn}.

An analytical expression that can be a source of insight into the production of an EPSP by the engagement of a synaptic conductance can be derived by examining the current flowing in each of the two conductance branches of the circuit in Figure 10.5C. As shown previously (Eq. 10.3), current flowing in the branch representing the synaptic conductance is equal to

$$I_{syn} = g_{syn} * (V_m - E_r).$$

Similarly, the current flowing through the leakage conductance is equal to

$$I_L = g_L * (V_m - E_L). \tag{10.4}$$

By conservation of current, the two currents must be equal and opposite. Therefore,

$$g_{syn} * (V_m - E_r) = -g_L * (V_m - E_L).$$

Rearranging and solving for V_m, we obtain

$$V_m = \frac{g_{syn} E_r + g_L E_L}{g_{syn} + g_L}. \tag{10.5}$$

Note that when the synaptic channels are closed (i.e., switch open), g_{syn} is 0 and

$$V_m = E_L.$$

Now consider the case of ligand-gated channels being opened by the release of transmitter from a presynaptic neuron (i.e., switch closed) and a neuron with g_L = 10 nS, E_L = −60 mV, g_{syn} = 0.2 nS, and E_r = 0 mV. Then

$$V_m = \frac{(0.2\times10^{-9} * 0) + (10\times10^{-9} * -60)}{10.2\times10^{-9}}.$$
$$= -59\,\text{mV}$$

Thus, as a result of the closure of the switch, the membrane potential has changed from its initial value of −60 mV to a new value of −59 mV; that is, an EPSP of 1 mV has been generated.

The preceding analysis ignored membrane capacitance (C_m), the charging of which makes the synaptic potential slower than the synaptic current. Thus, a more complete analytical description of the postsynaptic factors underlying the generation of a PSP must account for the fact that some of the synaptic current will flow into the capacitive branch of the circuit. Again, by conservation of current, the sum of the currents in the three branches must equal 0. Therefore,

$$0 = C_m \frac{dV_m}{dt} + I_L + I_{syn}, \tag{10.6}$$

$$0 = C_m \frac{dV_m}{dt} + g_L * (V_m - E_L) g_{syn}(t) * (V_m - E_r), \tag{10.7}$$

where C_m (dV_m/dt) is the capacitative current.

By solving for V_m and integrating the differential equation, we can determine the magnitude and time

course of a PSP. An accurate description of the kinetics of the PSP requires that the simple switch closure (all-or-none engagement of the synaptic conductance) be replaced with an expression [$g_{syn}(t)$] that describes the dynamics of the change in synaptic conductance with time.

Nonlinear I-V Relations of Some Ionotropic Receptors

For many PSPs mediated by ionotropic receptors, the current-voltage relation of the synaptic current is linear or approximately linear (Fig. 10.5B). Such ohmic relations are typical of nicotinic ACh channels and AMPA (alpha-amino-3-hydroxyl-5-methyl-4-isoxazolepropionate) glutamate channels (as well as many receptors mediating IPSPs). The linear I–V relation is indicative of a channel whose conductance is not affected by the potential across the membrane. Such linearity should be contrasted with the steep voltage dependency of the conductance of channels underlying the initiation and repolarization of action potentials (Chapter 5).

NMDA (*N*-methyl-D-aspartate) glutamate channels are a class of ionotropic receptors that have nonlinear current-voltage relations. At negative potentials, the channel conductance is low even when glutamate is bound to the receptor. As the membrane is depolarized, conductance increases and current flowing through the channel increases, resulting in the type of I–V relation illustrated in Figure 10.6A. This nonlinearity is represented by an arrow through the resistor representing this synaptic conductance in the equivalent circuit of Figure 10.6B. The nonlinear I–V relation of the NMDA receptor can be explained by a voltage-dependent block of the channel by Mg^{2+} (Fig. 10.7B). At normal values of the resting potential, the pore of the channel is blocked by Mg^{2+}. Thus, even when glutamate binds to the receptor (Fig. 10.7B), the blocked channel prevents ionic flow (and an EPSP). The block can be relieved by depolarization, which displaces Mg^{2+} from the pore (Fig. 10.7B). When the pore is unblocked, cations (i.e., Na^+, K^+, and Ca^{2+}) can flow readily through the channel, and this flux is manifested in the linear part of the I–V relation (Fig. 10.6A). AMPA channels (Fig. 10.7A) are not blocked by Mg^{2+} and have linear I–V relations (Fig. 10.5B).

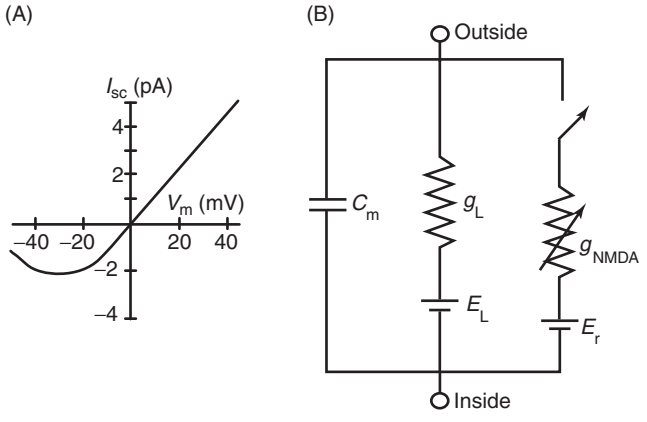

FIGURE 10.6 (A) I–V relation of the NMDA receptor. (B) Equivalent electrical circuit of a membrane containing NMDA receptors.

Inhibitory Postsynaptic Potentials Decrease the Probability of Cell Firing

Some synaptic events decrease the probability of generating action potentials in the postsynaptic cell. Potentials associated with these actions are called inhibitory postsynaptic potentials. Consider the inhibitory interneuron illustrated in Figure 10.2. Normally, this interneuron is activated by summating EPSPs from converging afferent fibers. These EPSPs summate in space and time such that the membrane potential of the interneuron reaches threshold and fires an action potential. This step can be bypassed by artificially depolarizing the interneuron to initiate an action potential. The consequences of that action potential from the point of view of the flexor motor neuron are illustrated in Figure 10.2. The action potential in the interneuron produces a transient increase in the membrane potential of the motor neuron. This transient hyperpolarization (the IPSP) looks very much like the EPSP, but it is reversed in sign.

What are the ionic mechanisms for these fast IPSPs and what is the transmitter substance? Because the membrane potential of the flexor motor neuron is about −65 mV, one might expect an increase in the conductance to some ion (or ions) with an equilibrium potential (reversal potential) more negative than −65 mV. One possibility is K^+. Indeed, the K^+ equilibrium potential in spinal motor neurons is about −80 mV; thus, a transmitter substance that produced a selective increase in K^+ conductance would lead to an IPSP. The K^+-conductance increase would move the membrane potential from −65 mV toward the K^+ equilibrium potential of −80 mV. Although an increase in K^+ conductance mediates IPSPs at some inhibitory synapses (see later), it does not at the synapse between the inhibitory interneuron and the spinal motor neuron. At this particular synapse, the IPSP seems to be due to a selective increase in Cl^- conductance. The equilibrium potential for Cl^- in spinal motor neurons is about −70 mV. Thus, the transmitter substance released by the inhibitory neuron diffuses across the cleft and interacts with receptor sites on the postsynaptic membrane. These receptors are normally closed, but when opened they become selectively permeable to Cl^-. As a result of the increase in Cl^- conductance, the membrane potential moves from a resting value of −65 mV toward the Cl^- equilibrium potential of −70 mV.

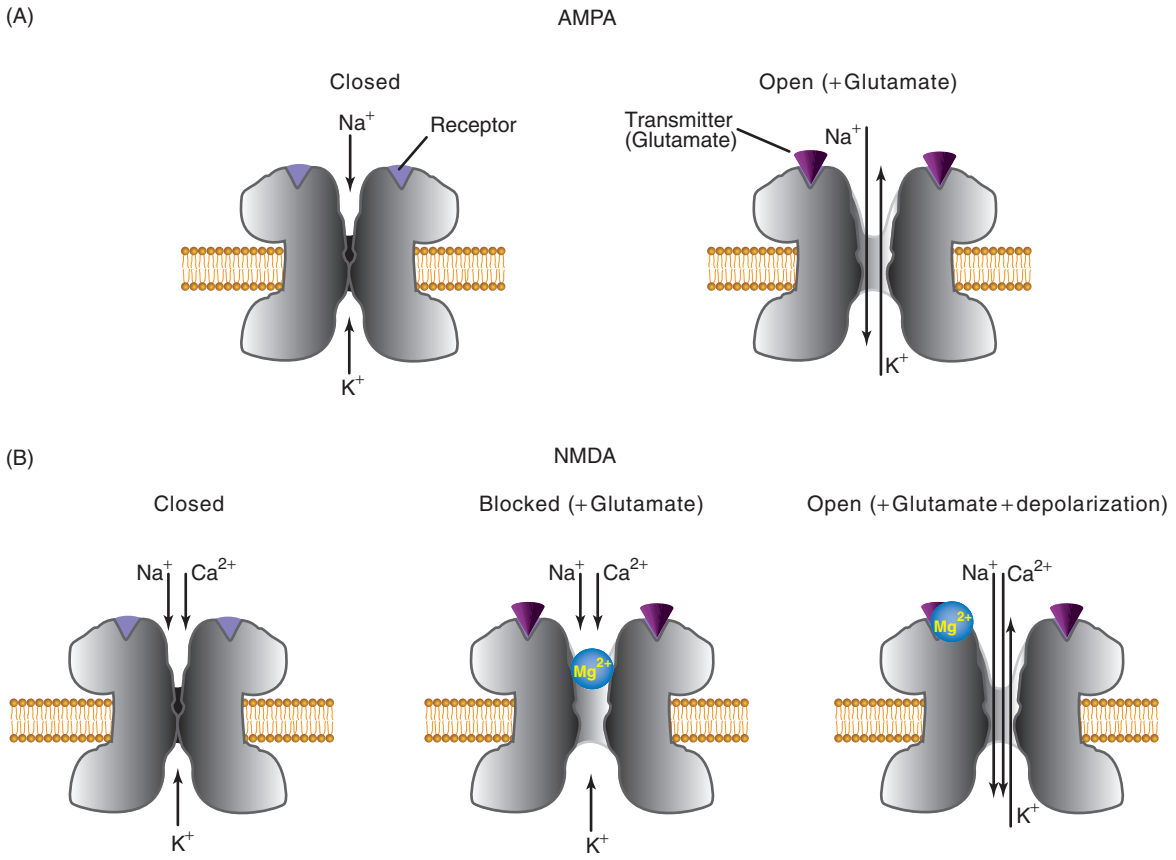

FIGURE 10.7 Features of AMPA and NMDA glutamate receptors. (A) AMPA receptors: (left) in the absence of agonist, the channel is closed, and (right) glutamate binding leads to channel opening and an increase in Na^+ and K^+ permeability. AMPA receptors that contain the GluR2 subunit are impermeable to Ca^{2+}. (B) NMDA receptors: (left) in the absence of agonist, the channel is closed; (middle) the presence of agonist leads to a conformational change and channel opening, but no ionic flux occurs because the pore of the channel is blocked by Mg^{2+}; and (right) in the presence of depolarization, the Mg^{2+} block is removed and the agonist-induced opening of the channel leads to changes in ion flux (including Ca^{2+} influx into the cell).

As in the sensory neuron–spinal motor neuron synapse, the transmitter substance released by the inhibitory interneuron in the spinal cord is an amino acid, but in this case the transmitter is glycine. The toxin strychnine is a potent antagonist of glycine receptors. Although glycine originally was thought to be localized to the spinal cord, it is also found in other regions of the nervous system. The most common transmitter associated with inhibitory actions in many areas of the brain is γ-aminobutyric acid (GABA; see Chapter 5).

GABA receptors are divided into three major classes: $GABA_A$, $GABA_B$, and $GABA_C$ (Billinton et al., 2001; Bormann & Fiegenspan, 1995; Bowery, 1993; Cherubini & Conti, 2001; Gage, 1992; Moss & Smart, 2001). As discussed in Chapter 7, $GABA_A$ receptors are ionotropic receptors, and, like glycine receptors, binding of transmitter leads to an increased conductance to Cl^-, which produces an IPSP. $GABA_A$ receptors are blocked by bicuculline and picrotoxin. A particularly striking aspect of $GABA_A$ receptors is their modulation by anxiolytic benzodiazepines. Figure 10.8 illustrates the response of a neuron to GABA before and after treatment with diazepam (Bormann, 1988). In the presence of diazepam, the response is potentiated greatly. In contrast to $GABA_A$ receptors that are pore-forming channels, $GABA_B$ receptors are G-protein coupled (see also Chapter 8). $GABA_B$ receptors can be coupled to a variety of different effector mechanisms in different neurons. These mechanisms include decreases in Ca^{2+} conductance, increases in K^+ conductance, and modulation of voltage-dependent A-type K^+ current. In hippocampal pyramidal neurons, the $GABA_B$-mediated IPSP is due to an increase in K^+ conductance. Baclofen is a potent agonist of $GABA_B$ receptors, whereas phaclofen is a selective antagonist. $GABA_C$ receptors are pharmacologically distinct from $GABA_A$ and $GABA_B$ receptors and are found predominantly in the vertebrate retina. $GABA_C$ receptors, like $GABA_A$ receptors, are Cl^- selective pores.

Ionotropic receptors that lead to the generation of IPSPs and ionotropic receptors that lead to the generation of EPSPs have biophysical features in common. Indeed, analyses of the preceding section are generally

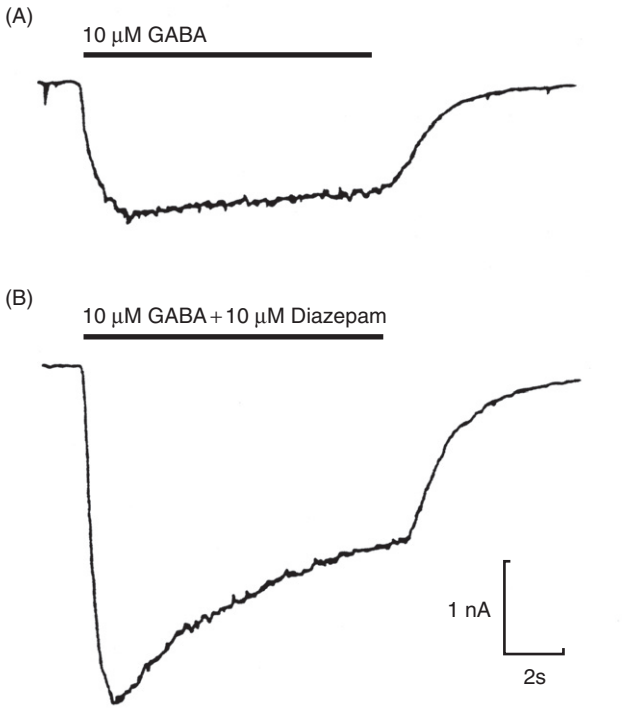

FIGURE 10.8 Potentiation of GABA responses by benzodiazepine ligands. (A) Brief application (bar) of GABA leads to an inward Cl^- current in a voltage-clamped spinal neuron. (B) In the presence of diazepam, the response is enhanced significantly. *From Bormann (1988).*

(1990).*

applicable. A quantitative understanding of the effects of the opening of glycine or $GABA_A$ receptors can be obtained by using the electrical equivalent circuit of Figure 10.5C and Eq. 10.5, with the values of g_{syn} and E_r appropriate for the respective ionotropic receptor. Interactions between excitatory and inhibitory conductances can be modeled by adding additional branches to the equivalent circuit (see Fig. 10.15D and Chapter 12).

Some PSPs Have More Than One Component

The transmitter released from a presynaptic terminal diffuses across the synaptic cleft, where it binds to ionotropic receptors. In many cases, the postsynaptic receptors are homogeneous. In other cases, the same transmitter activates more than one type of receptor. A major example of this type of heterogeneous postsynaptic action is the simultaneous activation by glutamate of NMDA and AMPA receptors on the same postsynaptic cell. Figure 10.9A illustrates such a dual-component glutamatergic EPSP in the CA1 region of the hippocampus. The cell is voltage clamped at various fixed holding potentials, and the macroscopic synaptic currents produced by activation of the presynaptic neurons are recorded. The experiment is performed in the presence and absence of the agent 2-amino-5-phosphonovalerate (APV), which is a specific blocker of NMDA receptors. When the cell is held at a potential of 20 or −40 mV, APV leads to a dramatic reduction of the late, but not the early, phase of the excitatory postsynaptic current (EPSC). In contrast, when the potential is held at −80 mV, the EPSC is unaffected by APV. These results indicate that the PSP consists of two components: an early AMPA-mediated component and a late NMDA-mediated component. In addition, results indicate that conductance of the non-NMDA component is linear, whereas conductance of the NMDA component is nonlinear. The I–V relations of the early (peak) and late (at approximately 25 ms) components of the EPSC are plotted in Figure 10.9B (Hestrin, Nicoll, Perkel, & Sah, 1990).

Dual-component IPSPs also are observed in the CNS, but here the transmitter (GABA) that mediates the inhibitory actions may be released from different neurons that converge on a common postsynaptic neuron. Stimulation of afferent pathways to the hippocampus results in an IPSP in a pyramidal neuron, which has a fast initial inhibitory phase followed by a slower inhibitory phase (Fig. 10.10). Application of $GABA_A$ antagonists blocks the early inhibitory phase, whereas the $GABA_B$ receptor antagonist phaclofen blocks the late inhibitory phase (not shown). Early and late IPSPs can also be distinguished based on their ionic mechanisms. Hyperpolarizing the membrane potential to −78 mV nulls the early response, but at this value of membrane potential, the late response is still hyperpolarizing (Figs. 10.10A and 10.10B). Hyperpolarizing the membrane potential to values more negative than −78 mV reverses the sign of the early response, but the slow response does not reverse until the membrane is made more negative than about −100 mV

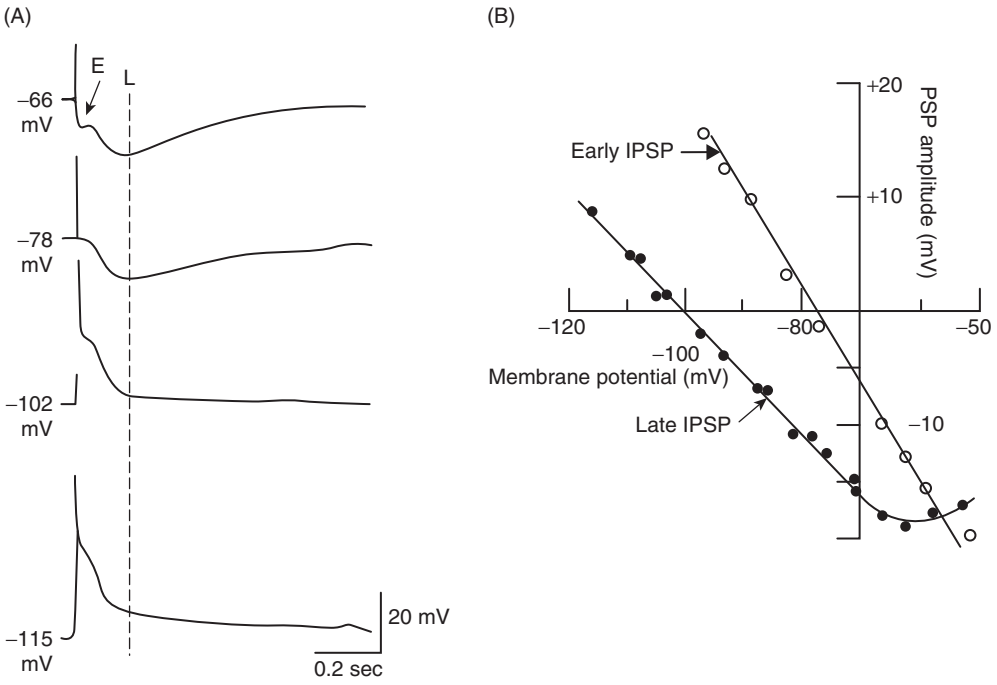

FIGURE 10.10 Dual-component IPSP. (A) Intracellular recordings from a pyramidal cell in the CA3 region of the rat hippocampus in response to activation of mossy fiber afferents. With the membrane potential of the cell at the resting potential, afferent stimulation produces an early (E) and late (L) IPSP. With increased hyperpolarization produced by injecting constant current into the cell, the early component reverses first. At more negative levels of the membrane potential, the late component also reverses. This result indicates that the ionic conductances underlying the two phases are distinct. (B) Plots of the change in amplitude of the early (measured at 25 ms) and the late (measured at 200 ms, dashed line in A) response as a function of membrane potential. Reversal potentials of the early and late components are consistent with a $GABA_A$-mediated chloride conductance and a $GABA_B$-mediated potassium conductance, respectively. *From Thalmann (1988).*

(Thalmann, 1988). The reversal potentials are consistent with a fast Cl^--mediated IPSP, mediated by fast opening of $GABA_A$ receptors and a slower K^+-mediated IPSP mediated by G-protein $GABA_B$ receptors.

Dual-component PSPs need not be strictly inhibitory or excitatory. For example, a presynaptic cholinergic neuron in the mollusk, *Aplysia*, produces a diphasic excitatory-inhibitory (E-I) response in its postsynaptic follower cell. The response can be simulated by local discrete application of ACh to the postsynaptic cell (Fig. 10.11) (Blankenship, Wachtel, & Kandel, 1971). The ionic mechanisms underlying this synaptic action were investigated in ion-substitution experiments, which revealed that the dual response is due to an early Na^+-dependent component followed by a slower Cl^--dependent component. Molecular mechanisms underlying such slow synaptic potentials are discussed next.

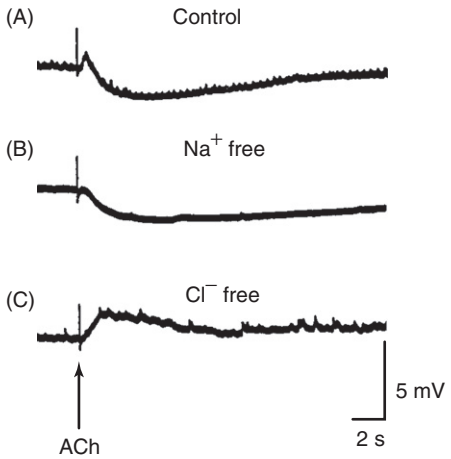

FIGURE 10.11 Dual-component cholinergic excitatory-inhibitory response. (A) Control in normal saline. Ejection of ACh produces a rapid depolarization followed by a slower hyperpolarization. (B) In Na^+-free saline, ACh produces a purely hyperpolarizing response, indicating that the depolarizing component in normal saline includes an increase in g_{Na}. (C) In Cl-free saline, ACh produces a purely depolarizing response, indicating that the hyperpolarizing component in normal saline includes an increase in g_{Cl}. *Reprinted with permission from Blankenship et al. (1971).*

Summary

Synaptic potentials mediated by ionotropic receptors are the fundamental means by which information is transmitted rapidly between neurons. Transmitters cause

channels to open in an all-or-none fashion, and the currents through these individual channels summate to produce the macroscopic postsynaptic potential. The sign of the postsynaptic potential is determined by the relationship between the membrane potential of the postsynaptic neuron and the ion selectivity of the ionotropic receptor.

METABOTROPIC RECEPTORS: MEDIATORS OF SLOW SYNAPTIC POTENTIALS

A common feature of the types of synaptic actions heretofore described is the direct binding of the transmitter with the receptor-channel complex. An entirely separate class of synaptic actions has as its basis the indirect coupling of the receptor with the channel. Two major types of coupling mechanisms have been identified: coupling of the receptor and channel through an intermediate regulatory protein, such as a G-protein, and coupling through a diffusible second-messenger system. Because coupling through a diffusible second-messenger system is the most common mechanism, it is the focus of this section.

A comparison of the features of direct, fast ionotropic-mediated and indirect, slow metabotropic-mediated synaptic potentials is shown in Figure 10.12. Slow synaptic potentials are not observed at every postsynaptic neuron, but Figure 10.12A illustrates an idealized case in which a postsynaptic neuron receives two inputs, one of which produces a conventional fast EPSP and the other of which produces a slow EPSP. An action potential in neuron 1 leads to an EPSP in the postsynaptic cell with a duration of about 30 ms (Fig. 10.12B). This type of potential might be produced in a spinal motor neuron by an action potential in an afferent fiber. Neuron 2 also produces a postsynaptic potential (Fig. 10.12C), but its duration (note the calibration bar) is more than three orders of magnitude greater than that of the EPSP produced by neuron 1.

How can a change in the postsynaptic potential of a neuron persist for many seconds as a result of a single action potential in the presynaptic neuron? Possibilities include a prolonged presence of the transmitter due to continuous release, to slow degradation, or to slow reuptake of the transmitter, but the mechanism here involves a transmitter-induced change in the metabolism of the postsynaptic cell. Figure 10.13 compares the general mechanisms for fast and slow synaptic potentials. Fast synaptic potentials are produced when a transmitter substance binds to a channel and produces a conformational change in the channel, causing it to become permeable to one or more ions (both Na^+ and K^+ in Fig. 10.13A). The increase in permeability leads

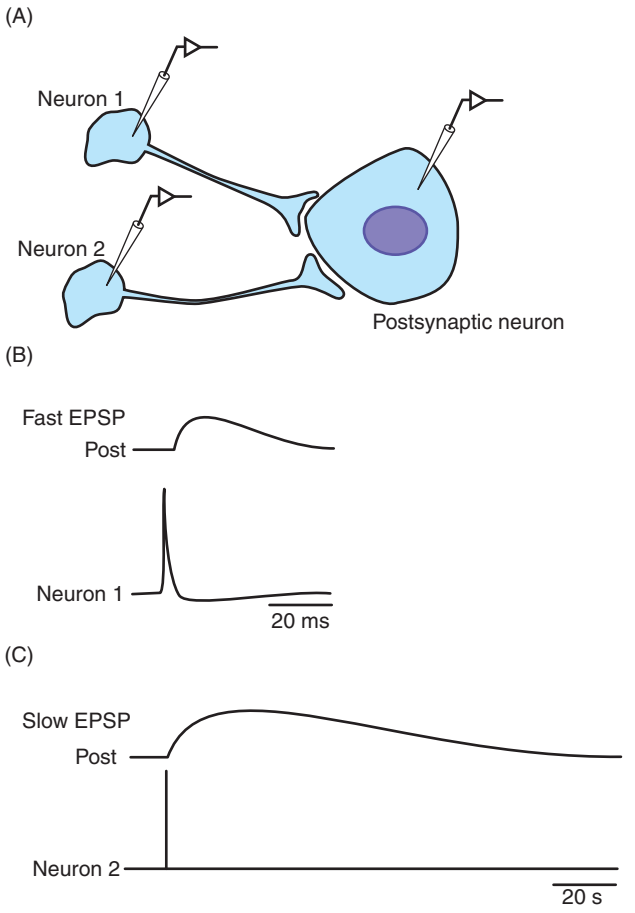

FIGURE 10.12 Fast and slow synaptic potentials. (A) Idealized experiment in which two neurons (1 and 2) make synaptic connections with a common postsynaptic follower cell (Post). (B) An action potential in neuron 1 leads to a conventional fast EPSP with a duration of about 30 ms. (C) An action potential in neuron 2 also produces an EPSP in the postsynaptic cell, but the duration of this slow EPSP is more than three orders of magnitude greater than that of the EPSP produced by neuron 1. Note the change in the calibration bar.

to a depolarization associated with the EPSP. The duration of the synaptic event critically depends on the amount of time during which the transmitter substance remains bound to the receptors. Acetylcholine, glutamate, and glycine remain bound only for a very short period. These transmitters are removed by diffusion, enzymatic breakdown, or reuptake into the presynaptic cell. Therefore, the duration of the synaptic potential is directly related to the lifetimes of the opened channels, and these lifetimes are relatively short (see Fig. 10.4B).

One mechanism for a slow synaptic potential is shown in Figure 10.13B. In contrast with the fast PSP for which the receptors are actually part of the ion channel complex, channels that produce slow synaptic potentials are not coupled directly to the transmitter receptors. Rather, the receptors are separated physically and exert their actions indirectly through changes

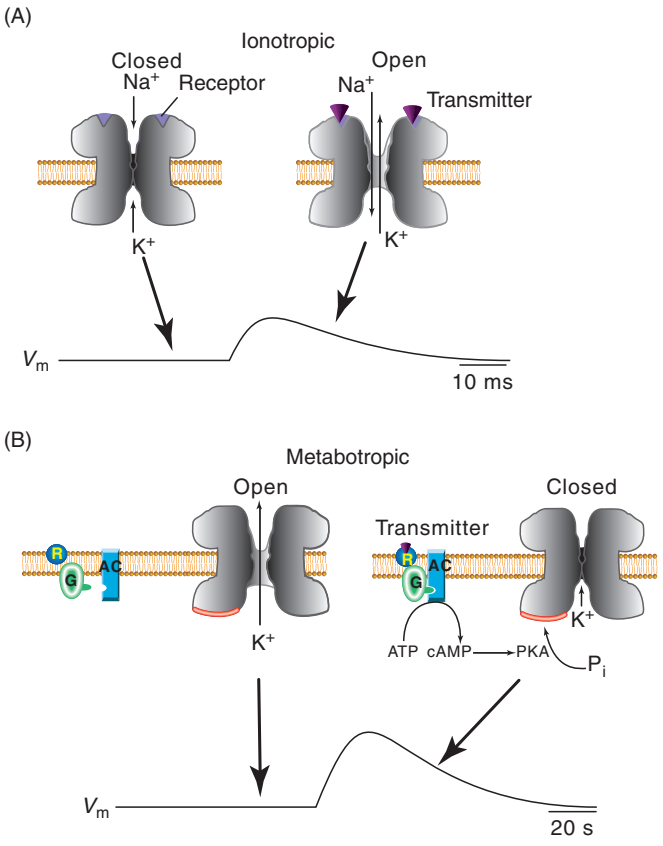

FIGURE 10.13 Ionotropic and metabotropic receptors and mechanisms of fast and slow EPSPs. (A, left) Fast EPSPs are produced by binding of the transmitter to specialized receptors that are directly associated with an ion channel (i.e., a ligand-gated channel). When the receptors are unbound, the channel is closed. (A, right) Binding of the transmitter to the receptor produces a conformational change in the channel protein such that the channel opens. In this example, the channel opening is associated with a selective increase in the permeability to Na^+ and K^+. The increase in permeability results in the EPSP shown in the trace. (B, left) Unlike fast EPSPs, which are due to the binding of a transmitter with a receptor-channel complex, slow EPSPs are due to the activation of receptors (metabotropic) that are not coupled directly to the channel. Rather, coupling takes place through the activation of one of several second-messenger cascades, in this example, the cAMP cascade. A channel that has a selective permeability to K^+ is normally open. (B, right) Binding of the transmitter to the receptor (R) leads to the activation of a G-protein (G) and adenylyl cyclase (AC). The synthesis of cAMP is increased, cAMP-dependent protein kinase (protein kinase A, PKA) is activated, and a channel protein is phosphorylated. The phosphorylation leads to closing of the channel and the subsequent depolarization associated with the slow EPSP shown in the trace. The response decays due to both the breakdown of cAMP by cAMP-dependent phosphodiesterase and the removal of phosphate from channel proteins by protein phosphatases (not shown).

in metabolism of specific second-messenger systems. Figure 10.13B illustrates one type of response in *Aplysia* for which the cAMP-protein kinase A (PKA) system is the mediator, but other slow PSPs use other second-messenger kinase systems (e.g., the protein kinase C system). In the cAMP-dependent slow synaptic responses in *Aplysia*, transmitter binding to membrane receptors activates G-proteins and stimulates an increase in the synthesis of cAMP. Cyclic AMP then leads to the activation of cAMP-dependent protein kinase (PKA), which phosphorylates a channel protein or protein associated with the channel (Siegelbaum, Camardo, & Kandel, 1982). A conformational change in the channel is produced, leading to a change in ionic conductance. Thus, in contrast with a direct conformational change produced by the binding of a transmitter to the receptor-channel complex, in this case, a conformational change is produced by protein phosphorylation. Indeed, phosphorylation-dependent channel regulation is a fairly general feature of slow PSPs. However, channel regulation by second messengers is not produced exclusively by phosphorylation. In one family of ion channels, the channels are gated or regulated directly by cyclic nucleotides. These cyclic nucleotide-gated channels require cAMP or cGMP to open but have other features in common with members of the superfamily of voltage-gated ion channels (Kaupp, 1995; Zimmermann, 1995).

Another interesting feature of slow synaptic responses is that they are sometimes associated with decreases rather than increases in membrane conductance. For example, the particular channel illustrated in Figure 10.13B is selectively permeable to K^+ and is normally open. As a result of the activation of the second messenger, the channel closes and becomes less permeable to K^+. The resultant depolarization may seem paradoxical, but recall that the membrane potential is due to a balance between resting K^+ and Na^+ permeability. K^+ permeability tends to move the membrane potential toward the K^+ equilibrium potential (−80 mV), whereas Na^+ permeability tends to move the membrane potential toward the Na^+ equilibrium potential (55 mV). Normally, K^+ permeability predominates, and the resting membrane potential is close to, but not equal to, the K^+ equilibrium potential. If K^+ permeability is decreased because some of the channels close, the membrane potential will be biased toward the Na^+ equilibrium potential and the cell will depolarize.

At least one reason for the long duration of slow PSPs is that second-messenger systems are slow (from seconds to minutes). Take the cAMP cascade as an example. Cyclic AMP takes some time to be synthesized, but, more importantly, after synthesis, cAMP levels can remain elevated for a relatively long period (minutes). The duration of the elevation of cAMP depends on the actions of cAMP-phosphodiesterase, which breaks down cAMP. However, duration of an effect could outlast the duration of the change in the second messenger because of persistent phosphorylation of the substrate protein(s). Phosphate groups are removed from substrate proteins by protein phosphatases. Thus, the net duration of a

response initiated by a metabotropic receptor depends on the actions of not only the synthetic and phosphorylation processes, but also the degradative and dephosphorylation processes.

Activation of a second messenger by a transmitter can have a localized effect on the membrane potential through phosphorylation of membrane channels near the site of a metabotropic receptor. The effects can be more widespread and even longer lasting than depicted in Figure 10.13B. For example, second messengers and protein kinases can diffuse and affect more distant membrane channels. Moreover, a long-term effect can be induced in the cell by altering gene expression. For example, protein kinase A can diffuse to the nucleus, where it can activate proteins that regulate gene expression. Detailed descriptions of second messengers and their actions are given in Chapter 9.

Summary

In contrast to the rapid responses mediated by ionotropic receptors, responses mediated by metabotropic receptors are generally relatively slow to develop and persistent. These properties arise because metabotropic responses can involve the activation of second-messenger systems. By producing slow changes in the resting potential, metabotropic receptors provide long-term modulation of the effectiveness of responses generated by ionotropic receptors. Moreover, these receptors, through the engagement of second-messenger systems, provide a vehicle by which a presynaptic cell can not only alter the membrane potential, but also produce widespread changes in the biochemical state of a postsynaptic cell.

INTEGRATION OF SYNAPTIC POTENTIALS

The small amplitude of the EPSP in spinal motor neurons (and other cells in the CNS) poses an interesting question. Specifically, how can an EPSP with an amplitude of only 1 mV drive the membrane potential of the motor neuron (i.e., the postsynaptic neuron) to threshold and fire the spike in the motor neuron that is necessary to produce the contraction of the muscle? The answer to this question lies in the principles of temporal and spatial summation.

When the ligament is stretched (Fig. 10.1), many stretch receptors are activated. Indeed, the greater the stretch, the greater the probability of activating a larger number of the stretch receptors; this process is referred to as recruitment. However, recruitment is not the complete story. The principle of frequency coding in the nervous system specifies that the greater the intensity of a stimulus, the greater the number of action potentials per unit time (frequency) elicited in a sensory neuron. This principle applies to stretch receptors as well. Thus, the greater the stretch, the greater the number of action potentials elicited in the stretch receptor in a given interval and therefore the greater the number of EPSPs produced in the motor neuron from that train of action potentials in the sensory cell. Consequently, the effects of activating multiple stretch receptors add together (spatial summation), as do the effects of multiple EPSPs elicited by activation of a single stretch receptor (temporal summation). Both of these processes act in concert to depolarize the motor neuron sufficiently to elicit one or more action potentials, which then propagate to the periphery and produce the reflex.

Temporal Summation Allows Integration of Successive PSPs

Temporal summation can be illustrated by firing action potentials in a presynaptic neuron and monitoring the resultant EPSPs. For example, in Figures 10.14A and 10.14B, a single action potential in sensory neuron 1 produces a 1-mV EPSP in the motor neuron. Two action potentials in quick succession produce two EPSPs, but note that the second EPSP occurs during the falling phase of the first, and the depolarization associated with the second EPSP adds to the depolarization produced by the first. Thus, two action potentials produce a summated potential that is about 2 mV in amplitude. Three action potentials in quick succession would produce a summated potential of about 3 mV. In principle, 30 action potentials in quick succession would produce a potential of about 30 mV and easily drive the cell to threshold. This summation is strictly a passive property of the cell. No special ionic conductance mechanisms are necessary. Specifically, the postsynaptic conductance change (g_{syn} in Eq. 10.3) produced by the second of two successive action potentials adds to that produced by the first. In addition, the postsynaptic membrane has a capacitance and can store charge. Thus, the membrane temporarily stores the charge of the first EPSP, and the charge from the second EPSP is added to that of the first.

However, the "time window" for this process of temporal summation very much depends on the duration of the postsynaptic potential, and temporal summation is possible only if the presynaptic action potentials (and hence postsynaptic potentials) are close in time to each other. The time frame depends on the duration of changes in the synaptic conductance and the time constant (Chapter 5). Temporal summation, however, rarely is observed to be linear as in the preceding examples, even when the postsynaptic conductance change (g_{syn} in Eq. 10.3) produced by the second of two successive action potentials is identical with that produced by the

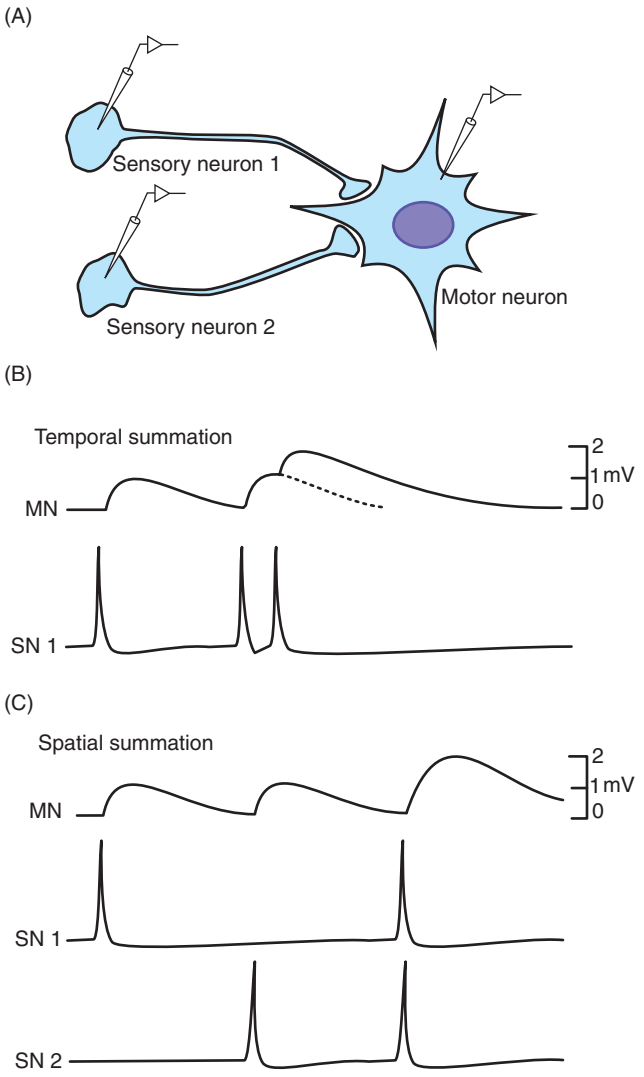

FIGURE 10.14 Temporal and spatial summation. (A) Intracellular recordings are made from two idealized sensory neurons (SN1 and SN2) and a motor neuron (MN). (B) Temporal summation. A single action potential in SN1 produces a 1-mV EPSP in the MN. Two action potentials in quick succession produce a dual-component EPSP, the amplitude of which is approximately 2 mV. (C) Spatial summation. Alternative firing of single action potentials in SN1 and SN2 produce 1-mV EPSPs in the MN. Simultaneous action potentials in SN1 and SN2 produce a summated EPSP, the amplitude of which is about 2 mV.

first (i.e., no presynaptic facilitation or depression) and the synaptic current is slightly less because the first PSP reduces the driving force ($V_m - E_r$) for the second. Interested readers should try some numerical examples.

Spatial Summation Allows Integration of PSPs from Different Parts of a Neuron

Spatial summation (Fig. 10.14C) requires a consideration of more than one input to a postsynaptic neuron. An action potential in sensory neuron 1 produces a 1-mV EPSP, just as it did in Figure 10.14B. Similarly, an action potential in a second sensory neuron by itself also produces a 1-mV EPSP. Now, consider the consequences of action potentials elicited simultaneously in sensory neurons 1 and 2. The net EPSP is equal to the summation of the amplitudes of the individual EPSPs. Here, the EPSP from sensory neuron 1 is 1 mV, the EPSP from sensory neuron 2 is 1 mV, and the summated EPSP is approximately 2 mV (Fig. 10.14C). Thus, spatial summation is a mechanism by which synaptic potentials generated at different sites can summate. Spatial summation in nerve cells is influenced by the space constant—the ability of a potential change produced in one region of a cell to spread passively to other regions of a cell (see Chapter 11).

SYNAPTIC PLASTICITY

Synaptic plasticity refers to the ability of synaptic connections to change their strength, a process that is believed critical for regulating the flow of information in neuronal circuits and for mediating learning and memory. Synaptic plasticity has two major forms, homosynaptic plasticity and heterosynaptic plasticity. Homosynaptic plasticity refers to the ability of a synapse to change its strength as a result of activity in that synapse, whereas heterosynaptic plasticity refers to the ability of a synapse to change its strength as a result of activity in another neuron or pathway.

Homosynaptic plasticity has two basic forms: homosynaptic depression and homosynaptic facilitation. Homosynaptic depression refers to a decrease in the strength of a synaptic connection with repeated activation. For example, if the afferent sensory neuron in Figure 10.2 is stimulated a second time 100 ms after the first, the second EPSP will have a lower amplitude. The mechanisms underlying synaptic depression are diverse and range from depletion of the pools of transmitter in the presynaptic terminal to desensitization of transmitter receptors on the postsynaptic neuron. The various possibilities are not mutually exclusive. Homosynaptic facilitation is a phenomenon opposite to homosynaptic depression. It generally occurs when multiple action potentials are fired in quick succession in a presynaptic neuron. For example, if the afferent sensory neuron in Figure 10.2 is stimulated a second time 10 ms after the first, the second EPSP will have a greater amplitude. This particular example of homosynaptic facilitation is frequently called paired-pulse or twin-pulse facilitation (PPF). A common mechanism for PPF involves residual calcium. If the second presynaptic action potential is initiated during a time when Ca^{2+} levels remain elevated after the first, the Ca^{2+} influx from the second spike will add to it. Consequently, more transmitter will be released because of the greater net Ca^{2+} concentration in the

presynaptic terminal. When two spikes are close together PPF occurs rather than homosynaptic depression presumably because the increase in the probably of release caused by the enhanced Ca^{2+} is much greater than the decrease in the pool size due to the depletion of transmitter. A more dramatic example of homosynaptic facilitation is post-tetanic potentiation (PTP). Here, rather than two spikes a high frequency burst of spikes (tetanus) is delivered to the presynaptic neuron and subsequent test EPSPs are enhanced.

Like homosynaptic plasticity, heterosynaptic plasticity has two forms: heterosynaptic inhibition and heterosynaptic facilitation. In both cases, the strength of the synapse between two neurons is regulated by a third neuron or pathway. The prime example of heterosynaptic inhibition is presynaptic inhibition in the spinal cord where descending control pathways regulate the strength of connections between sensory neurons and their postsynaptic targets. At the mechanistic level, presynaptic inhibition appears to be due to a down regulation of voltage-dependent Ca^{2+} conductances in the presynaptic terminals. Consequently, action potentials in the sensory neurons lead to less influx of Ca^{2+} and less transmitter release. Therefore, the amplitude of the EPSP in the postsynaptic cell is reduced (i.e., inhibited). The most extensively studied example of heterosynaptic facilitation is the serotonin-induced facilitation of the *Aplysia* sensorimotor synapse, which has both short lasting (min) and long lasting (days) forms. This process is described in detail in Chapter 47. Other more enduring forms of synaptic plasticity such as long-term potentiation (LTP) and long-term depression (LTD) are also described in Chapter 47.

Summary

Whether a neuron fires in response to synaptic input depends, at least in part, on how many action potentials are produced in any one presynaptic excitatory pathway and on how many individual convergent excitatory input pathways are activated. The summation of EPSPs in time and space is only part of the process, however. The final behavior of the cell is also due to the summation of inhibitory synaptic inputs in time and space, as well as to the properties of the voltage-dependent currents (Fig. 10.15) in the soma and along the dendrites (Koch & Segev, 1989; Ziv, Baxter, & Byrne, 1994). For example, voltage-dependent conductances such as A-type K^+ conductance have a low threshold for activation and can thus oppose the effectiveness of an EPSP to trigger a spike. Low-threshold Na^+ and Ca^{2+} channels can boost an EPSP. Finally, we need to consider that spatial distribution of the various voltage-dependent channels, ligand-gated receptors, and metabotropic receptors is not uniform. Thus, each segment of the neuronal membrane can perform selective integrative functions. Clearly, this system has an enormous capacity for the local processing of information and for performing logical operations.

The flow of information in dendrites and the local processing of neuronal signals are discussed in Chapter 12. Several software packages are available for the development and simulation of realistic models of single neurons and neural networks. One, Simulator for Neural Networks and Action Potentials (SNNAP) (http://nba.uth.tmc.edu/snnap/), provides mathematical descriptions of ion currents, intracellular second messengers, and ion pools, and allows simulation of current flow in multicompartment models of neurons.

Information Processing in Dendrites and Spines

INTRODUCTION

A central goal of neuroscience is to understand how neural circuits control sensation and action, perception, and cognition. These circuits are constructed of neurons, most of which have elaborately branching dendritic trees. Dendrites receive and integrate a wealth of information; in many cases tens of thousands of synapses are formed on the dendritic tree of a single neuron. Activation of these synapses results in complex spatiotemporal signal integration involving current flow that ultimately converges in the axon, where "decisions" are made regarding action potential initiation. Signal integration in dendrites is central to the function of neural circuits and therefore contributes to the brain's ability to perform the multimodal integrative tasks that are key to survival. Thus, a detailed analysis of how synaptic inputs are integrated in dendrites is essential to an understanding of the neural control of behavior and cognition.

A traditional approach to investigating the function of neural circuits is through modeling of neural networks. Typically, these models are built using simple neurons that integrate excitatory and inhibitory inputs until a fixed threshold for action potential firing is reached. Some real neurons might function like this. For example, the most numerous cell type in the brain—the granule cells of the cerebellum—integrates just a few excitatory inputs on very small dendrites. In these neurons, synaptic integration is relatively simple. Most other neurons in the brain, however, have much more elaborate dendritic trees, and accordingly, synaptic integration is much more complex.

The structure of dendritic trees is very diverse (Fig. 11.1), likely reflecting diversity in the functional properties and the types of computations performed by different types of neurons. To fully understand synaptic integration and, ultimately, the computations performed by neurons and circuits, it is necessary to achieve an appreciation of how synaptic inputs are processed in a variety of neuronal types. Dendritic integration has been studied in several types of neurons, with an emphasis on pyramidal neurons of the neocortex and hippocampus and Purkinje cells of the cerebellum. From this work a number of general principles have been learned, which will facilitate the analysis of dendritic integration in other cell types as the field advances.

How does the presence of dendrites affect synaptic integration? The answer is complex, but it has its roots in the fact that the interactions between multiple synapses, and the mechanisms that ultimately lead to action potential firing in the axon, are determined by current flow both across the membrane and longitudinally along dendritic branches. Thus, a key component to understanding how synaptic inputs are integrated is to quantitatively analyze how current flows in dendritic trees. This first became possible with the development of neuronal cable theory by Wilfrid Rall (Box 11.1).

Rall took the mathematics originally developed to describe the flow of current (and the resultant voltage changes) in transatlantic telegraph cables and applied it to branching structures, in particular dendrites. Rall's theory is sometimes called "passive cable theory," because it is based on the passive membrane properties of neurons (see Chapter 6). Rall recognized, however, that not all neuronal cables are passive; axons certainly are not, and at the time the theory was developed, it was already becoming clear that dendrites might also be excitable (i.e., contain voltage-gated channels that provide inward current). Rall nevertheless realized that

BOX 11.1

NEURONAL CABLE THEORY AND COMPUTATIONAL MODELING

One of the seminal contributions to neuroscience is neuronal cable theory, which was developed by Wilfrid Rall in the 1950s–1960s. The theory provided a framework for quantitatively analyzing the effects of dendrites and dendritic spines on the process of synaptic integration. The central concept is that dendrites are conductive cables separated from a conducting surrounding medium (the extracellular space) by a mostly insulating membrane. The cable is characterized by its intracellular resistivity (R_i), its membrane resistivity (R_m), and its specific membrane capacitance (C_m). If the membrane potential is changed at the sealed end of a cable that extends infinitely in one direction, the voltage will decay exponentially, according to the equation:

$$\Delta V_x = \Delta V_0 * \exp(-x/\lambda)$$

where ΔV_0 is the voltage change imposed at the end, ΔV_x is the voltage change at distance x along the cable, and λ is the "space constant" of the cable, given by $\lambda = [(d/4)(R_m/R_i)]^{1/2}$, where d is the diameter of the cable. For transient voltage changes, the terminal decay of the voltage over time is governed by the membrane time constant, $\tau = R_m C_m$.

BOX 11.1 (*cont'd*)

The mathematical centerpiece of neuronal cable theory is the cable equation:

$$\frac{\partial V}{\partial T} = \frac{\partial^2 V}{\partial X^2} - V$$

This differential equation describes the change in voltage along a cable in both time and space, where X and T are dimensionless variables ($X = x/\lambda$ and $T = t/\tau$). The cable equation had been used previously for axons (Cole & Hodgkin, 1939; Davis & Lorente de Nó, 1947; Hodgkin & Rushton, 1946), but Rall extended its application to dendrites. Although much of Rall's work used this equation to analyze voltage changes in simple linear cables, he also applied it to branching cables and showed that it could be used to analyze dendrites with arbitrary branching geometries. Indeed, one of Rall's (1959) key contributions was his analysis of the effects of branching in cables: primarily in dendrites, but also in axons (Goldstein & Rall, 1974).

In its analytical form, the cable equation can only be applied to passive dendrites with current sources (i.e., no synaptic or voltage-gated conductances). Rall realized, however, that dendrites were not likely to function as purely passive cables, so he also applied the cable equation to numerical simulations in order to facilitate simulation of more complex conditions, such as the activation of time- and voltage-dependent conductances in dendrites. Central to this approach is the concept that each segment of a dendrite can be broken up into a number of isopotential compartments, with changes in membrane potential between compartments computed using the cable equation with discrete time steps. The accuracy of such simulations therefore depends on the assignment of appropriately small compartments and short time steps.

Rall's calculations and computer simulations provided myriad insights, including many of the principles described in this chapter. Two of them are illustrated here: the distance-dependent filtering of synaptic potentials along cables and the difference in responses to groups of synapses activated in different spatio-temporal patterns along a dendrite (Fig. B11.1). His many other findings are reviewed in the book *Theoretical Foundation of Dendritic Function* (Segev, Rinzel, & Shepherd, 1995), which compiles and summarizes Rall's most important contributions to the field.

Two other aspects of Rall's work are just as important as his papers. First, Rall pioneered the use of computers to simulate not only single neurons but also small circuits of neurons. Second, Rall realized the importance of a close alliance between theorists and experimentalists, and his work is a testament to the progress that can be achieved using this approach.

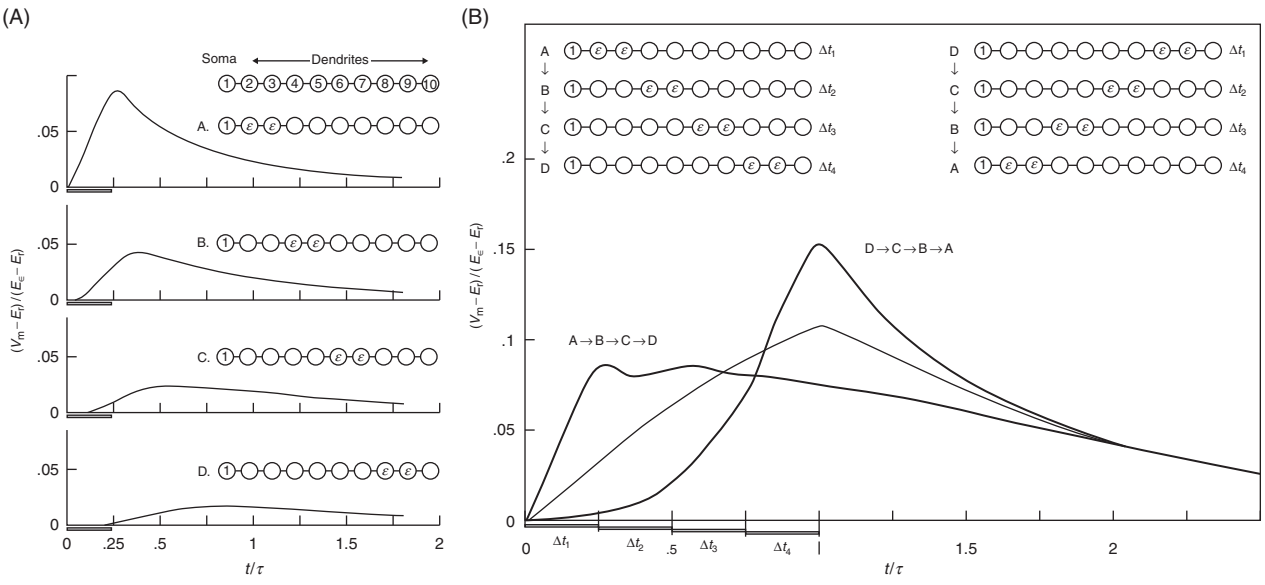

FIGURE B11.1 Simulations of excitatory synaptic inputs in a model dendrite. (A) Somatic membrane potential for excitatory synapses (ε) positioned in different compartments of a dendrite. Synapses positioned further from the soma resulted in progressively smaller and slower somatically recorded synaptic potentials. EPSP amplitude is normalized to the driving force and time is normalized to the membrane time constant. (B) Somatic membrane potential for activation of excitatory synapses in opposite order. For A->B->C->D the proximal synapses were activated first; for D->C->B->A the distal synapses were activated first. Synapses were simulated at temporal increments of 0.25τ. *Source: Rall (1964).*

passive cable theory could provide the necessary foundation for a more in-depth analysis of the complex processing that would occur in excitable dendrites. He also showed that cable theory could be used to develop computational models of elaborately branching dendritic trees. Computational modeling based on cable theory has taken a central place in the field of neuroscience, allowing for complex integrative processes to be analyzed quantitatively, leading to new insights and experiments that have resulted in new discoveries. In fact, in the decades that have followed Hodgkin and Huxley's landmark experimental and theoretical analysis of the action potential and its propagation along axons, the field of dendritic integration is one of the areas in neuroscience where the combination of experimental and theoretical approaches has been employed very effectively.

Following the logical sequence pioneered by Rall, we begin by considering how the integration of synaptic inputs occurs in passive dendrites, and continue by considering how synaptic integration is affected by active dendritic properties.

SYNAPTIC INTEGRATION IN PASSIVE DENDRITES

Decades ago, Rall used his theory to predict that somatically recorded synaptic potentials would be much smaller when the activated synapses are located in distal dendrites than if the same synapses were located close to the soma. In addition, he predicted that the filtering effects of dendrites would have effects on the time course of EPSPs and the interactions between synapses. More recently, Rall's predictions have been validated by experimental measurements, made possible by the development of methods for recording directly from the dendrites of neurons (Box 11.2).

Effects of Dendrites on Synaptic Potentials at the Soma

In most neurons, the soma is an important location for a number of reasons. Dendrites converge on the soma, forming a confluence for current flowing from the dendrites (Fig. 11.2A). Current that reaches the soma flows from there to the axon, which usually emerges at or very near the soma. This integrated current changes the membrane potential in the axon initial segment, where action potentials are initiated if the depolarization is sufficiently large. The soma also happens to be the location at which most electrophysiological recordings are obtained. This is convenient, because somatic recordings reflect the integration occurring at a location very near the action potential initiation zone, but it is important to understand how the presence of dendrites influences the current flowing into and out of the soma and how this shapes the membrane potential that is recorded there. The magnitude of the dendritic filtering of synaptic potentials depends on the overall structure of the dendritic tree, the membrane properties of dendrites, and the location of the synapses. In most neurons, dendrites exert a powerful filtering effect on synaptic potentials spreading through them, and as a result somatically recorded potentials are much smaller than the same events recorded in the dendrites (Fig. 11.2).

Two effects influence the difference between somatic and dendritically recorded EPSPs. First, some of the charge that enters the neuron at a synapse never reaches the soma. When a synapse depolarizes a dendrite, there is a voltage difference between the dendrite and the soma, which will promote current flow toward the soma (where the direction of current flow is defined by the movement of positive charge). Current travels within dendrites via electron transfer between charged particles in the cytoplasm, but because the density of charged particles is relatively low (compared to a copper wire, for instance), dendrites have a significant longitudinal resistance. As a result, some current will flow along alternate paths, such as onto the capacitance of the dendritic membrane and across its resistance (Fig. 11.2B). Most dendritic trees have a lot of branches and a large surface area, so there can be significant loss of synaptic current as it flows into dendritic branches on its way to the soma. In fact, in many cases only a small fraction of the total synaptic current reaches the soma and contributes to the local depolarization observed there.

Computational analyses, based on realistic models of pyramidal neurons with complex dendritic trees, suggest that for the most distal synapses on a pyramidal neuron, less than 10% of the synaptic charge will ultimately reach the soma. The same computational analyses, however, have shown that EPSPs in the soma are 100-fold smaller than the same EPSPs measured in distal dendrites, as observed in experiments (Fig. 11.2C and 11.2D). Why is there a 100-fold difference between dendritic and somatic EPSP amplitude if 10% of the synaptic charge reaches the soma? This is because a second factor influences the size of the EPSP at each location: the local input resistance (or impedance, the frequency-dependent equivalent of resistance). Small-diameter dendrites have very high input impedances, while the soma typically has a much lower input impedance, because of its larger size. Ohm's law dictates that a given amount of synaptic charge will produce a much larger EPSP in high-impedance dendrites than in the low-impedance soma, even if no charge were lost via alternative pathways.

These two effects—charge loss and difference in local input impedance—combine to produce very large differences between the amplitude of the EPSP at the synapse

BOX 11.2

DENDRITIC RECORDING

Ever since Santiago Ramón y Cajal looked down a microscope over a hundred years ago and observed that individual nerve cells have complex processes called dendrites neuroscientists have wondered at their properties. How dendrites influence the way neurons process synaptic input remained a mystery until the 1950s and 1960s, when theoretical models were used to explore dendritic function (Box 11.1). Experimental observations of dendritic properties had to wait until the 1970s and 1980s, when the first recordings were made from neuronal dendrites using sharp microelectrodes (Fig. 11.4). Due to their small size, these recordings, while very influential, were rare. Furthermore, because these recordings were performed "blind" (without visual information to guide microelectrode placement), identification of the site of recording was difficult, and recordings were restricted to brain regions where dendrites predominated.

The application of differential interference contrast optics to visualize neurons in brain slices allowed the possibility to record from neurons under visual control (Takahashi, 1978). This method was significantly enhanced by the introduction of the patch-clamp technique (Edwards, Konnerth, Sakmann, & Takahashi, 1989). Advances in optics, as well as the use of both infrared light, which reduces light scattering, and video microscopy, to enhance contrast, allowed dendrites to be visualized in living brain tissue for the first time (Dodt & Zieglgansberger, 1990). By combining these methods, it was possible to routinely record from dendrites under visual control (Stuart, Dodt, & Sakmann, 1993). This opened the door for direct experimental recordings to be made from dendrites using the power of the patch-clamp technique (Hamill, Marty, Neher, Sakmann, & Sigworth, 1981), allowing their properties and function to be investigated in detail. Using outside out and cell-attached recording, it has been possible to map the density and properties of voltage- and ligand-gated channels in the dendrites of different neuronal types. Furthermore, since both the dendrites and the cell body of neurons can be visually identified simultaneously, whole-cell recordings can be made from multiple locations on the same neuron, allowing the propagation of a variety of voltage signals in dendrites to be directly examined (Fig. B11.2).

As described in this chapter, these technical developments have led to a number of important discoveries about dendritic function in a variety of neuronal cell types, including direct observations of dendritic membrane properties, the finding that action potentials actively propagate back into the dendrites of many but not all neurons, and the description of a variety of different types of dendritic spikes and how they influence neuronal output. Critical to an understanding of how these dendritic properties influence brain function will be to determine how dendrites work in the intact brain. While we are still some way off achieving this goal, dendritic whole-cell recordings have been obtained *in vivo* in anesthetized preparations (Waters & Helmchen, 2004), and somatic whole-cell recordings can be obtained in awake, behaving animals (Lee, Manns, Sakmann, & Brecht, 2006). Using these methods, combined with optical techniques (Box 11.3), offers the possibility to observe dendritic activity at high resolution using the patch-clamp technique in the working brain.

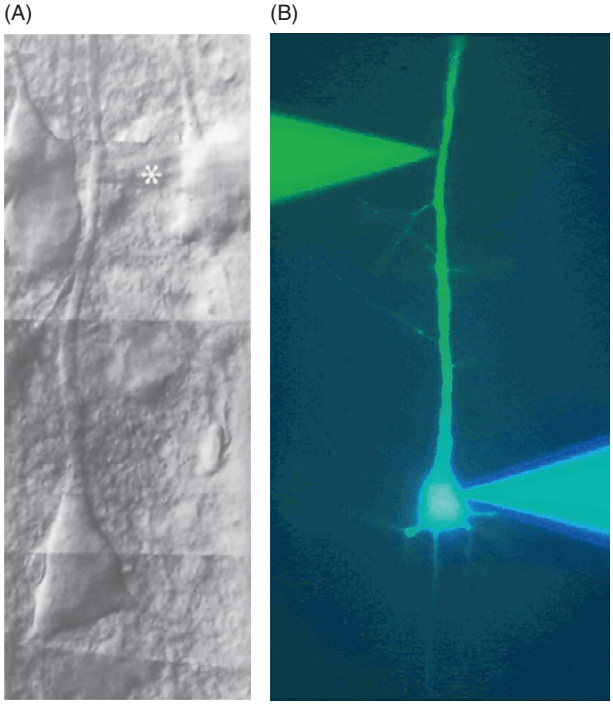

FIGURE B11.2 Examples of dendritic recording. (A) Differential interference contrast image of a cortical layer 5 pyramidal neuron in a living brain slice from rat somatosensory cortex. A patch pipette (asterisk) can be seen recording from the main apical dendrite. (B) Fluorescent image of a simultaneous somatic (blue) and dendritic (green) patch pipette recording from a cortical layer 5 pyramidal neuron. *Sources: (A) Adapted from Stuart, et al., 1993; (B) Adapted from Stuart and Sakmann, 1994.*

and at the soma. In passive dendrites, when comparing the ability of two synapses at different locations to depolarize the soma or axon (thereby influencing action potential initiation), only the first effect is relevant, because it is the amount of charge reaching the soma that matters. Distal synapses are located on small dendrites with high input impedance, which magnifies the local voltage change, thus resulting in very large local

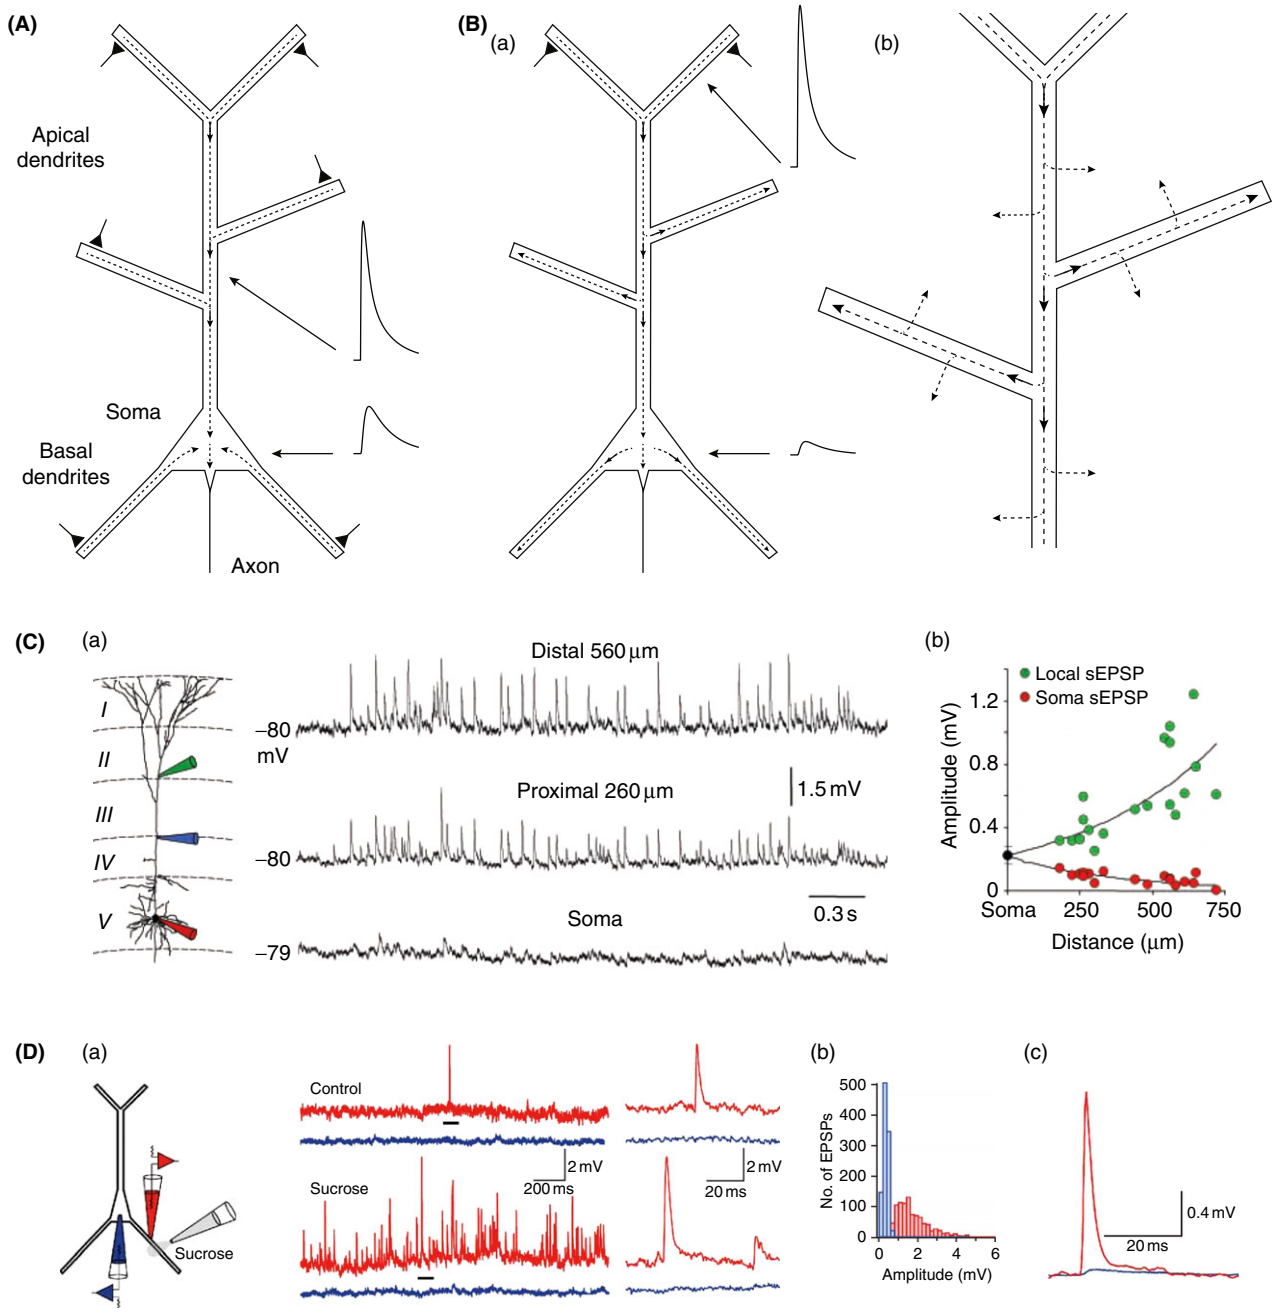

FIGURE 11.2 EPSPs are larger in dendrites than in the soma. (A) Schematic diagram of a pyramidal neuron illustrating synaptic current from the dendrites converging at the soma. Triangles indicate active excitatory synapses. Dashed lines indicate axial dendritic current, with arrowheads indicating direction of current flow. Schematic showing attenuation of EPSP from dendrite to the soma. Dendritic EPSP is larger than somatic EPSP because of higher input impedance of dendrite than soma and loss of charge between dendrite and soma. (B) (a) Similar to A, but showing different current flow when only distal apical synapses are activated. Dendritic EPSP is larger than in A because of higher input impedance of distal dendrite. Somatic EPSP is smaller than in A both because of fewer synapses and maximal loss of charge from distal dendrites. (b) Magnified view showing that some of the current flowing in dendrites is also lost across the dendritic membrane leak. Some membrane current would also flow in A. (C) (a) Triple whole-cell patch-clamp recordings from the soma, proximal dendrite, and distal dendrite. Spontaneous EPSPs were measured simultaneously at all three recording locations. (b) Amplitude of spontaneous EPSPs (sEPSP) measured locally and at the soma, as a function of sEPSP generation (i.e., the dendritic recording location at which the sEPSP was largest). (D) (a) Dual whole-cell patch-clamp recordings from the soma (blue) and a basal dendrite (red, 124 µm from soma) of a layer 5 neocortical pyramidal neuron. Sucrose was applied to evoke unitary EPSPs (by enhancing vesicle release), which are measured in the dendrite and soma. Traces at right are expansions of regions indicated by black bars. (b) Histogram of EPSP amplitudes measured in the soma (blue) and dendrite (red). (c) Average of EPSPs measured in the soma and dendrite. *Sources: (A, B) N. Spruston; (C) Williams and Stuart, 2002; (D) Nevian et al., 2007.*

EPSPs, but in passive dendrites this does not increase the efficacy of a synapse on action potential generation, because irrespective of whether a synapse is on the soma or on a distal dendrite, the amplitude of the somatic EPSP is determined solely by the synaptic charge that reaches the soma and the somatic input impedance. In the case of passive dendrites, only the extent to which synaptic charge is lost as current flows from the synapse to the soma affects the final impact of a distal synapse on action potential output. Thus, in the example above, the distal dendritic synapse would be only 10-fold less effective at depolarizing the soma than the same synapse located on a very proximal dendrite. As a result, it is important to realize that, in the passive case, the larger local voltage produced by more distal synapses does not in any way compensate for the distal location of these synapses, since this does not increase the amount of charge that flows into the cell at the synapse. In fact, the larger local voltage change in distal dendrites will reduce the electrical driving force for current flow at the synapse or, alternatively, may lead to activation of voltage-gated channels—important effects that are discussed later in the chapter.

Effects of Synaptic Kinetics on Dendritic Filtering

Another factor that affects the difference in amplitude of synaptic potentials in the dendrites versus the soma is the kinetics of synaptic current. As discussed in Chapter 6, current flow across the membrane is frequency dependent because of the membrane capacitance. Charge that is deposited onto the membrane capacitance can reach the soma eventually, but it is delayed. Thus, although the total amount of charge reaching the soma is not dependent on the kinetics of the synaptic current, the peak of the EPSP is attenuated more for fast synaptic potentials, such as EPSPs mediated by synchronous activation of AMPA-type glutamate receptors (GluRs), than for slow synaptic potentials, such as EPSPs mediated by activation of NMDA receptors.

The time course of synaptic potentials is faster in the dendrites than for a similar synaptic input to the soma (Fig. 11.3A); the time course of an EPSP in a dendritic spine is expected to be even faster. Near the synapse, membrane potential rises rapidly during synaptic current, owing to the rapid onset of synaptic currents. The decay of the dendritic EPSP is also quite fast as a result of current flowing axially along the dendrites, away from the synapse (Fig. 11.2B). The somatic EPSP is much slower, however. Its rise time is slower because of the delayed arrival of synaptic current from the dendrites and its decay, like the terminal decay of the dendritic EPSP, is relatively slow because it is governed by the membrane time constant (Fig. 11.3A), which is relatively slow because of the high membrane resistance and capacitance in most neurons (see Chapter 6). These factors combine to produce relatively slow EPSPs at the soma, resulting in a longer time window for summation of synaptic potentials in the soma than in the dendrites.

A special case that needs to be considered is experiments where an attempt is made to measure synaptic currents using voltage clamp. In order to obtain accurate measures of the amplitude and kinetics of synaptic currents, it is essential that the activated synapse be located very close to the voltage-clamp electrode. When attempting to voltage clamp synapses on distal dendrites using a somatic electrode, the resultant errors are very large (so-called "space-clamp" errors). Not only are the amplitude and kinetics of the synaptic current affected by the same factors as those described above for the filtering of synaptic potentials, but an additional error is caused by the difficulty of actually clamping the synaptic membrane potential using a somatic electrode. The distance between the somatic electrode and the synapse makes it impossible for the voltage clamp to control the voltage at the synapse, resulting in "voltage escape" at the synapse. This problem is greatest for fast synapses. Space-clamp errors—caused by loss of current from synapse to soma and escape of the synaptic potential from the voltage clamp—combine to produce very large distortions of the amplitude and kinetics of synaptic currents. The magnitude of these errors has been predicted and estimated using computational models but also validated using direct experimental measurements involving simultaneous dendritic and somatic recordings.

Interactions between Synapses in Passive Dendrites

If synapses were only activated one at a time, most cells would never fire an action potential. This is because the concerted action of many excitatory synapses is required to span the gap between the resting potential and action potential threshold. This gap is typically around 20 mV, so with an average EPSP amplitude of 0.2 mV, we can estimate that about 100 excitatory synapses would need to be activated to generate an action potential. This is at best a crude estimate, however, because it fails to take into account the influence of complexities such as inhibition, dendritic filtering, changes in driving force, and dendritic excitability. It is clear that interactions that occur between synapses in dendrites play a critical role in determining the impact of EPSPs on action potential output. While these interactions can be very complicated, a few simple principles can be described.

The first important point is that excitatory synapses summate in a sublinear fashion in passive dendrites

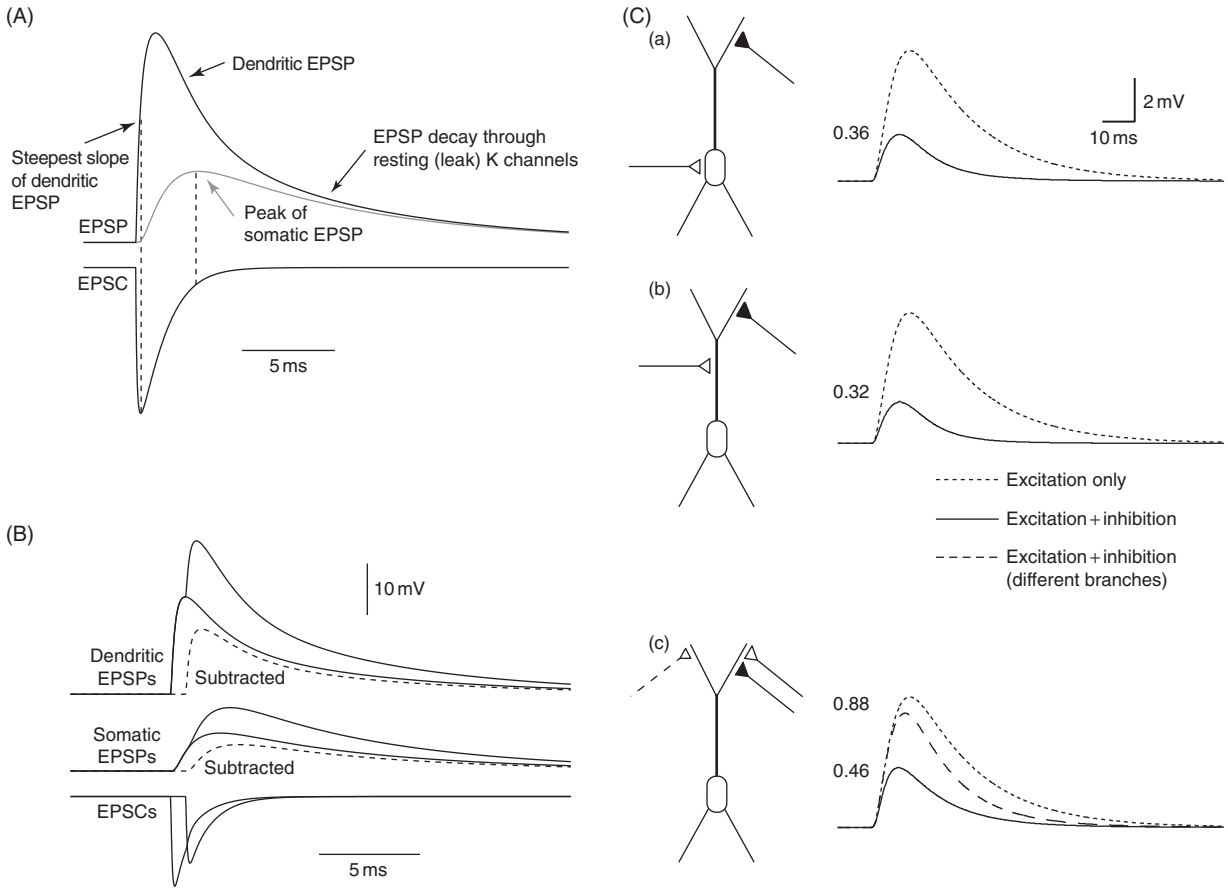

FIGURE 11.3 Synaptic interactions in passive dendrites. (A) Simulations showing the temporal relationship between the EPSP and the EPSC. Note the steepest slope of the dendritic EPSP occurs at the peak of the EPSC. The peak of the somatic EPSP occurs when the EPSC is very small (equal to leak current). The terminal decay of the EPSP (somatic and dendritic) is governed by the membrane time constant, but the initial decay of the dendritic EPSP is faster because of axial flow of current in the dendrites, away from the synapse. Amplitude scale is arbitrary. (B) Nonlinear summation of EPSPs in passive dendrites. Simulation of two excitatory synapses activated 0.75 ms apart. EPSPs and EPSCs are shown for activation of one synapse and activation of both synapses. Dashed line: arithmetic difference between EPSP for two synapses and one synapse. The single EPSP is about 20 mV; thus, the driving force for the second EPSC is reduced by about 33%, and the EPSPs and EPSCs are accordingly smaller. (C) Simulations of the effects of inhibition on a simple pyramidal cell model. Solid lines indicate response to excitation and inhibition. Inhibition slightly precedes excitation, but has a reversal potential equal to the resting potential, thus not producing any hyperpolarization on its own (i.e., only shunting inhibition). Dotted lines are excitation alone; dashed line is excitation and inhibition for alternate location of inhibition. Numbers indicate ratio of inhibited/uninhibited EPSP. (a) Distal excitation and somatic inhibition. (b) Distal excitation and on-path dendritic inhibition. (c) Distal excitation and distal dendritic inhibition, either on the same branch as excitation or on a different branch. *Sources: (A, B) Simulations by W.L. Kath and N. Spruston; (C) Spruston et al., 2008.*

(Fig. 11.3B). The reason for this is simple. If the resting potential of a neuron is –60 mV and the reversal potential of an excitatory synapse is 0 mV, then each synapse has a driving force of 60 mV. However, if enough synapses are activated to depolarize the dendrite to –40 mV, for example, the next activated synapse will have a driving force of 40 mV, which is 33% less than if that synapse were activated on its own. In other words, when multiple excitatory synapses are activated, each synapse has a reduced driving force compared to when it is activated on its own. It is not instructive to think of excitatory synapses as inhibiting each other because they always depolarize the neuron toward threshold for action potential firing; they can never do otherwise, but in passive dendrites the effect of activating multiple excitatory synapses is always less than the sum of the effects of each synapse individually.

A second important principle is that the magnitude of this sublinearity depends on the distance between the synapses. The same physical principles that govern the attenuation of EPSPs as they propagate to the soma also influence the extent of sublinear summation of activated synapses, as the depolarization experienced by one synapse depends on its distance from the other activated synapses. If the two synapses are close together, they have a strong influence on each other's driving force, and their summation will be

sublinear. On the other hand, if the synapses are far apart on the dendritic tree, each affects the other only minimally, so the net effect of activating both synapses will be closer to their linear sum.

When the interactions between synapses include inhibition, a third important principle is that "on-path" inhibition is more effective than "off-path" inhibition (Fig. 11.3C). Here, the "path" runs from the excitatory synapses in the dendrites to the action potential initiation zone in the axon. In order to effectively inhibit action potential initiation, inhibitory synapses must reduce the current that would have otherwise depolarized the action potential initiation zone. This happens best for on-path inhibition.

When considering inhibition, it is important to realize that inhibitory synapses can be effective even if they produce little or no hyperpolarization of the membrane potential on their own. This is often referred to as "shunting inhibition." This occurs most obviously when the reversal potential of an inhibitory synapse is the same as the resting potential. When activated on its own, such an inhibitory synapse has no effect on the membrane potential, because there is no driving force for current flow through the activated channels. When activated together with excitatory synapses, however, the inhibitory synapse shunts the current from the excitatory synapse, thus reducing the resultant somatic depolarization. In this scenario, the depolarization from the excitatory synapse creates a driving force for current flow through the inhibitory synapse. As a result, the depolarizing effect of Na^+ ions entering through excitatory channels (e.g., AMPA receptors) is reduced by the hyperpolarizing effect of Cl^- ions entering through the inhibitory channels ($GABA_A$ receptors).

Functional Implications of Dendritic Filtering

The fact that synaptic potentials are filtered between the synapse and the soma, affecting both their amplitude and time course, has important functional implications for synaptic integration. As mentioned above, excitatory synapses located on distal dendrites of large neurons (such as pyramidal neurons) are expected to produce somatic EPSPs that are less than one-tenth that of their more proximal counterparts. This means that in many neurons, such as pyramidal neurons of the CNS, activation of a single distal synapse could have an almost negligible effect at the soma.

Although distal synapses are expected, based on theoretical considerations, to have reduced impact at the soma compared to more proximal synapses, it is possible that at least some distal synapses might compensate for this disadvantage by having more AMPA receptors than more proximal synapses. While there is some experimental evidence that this is the case in CA1 pyramidal neurons, this is not a general principle of synaptic organization. In fact, reconstruction of synapse morphologies using serial-section electron microscopy has indicated that most (~80%) of the synapses on CA1 pyramidal neurons are very small, and immunostaining has indicated that these small synapses have very few AMPA receptors. The other 20% of the synapses have much larger PSDs and a higher density of AMPA receptors. These synapses are likely to have a larger impact at the soma. Evidence exists that they are more numerous in distal dendrites than in proximal dendrites, but they are nevertheless a minority. What is the purpose of covering dendrites with a large number of synapses that are very small? While it is true that if enough (e.g., hundreds) of these weak synapses are activated, they could indeed result in action potential initiation in the axon, it seems equally likely that these distal synapses have a different role. One possibility is that these synapses represent a large pool of synapses that can be recruited for conversion to the more powerful class of synapses through synaptic plasticity such as LTP. Another possibility, however, is that even small synapses can have significant local effects, because of the magnification of local potential by the high impedance of small dendritic branches, thus resulting in activation of dendritic voltage-gated channels. For this reason, to answer the question of how distal synapses influence the processes of synaptic integration and action potential generation, it is necessary to consider the more complex case of synaptic integration in active dendrites.

SYNAPTIC INTEGRATION IN ACTIVE DENDRITES

The foregoing discussion was based on considering how synaptic potentials are integrated in passive dendrites. While this serves as a good starting point for understanding synaptic integration, another layer of complexity exists: in every dendrite where neuroscientists have looked, voltage-gated channels have been found. Among the most important of these dendritic channels are voltage-gated Na^+ channels (Na_v), Ca^{2+} channels (Ca_v), and K^+ channels (K_v). These channels have been observed in dendrites using immunostaining of the channels with both light and electron microscopy, and their functional properties have been studied using dendritic patch-clamp recording and imaging. The identification of these channels in dendrites using modern methods that allowed direct observation of the channels validated earlier studies that inferred the excitability of dendrites from the properties of extracellular field potentials.

Intracellular recordings have also been used to study dendritic excitability. Initially, these recordings were performed using sharp microelectrodes (Fig. 11.4). More recently, however, whole-cell patch-clamp recordings

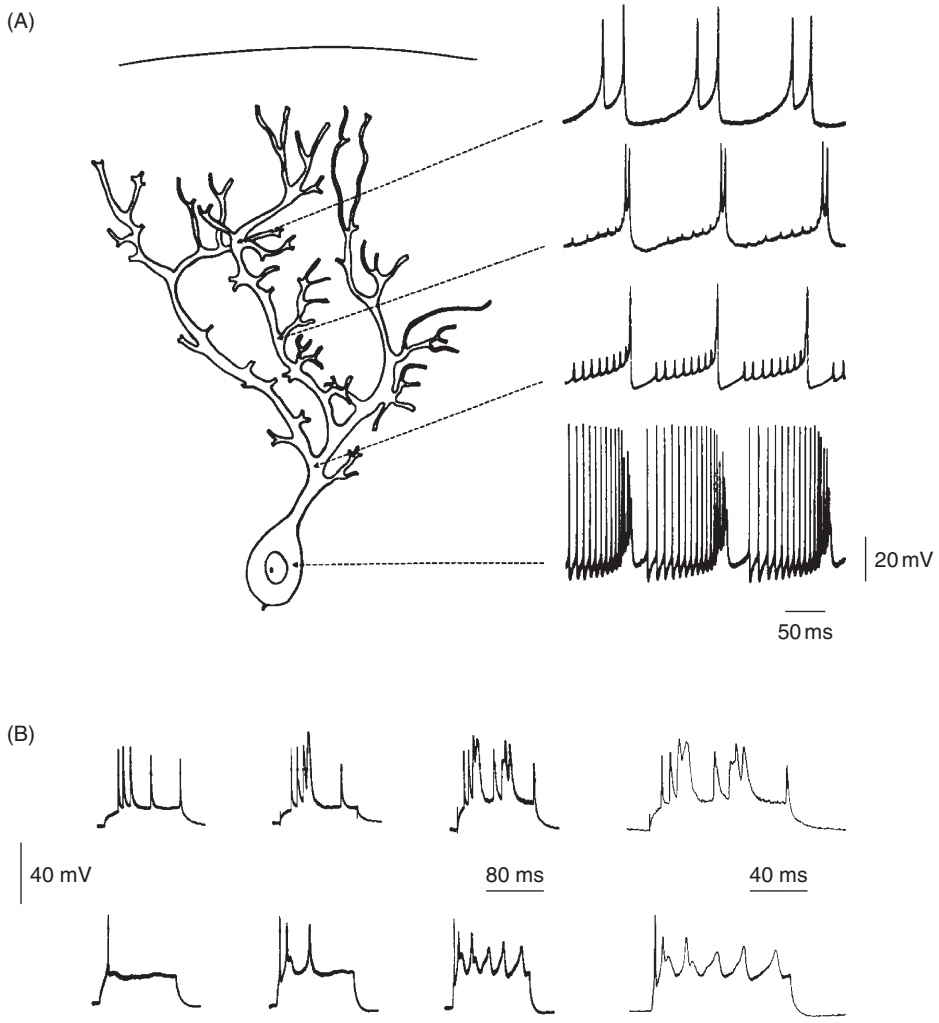

FIGURE 11.4 Early examples of dendritic recordings. (A) Dendritic and somatic recordings obtained from cerebellar Purkinje neurons (composite of separate recordings). Large action potentials at the soma are severely attenuated in the dendrites. Distal dendritic recordings show large, slow spikes mediated by Ca_v channels. (B) Recordings from dendrites of CA1 pyramidal neurons in intact slices (top) and after separation of dendrites from somata (bottom). All traces are responses to current steps. The rightmost trace is a temporally expanded view of the response to the left. *Sources: (A) Llinás and Sugimori, 1980; (B) Benardo et al., 1982.*

have been obtained from dendrites (Box 11.2). Most of these experiments have been performed using *in vitro* brain-slice preparations, but some dendritic recordings have also been obtained *in vivo*. In addition to single whole-cell recordings, simultaneous recordings have been performed from multiple locations on the same neuron, facilitating careful analysis of the relative size and timing of various events (e.g., EPSPs, IPSPs, spikes) in different parts of the neuron.

Dendritic excitability has now been studied in several cell types, but the ones most intensively studied are pyramidal neurons (hippocampal CA1 and neocortical layer 5 and layer 2/3) and cerebellar Purkinje cells. Studies of these and other neurons have revealed that the excitable properties of dendrites depend on the cell type. For example, CA1 pyramidal neurons are quite different from layer 5 pyramidal neurons, and Purkinje cells are even more different (as one might expect from the very distinct morphology of their dendritic tree). Despite differences between neuronal types, it is possible to extract a number of important general principles from these studies.

Weakly Excitable Dendrites and Backpropagating Action Potentials

One of the central principles is that dendrites are weakly excitable; that is, they contain voltage-gated channels that can support action potential propagation and dendritic spike generation, but they are not as excitable as the axon. The most direct evidence for this comes from studies involving simultaneous recording from the soma and a dendrite. These experiments have revealed that action potentials occur first in the axon and later in the soma and dendrites (Fig. 11.5). This is true even when the stimulus leading to the action potential is dendritic (e.g., activation of synapses near the dendritic recording electrode). This result has been interpreted to indicate that the action potential is initiated in the axon (in the axon initial segment), then "backpropagates" into the soma and dendrites. Indeed, experiments involving simultaneous recording from the axon and the soma have revealed that the axonal action potential precedes the somatic action potential, again confirming

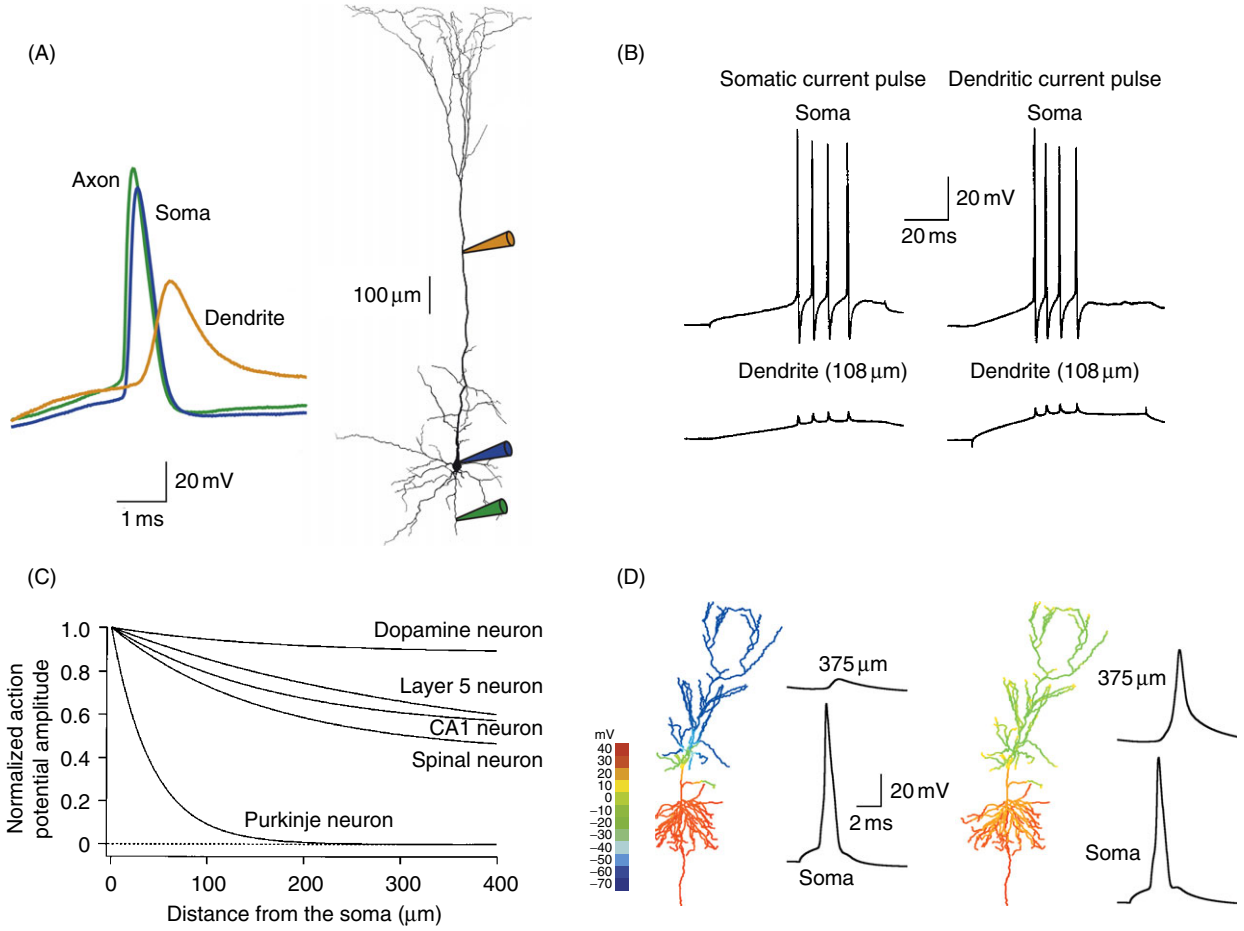

FIGURE 11.5 Backpropagating action potentials. (A) Triple recording from a neocortical layer 5 pyramidal neuron shows action potential initiation in the axon and backpropagation into the soma and dendrites. (B) Simultaneous dendritic recording from soma and dendrites of cerebellar Purkinje cell shows severe attenuation of action potentials recorded in the dendrites, regardless of the site of current injection. (C) Variable amplitude attenuation of backpropagating action potentials in different types of neurons. (D) Simulations of backpropagating action potentials in CA1 pyramidal neurons reveal sensitivity to Na_v and K_v channel density in the distal dendrites, which determines whether or not the action potential successfully invades the apical dendritic tuft. The model shown on the right has a higher density of dendritic Na_v channels than the model on the left. *Sources: (A) Häusser et al., 2000; (B) Stuart and Häusser, 1994; (C) Stuart et al., 1997b; (D) Golding et al., 2001.*

earlier conclusions based on extracellular recordings. Thus, the axon appears to have a much lower threshold for action potential initiation than the dendrites. The low axonal threshold results from the fact that, compared to the dendrites, the axon has a much higher density of Na_v channels and possibly a higher density of K_v channels.

Another observation indicating that dendrites are only weakly excitable is that backpropagating action potentials tend to attenuate as they propagate (Fig. 11.5). Dendritic recordings have revealed that the amplitude of the backpropagating action potential decreases with distance from the soma. The steepness of this attenuation (amplitude as a function of distance), however, varies between cell types. Pyramidal neurons have intermediate attenuation, while Purkinje cells exhibit much greater attenuation and dopamine neurons in substantia nigra have almost no attenuation. The degree of attenuation depends on two factors. One is the density and ratio of Na_v and K_v channels, and the other is the amount of branching in the dendritic tree. Branch points create impedance mismatches and capacitance loads, which means more current is required to support reliable propagation of the action potential through each branch point. This effect can be small for individual branch points, but the cumulative effect of many branch points can be very significant. For example, in cerebellar Purkinje cells, there are so many branch points that active action potential backpropagation is completely inhibited. Though this is in part due to the low density of Na_v channels in Purkinje cell dendrites, simulations have shown that very high densities of Na_v channels would be required to overcome the extensive branching in these dendrites.

Most of our knowledge about the amplitude of backpropagating action potentials at different distances from the soma comes from dendritic patch-clamp recording. Because these recordings have mostly been made from relatively large-diameter dendrites, less is known about the amplitude of backpropagating action potentials in smaller dendrites, such as basal, apical oblique, or apical tuft branches in pyramidal neurons or the fine branchlets of Purkinje cells. It is extremely difficult to place electrodes on such small dendrites, so imaging is a valuable complement to electrophysiological recording (Box 11.3). Indeed, imaging experiments have provided experimental support for the notion that even small-diameter dendrites are excitable.

Nonuniform Distribution of Voltage-Gated Channels in Dendrites

Another important principle of dendritic excitability is that the expression of voltage-gated channels is not uniform across the dendritic tree. The two best-characterized examples of this are the A-type K_v channels (K_v4) in CA1 pyramidal neurons and the hyperpolarization-activated cation (HCN) channels in CA1 and layer 5 pyramidal neurons. Patch-clamp recordings from these currents have shown that both channel types have much higher densities in distal apical dendrites than in the soma or proximal apical dendrites. Immunostaining has verified and extended these findings, but important questions

BOX 11.3

IMAGING DENDRITIC FUNCTION

The microscope was for a long time the only method by which experimentalists could gain information about the properties of dendrites, though the information yielded by light and electron microscopes was initially purely structural. The advent of dendritic microelectrode recording in the 1970s, and subsequently patch-clamp recording from dendrites in the 1990s (see Box 11.2), transformed our view of the functional properties of dendrites, offering us direct information about the electrical events taking place within the dendritic tree. Over the last 15 years, however, a variety of new imaging techniques have emerged as alternatives to electrophysiological approaches for investigating the functional properties of dendrites. Using light to probe function has several key advantages over conventional electrophysiological techniques (Scanziani & Häusser, 2009): light is noninvasive in that it normally does not interact with neurons; it can penetrate deep into tissue; offers outstanding spatial resolution; can permit detection of single molecular events; allows simultaneous measurement from multiple locations; and, crucially (with the advent of genetic and subcellularly targetable probes), permits recording from specific cell types and precisely defined subcellular compartments.

Early approaches for harnessing the power of imaging to probe the functional properties of dendrites involved the use of fluorescence microscopy, using confocal microscopes, CCD cameras, or photodiode arrays. In conjunction with the use of sensitive calcium indicators, introduced into the cell by microelectrodes, these approaches permitted the investigation of calcium signaling in distal dendrites, and even individual dendritic spines, to be probed for the first time. Calcium has often been used as a surrogate for electrical activity, particularly in compartments inaccessible to recording electrodes, but with the caveat that Ca^{2+} signals are affected not just by membrane potential, but also by other factors, including channel density, surface-to-volume ratio, and Ca^{2+} buffering and transport. Of course, calcium dynamics have also been studied in their own right due to the immense importance of calcium as a biochemical signalling molecule. The advent of improved voltage-sensitive dyes, together with faster and more sensitive CCD cameras, has more recently enabled voltage-sensitive dye measurements to be made directly from dendrites, allowing direct measurements of voltage in small dendritic compartments (though with limitations due to intracellular compartmentalization of dye; lack of calibration in distal dendrites; and problems with dye toxicity).

A fundamental breakthrough in using light to probe dendritic function came with the invention of two-photon microscopy (Denk & Svoboda, 1997). This approach harnesses the highly nonlinear nature of two-photon absorption to limit excitation to a tiny (femtoliter) volume, permitting high-resolution imaging deep within tissue (Fig. B11.3). Two-photon microscopy has been applied to study the structural and functional properties of dendrites and spines both in brain slices and more recently also *in vivo* (see Figure; Denk & Svoboda, 1997). It has led to numerous important discoveries both about the morphological and functional dynamics of dendritic spines as well as information processing within the dendritic tree. Furthermore, two-photon microscopy allows patch-clamp recordings to be targeted to particular cell types, and even to individual dendrites, and also allows recording locations to be verified with high precision, both in brain slices and *in vivo*, and has thus become an indispensible tool for dendritic physiologists. Recent developments in the miniaturization of two-photon optics have enabled imaging of neuronal calcium signals in freely moving animals equipped with head-mounted two-photon microscopes.

BOX 11.3 (*cont'd*)

Another important optical approach for probing dendritic function is the use of two-photon excitation for uncaging of neurotransmitters, which in conjunction with appropriate cages now allows individual glutamatergic and GABAergic synapses on dendrites to be activated with high temporal and spatial precision. This approach has allowed the input-output function of individual dendrites to be probed with unrivalled temporal and spatial precision (e.g., Branco, Clark, & Häusser, 2010) and has also permitted the investigation of dendritic plasticity rules.

There is currently tremendous enthusiasm about the use of imaging techniques for examining dendritic function, driven by advances in microscope resolution (Hell, 2007), innovative sample preparation (Micheva & Smith, 2007), and development of new sensors (Miyawaki, 2011). In particular, the advent of new genetically encoded probes for calcium, voltage, and a variety of signal transduction molecules, as well as the ability to target these probes to specific cell types and/or subcellular compartments, promise to offer us unprecedented insights into both electrical and chemical signaling in the most distal corners of dendritic trees. While electrophysiological approaches will probably always maintain their status as the "gold standard" for investigating electrical signaling in dendrites, due to their superior sensitivity and temporal resolution (Scanziani & Häusser, 2009), it is clear that optical solutions for probing dendritic function will become increasingly popular.

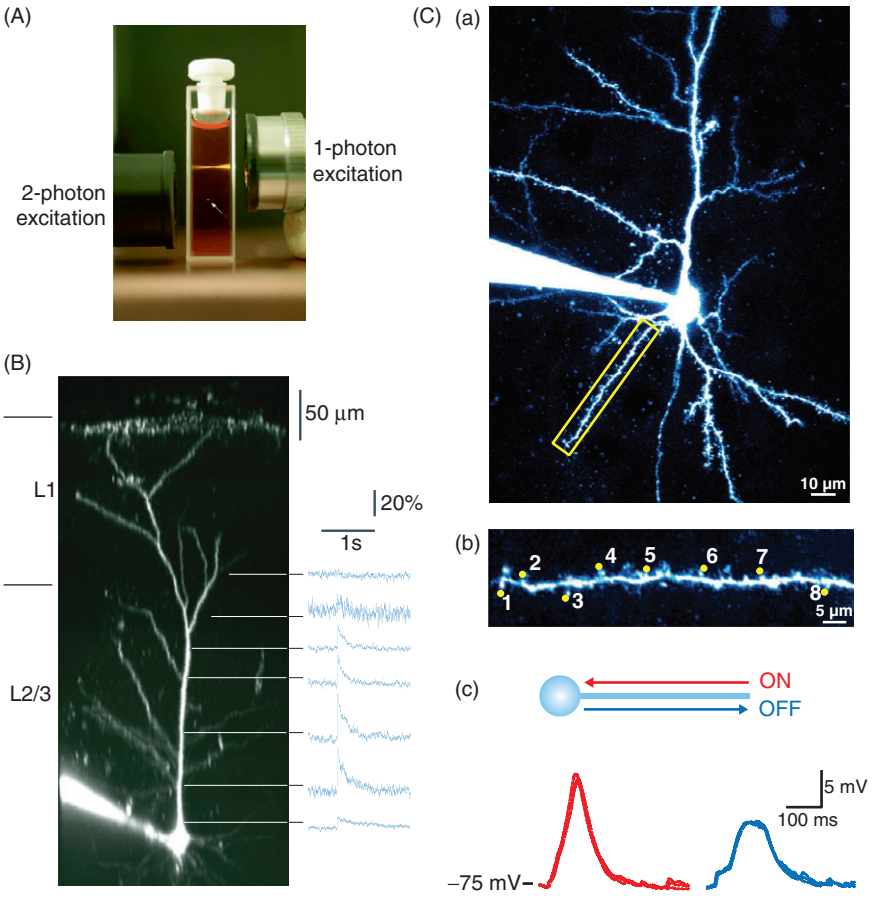

FIGURE B11.3 Using optical techniques to probe dendritic function. (A) A cuvette filled with a fluorescent dye is illuminated with either one-photon or two-photon excitation (top and bottom objectives, respectively). Note the remarkable spatial precision of the two-photon excitation. (B) *In vivo* imaging of dendritic calcium signaling. Left, a single layer 2/3 pyramidal cell in an anaesthetized rat is filled with a calcium dye (Oregon Green BAPTA-1) via a somatic patch-clamp recording and imaged using 2-photon microscopy. Right, Ca^{2+} transients (averages of 3–5 trials) that were evoked by single backpropagating action potentials at the positions indicated along the dendrite. (C) Probing computational properties of single dendrites using two-photon glutamate uncaging. (a) A pyramidal cell in a neocortical slice is filled with a fluorescent dye via a somatic patch pipette. (b) Spines along a single dendrite are imaged using two-photon microscopy, and the dendrite is bathed with a caged glutamate compound (MNI-glutamate). Synaptic transmission is then mimicked by brief two-photon uncaging at individual spines (yellow dots). (c) The synapses are activated in a sequence, either moving towards the soma (ON, red trace), or away from the soma (OFF, blue trace), producing a directionally selective EPSP at the soma. *Sources: (A) Courtesy of Brad Amos, MRC, LMB, Cambridge; (B) Waters et al., 2003; (C) Branco et al., 2010.*

remain about the distribution of these and other channels. Numerous challenges must be overcome before we can determine the distribution and functional properties of voltage-gated channels in dendrites from which direct recordings are very difficult. These challenges include questions about antibody specificity, difficulty distinguishing proximal versus distal dendrites when they are overlapping (as in apical oblique branches of pyramidal neurons), or expression of channels in closely apposed presynaptic and postsynaptic structures (e.g., boutons and spines). Furthermore, expression does not always equate to function, so while staining methods can in principle tell whether or not a channel type is present in a particular dendrite, staining cannot be used to determine if the observed channels are functional and, if so, what their specific properties are.

The nonuniform expression of voltage-gated channels in dendrites is likely to have significant functional implications. This is best understood for the case of K_v4 channels in CA1 pyramidal neurons, where the increasing density at more distal locations contributes to the distance-dependent attenuation of backpropagating action potentials and raises the threshold for generation of dendritic spikes in these neurons (see below). Because there are so many different types of channels (e.g., low- and high-threshold Ca_v channels; Ca^{2+}-activated K^+ channels), determining the subtypes, distribution, and properties of these channels in dendrites of different types of neurons will be critical to a better understanding of how synaptic inputs are integrated in the brain.

Dendritic Spikes

Although the lowest threshold for action potential initiation is in the axon, most dendrites can generate dendritic spikes (Figs. 11.6 and 11.7). Because of the weakly excitable nature of the dendritic tree, dendritic spikes have a relatively high voltage threshold. Recall, however, that dendrites locally magnify synaptic potentials because of their high input impedance. Thus, even a small number of synapses can produce local depolarizations that are large enough to activate voltage-gated channels in the dendrites.

One consequence of the weakly excitable nature of dendritic trees is that dendritic spikes do not propagate reliably throughout them. Like the backpropagating action potential, the attenuation of forward propagating dendritic spikes depends both on the types of channels activated during the spike and on the branching of the dendritic tree. Because of the structure of branch points, however, forward propagation is even less reliable than backpropagation. The difference arises from the geometry of the dendritic tree. Consider a backpropagating action potential traveling from the main apical trunk into an oblique branch in a pyramidal neuron. The amount of current required to generate the action potential in the trunk is quite large because of the large size of this dendrite. The oblique branch is much smaller, so a small fraction of the charge in the trunk is able to depolarize the oblique branch to threshold, thus resulting in successful backpropagation through the branch point. If an action potential is generated in the oblique branch and propagates toward the apical trunk, however, the situation is very different. The amount of charge required to generate a dendritic spike in the oblique branch is small because of the small diameter of the dendrite. As this charge flows into the apical trunk, there is too little current to depolarize the trunk to threshold, so the dendritic spike fails at the branch point. The asymmetry of propagation through dendritic branches is caused by an impedance mismatch: the apical trunk has a low input impedance and the oblique branch has a high input impedance. It is relatively easy for a regenerative event such as an action potential or dendritic spike to propagate from a low-impedance to a high-impedance structure but relatively hard for propagation to occur from a high-impedance to a low-impedance structure.

Dendritically initiated spikes come in different varieties: Na^+ spikes, Ca^{2+} spikes, and NMDA spikes (Figs. 11.6 and 11.7). These spikes are named for the dominant channel type activated during the spike, although in fact multiple types of channels are usually activated during each type of event. For example, even when a Na^+ spike is observed, NMDA receptor activation might be critical for providing the depolarization that triggers it, and the resulting depolarization from the spike is usually large enough to activate Ca_v channels. The spike is still called a Na^+ spike—typically identified as the fastest dendritic event (because of the fast kinetics of Na_v channels)—but a significant increase in intracellular Ca^{2+} would be observed in a Ca^{2+} imaging experiment because of the activation of NMDA receptors and Ca_v channels.

The first dendritically initiated spikes to be described were dendritic Ca^{2+} spikes, which were observed in experiments performed in the 1970s and 1980s using sharp microelectrodes to record from the dendrites of Purkinje neurons and pyramidal neurons (Fig. 11.4). These spikes were initiated in response to strong excitatory synaptic inputs and were presumed to have a dendritic origin because of their large amplitude in dendritic recordings. Subsequent to these early experiments, the dendritic origin of these Ca^{2+} spikes was confirmed in simultaneous somatic and dendritic recordings using patch-clamp recording (Box 11.2). Ca^{2+} spikes have a long duration (relative to Na^+ spikes), consistent with the slow kinetics of Ca_v channels compared to Na_v channels. In some cases, dendritic Ca^{2+} spikes of especially long duration have been called "plateau potentials." Although dendritic Ca^{2+} spikes were first observed only with strong synaptic stimulation, they have also been

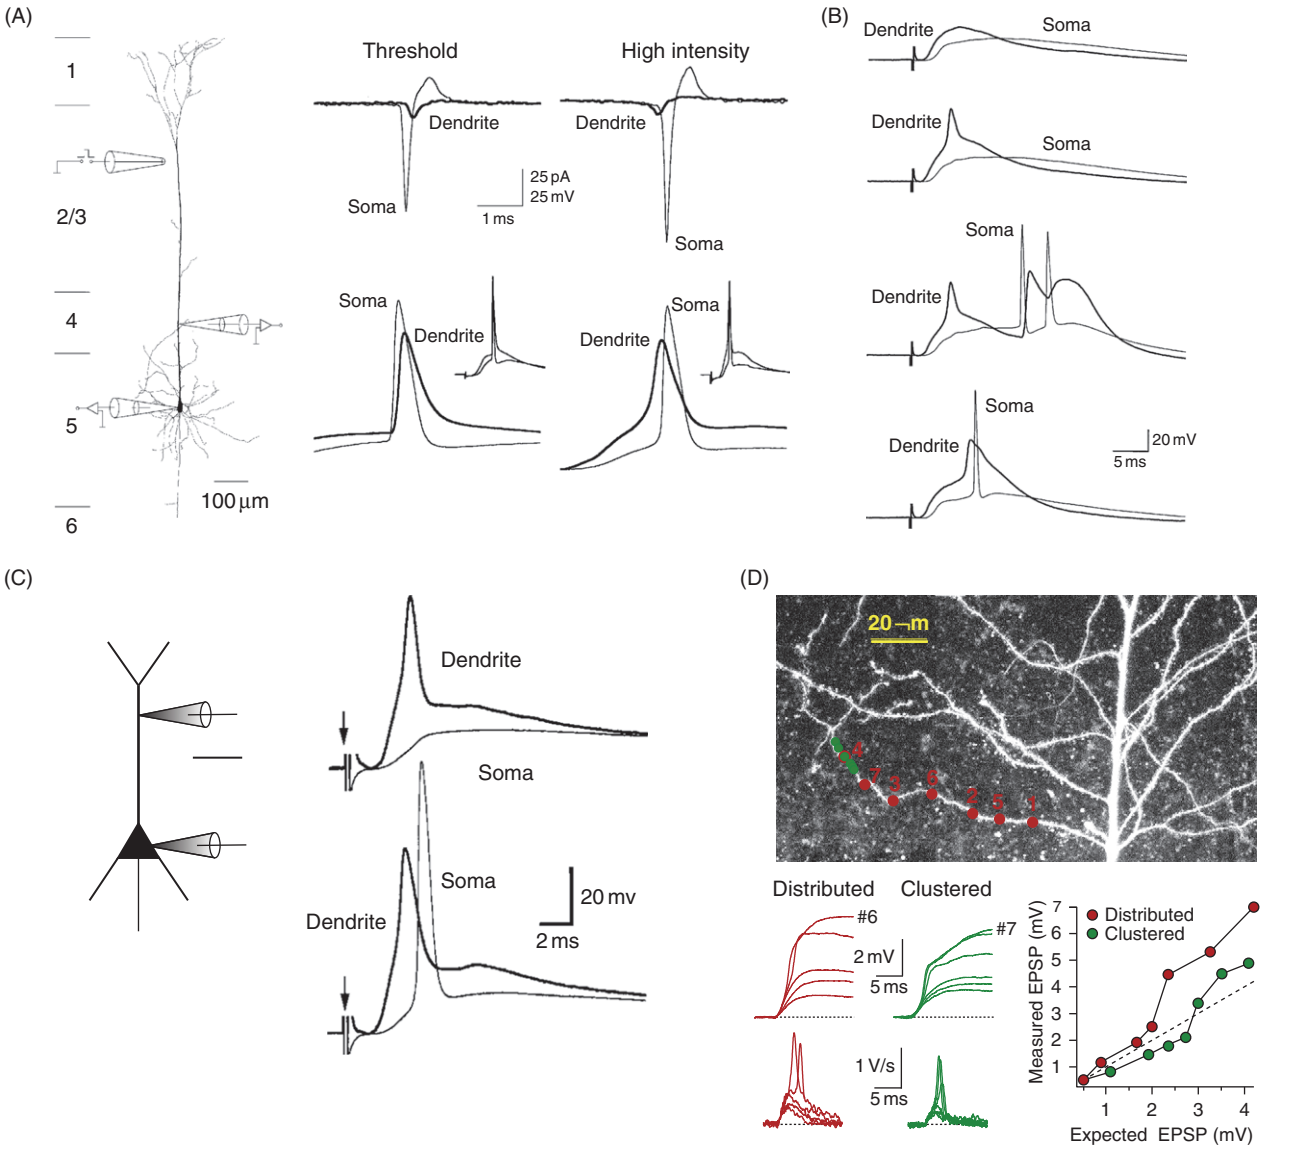

FIGURE 11.6 Dendritic sodium spikes. (A) Simultaneous somatic and dendritic (175 µm from soma) recordings from a neocortical layer 5 pyramidal neuron. Using synaptic stimulation at threshold for action potential initiation (left), the somatic action potential precedes the dendritic action potential, both in cell-attached (top) and whole-cell (bottom) recordings. At higher synaptic stimulus intensity (right) the action potential occurs first in the dendrites. (B) Similar recording configuration with dendritic recording 440 µm from the soma. Example traces show (top to bottom): subthreshold EPSP, isolated dendritic spike, dendritic spike followed by somatic burst, dendritic spike preceding somatic action potential. (C) Somatic and dendritic recordings in a hippocampal CA1 pyramidal neuron showing an isolated dendritic spike (top) and a dendritic spike preceding a somatic action potential (bottom). (D) Two-photon uncaging of glutamate onto the dendrites of a CA1 pyramidal neuron. Somatic recordings show a nonlinear increase in the somatic EPSP amplitude and slope, indicative of a dendritic spike that did not trigger an action potential in the axon or soma. *Sources: (A, B) Stuart et al., 1997a; (C) Golding and Spruston, 1998; (D) Losonczy and Magee, 2006.*

shown to occur in the apical tuft of pyramidal neurons when weaker synaptic excitation is paired with one or more backpropagating action potentials. These events have been called "backpropagating action potential evoked Ca^{2+} spikes" or "BAC spikes" (Fig. 11.7). They are of particular interest because they may signal the coincidence of synaptic input to the apical tuft and other dendritic domains of pyramidal neurons.

Dendritic Na^+ spikes are fast events (compared to Ca^{2+} spikes), so they tend to be very localized and do not propagate reliably out of the branch in which they were generated (Fig. 11.6). This fact is likely responsible for the relatively late discovery of dendritic Na^+ spikes, compared to Ca^{2+} spikes. Dendritic Na^+ spikes were first definitively identified when it became possible to simultaneously monitor somatic and dendritic membrane potential using

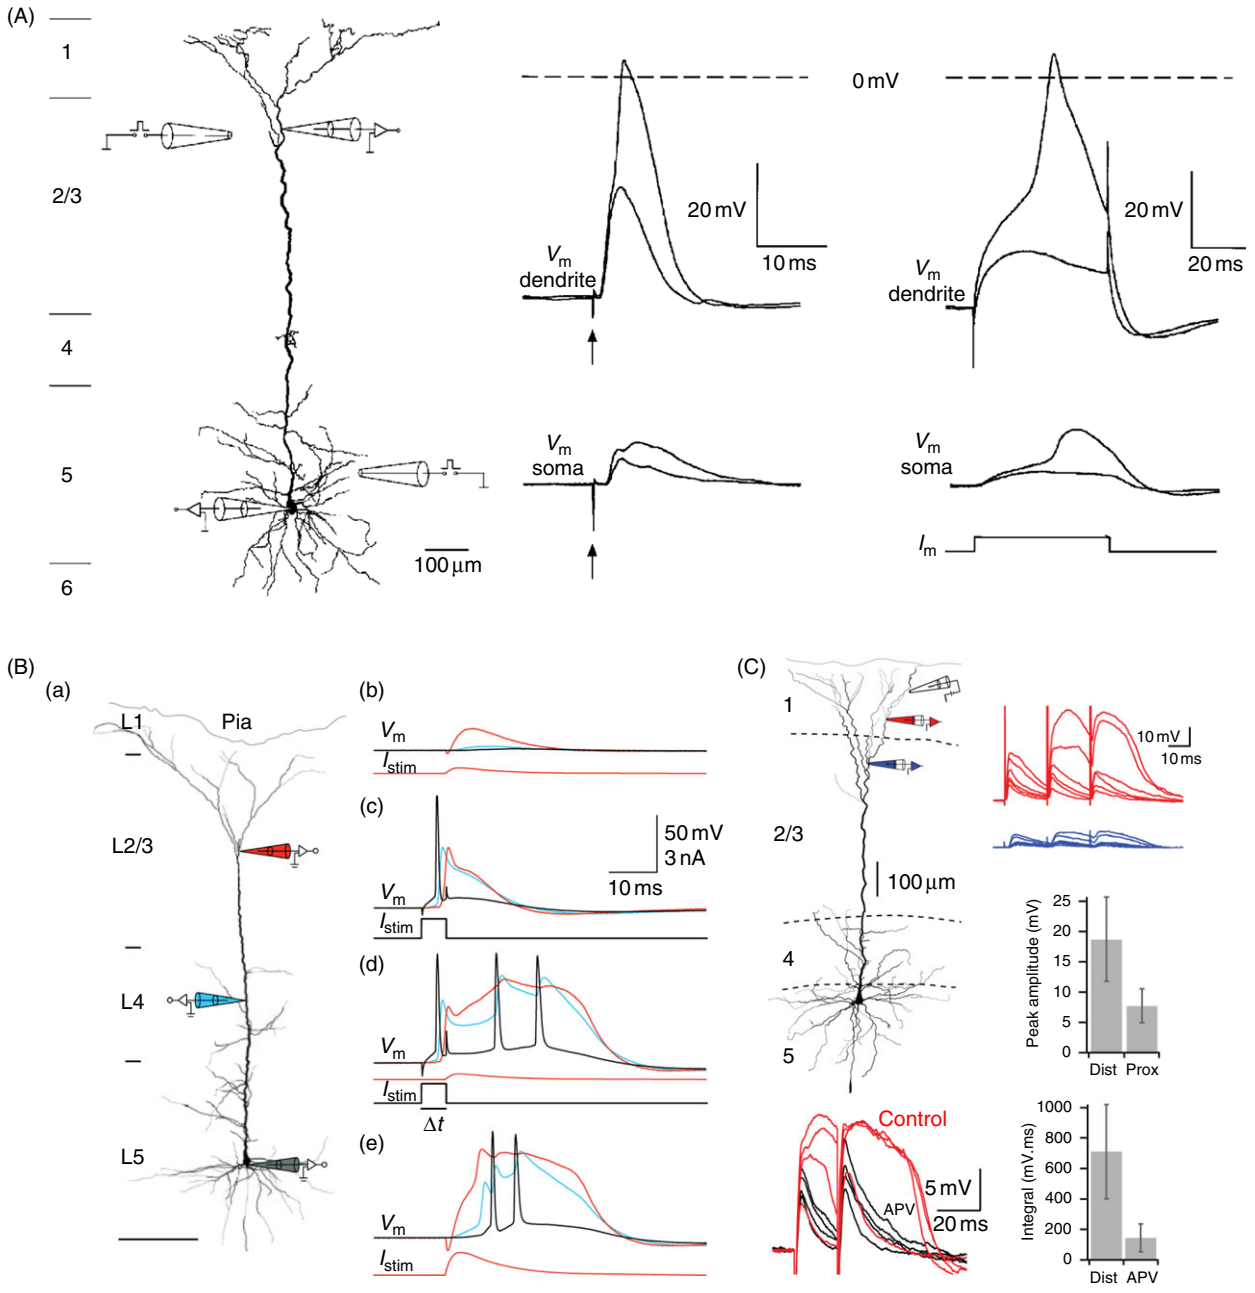

FIGURE 11.7 Dendritic calcium spikes and NMDA spikes. (A) Simultaneous somatic and dendritic (920 µm from soma) recordings from a neocortical layer 5 pyramidal neuron. Synaptic stimulation in layer 2/3 (left traces) or current injection into the dendrite (right) resulted in a dendritic Ca^{2+} spike (subthreshold responses also shown) in the dendrites that did not propagate to the soma (soma, 440 µm and 770 µm from soma). (B) (a) Schematic of triple recording from a layer 5 pyramidal neuron. (b) Responses to EPSC-like dendritic current injection. (c) Responses to somatic current injection. (d) Responses to combined somatic and dendritic current injections. (e) Responses to larger dendritic current injection. (C) Dual recording 715 µm and 875 µm from the soma in a layer 5 pyramidal neuron. Synaptic stimulation in layer 1 yields dendritic spikes that are restricted to the distal dendritic recording location and blocked by the NMDA receptor antagonist APV. *Sources: (A) Schiller et al., 1997; (B) Larkum et al., 1999; (C) Larkum et al., 2009.*

patch-clamp recording in brain slices. This technique allowed definitive identification of dendritic spikes that occurred either before or in the absence of a somatic action potential. At first, dendritic Na^+ spikes were only observed in response to relatively strong stimulation of excitatory synapses. The strong stimulus used to evoke dendritic spikes suggested that they might only occur under conditions of extreme excitation, thus raising questions about their physiological significance. However, subsequent experiments using two-photon Ca^{2+} imaging

and glutamate uncaging (Box 11.3), combined with somatic and dendritic recording, have indicated that dendritic spikes may occur in response to clustered activation of a small number of synapses on a single branch (i.e., less than ten synapses). Dendritic Na^+ spikes are hard to detect, even with dendritic recording, because the spikes do not propagate reliably into the large-diameter dendrites from which dendritic recordings are typically obtained.

Dendritic NMDA spikes result from activation of NMDA receptor channels, which are voltage sensitive because of their block by Mg^{2+}. When glutamate is bound to NMDA receptors, they can produce a regenerative event, as depolarization leads to relief of Mg^{2+} block, resulting in more inward current and more depolarization. If enough NMDA receptors are activated, a regenerative spike can occur, even if significant numbers of Na_v and Ca_v channels are not activated. NMDA spikes have one important feature that is fundamentally different from Na^+ or Ca^{2+} spikes. NMDA spikes cannot propagate into regions of the dendrite where NMDA receptors are not activated by glutamate (or where they are activated only in small numbers). As noted above, dendritic Na^+ spikes also propagate poorly and typically remain restricted to the dendrite in which they were originated. Unlike NMDA spikes, however, dendritic Na^+ spikes can propagate into regions of the branch where synapses have not been activated. NMDA spikes cannot propagate in this way because of the additional requirement that the receptor needs to be activated by glutamate before it can respond to depolarization.

Functions of Dendritic Spikes

An important question regarding excitable dendrites is to determine the functions of dendritic spikes and backpropagating action potentials. Two key issues are which of these events occurs *in vivo*, and under what conditions? Although good progress is being made to develop the methods necessary to address these questions, they remain unanswered. Thus, most of what we can say about the function of dendritic spikes stems from what we have learned about them from *in vitro* brain-slice experiments. Generally, the possible functions of backpropagating action potentials and dendritic spikes can be divided into three categories: a role in synaptic integration, a role in local communication, and a role in plasticity.

Dendritically initiated spikes are likely to play a central role in the process of synaptic integration, but understanding how this works is not straightforward. For example, if a dendritic Na^+ spike does not propagate out of the dendritic branch in which it was generated, how can it influence action potential initiation in the axon? The most likely answer to this puzzling question is that the dendritic spike, although not propagating actively, does deliver additional charge to the axon, over and above the charge entering at synapses alone. In this way, dendritic excitability lowers the number of excitatory synapses required to initiate action potential firing in the axon. Thus, even though individual synapses in the distal dendrites minimally depolarize the axon (because of the dendritic filtering discussed above), the influence of distal synapses can be enhanced when they contribute to the generation of dendritically initiated spikes.

A leading theory in the field of dendritic integration is that dendritic spikes allow neurons to respond to coincident activation of multiple dendritic domains. For example, if Na^+ spikes or NMDA spikes are generated in two oblique branches of pyramidal neurons, enough charge can be delivered to the axon to generate an action potential, even though the dendritic spikes do not actively propagate all the way to the axon. Another example is the BAC spike, discussed above; when coincident input occurs to the apical tuft and the basal dendrites of pyramidal neurons, a BAC spike can be generated in the tuft, leading to a burst of action potentials at the soma. Yet another example from pyramidal neurons is that spikes generated in the apical tuft normally fail at the branch point between the tuft and the main apical dendrite. When this critical region near the branch point is depolarized by other synaptic inputs, however, the tuft spike can propagate actively along the main apical trunk and trigger action potential firing in the axon. Thus, dendritic spikes may allow the neuron to detect the coincident activation of excitatory synaptic inputs to different dendritic compartments. A central question, then, which is the focus of much ongoing work, is what kinds of inputs, carrying which kinds of information, arrive in the different dendritic compartments of pyramidal neurons.

The concept of coincidence detection through dendritic excitability is not restricted to pyramidal neurons. Cerebellar Purkinje neurons can also detect the coincidence of inputs via the parallel fibers and the climbing fiber. Although climbing fibers on their own are sufficiently strong to reliably evoke dendritic Ca^{2+} spikes in Purkinje cells, coincident input via the parallel fibers can increase the number of Ca^{2+} spikes evoked by a single presynaptic action potential in the climbing fiber. Furthermore, the Purkinje cell dendritic tree branches so extensively that Ca^{2+} spikes can cause larger depolarizations in the vicinity of the activated parallel fibers than in other portions of the dendrites. One important outcome of the larger dendritic spikes associated with such coincident activity is the induction of long-term depression (LTD) of the activated parallel fibers.

The end result of coincidence detection is usually a dendritic spike. As an outcome of synaptic integration, a dendritic spike can enhance action potential firing in the axon. In the case of Ca^{2+} spikes (including BAC spikes),

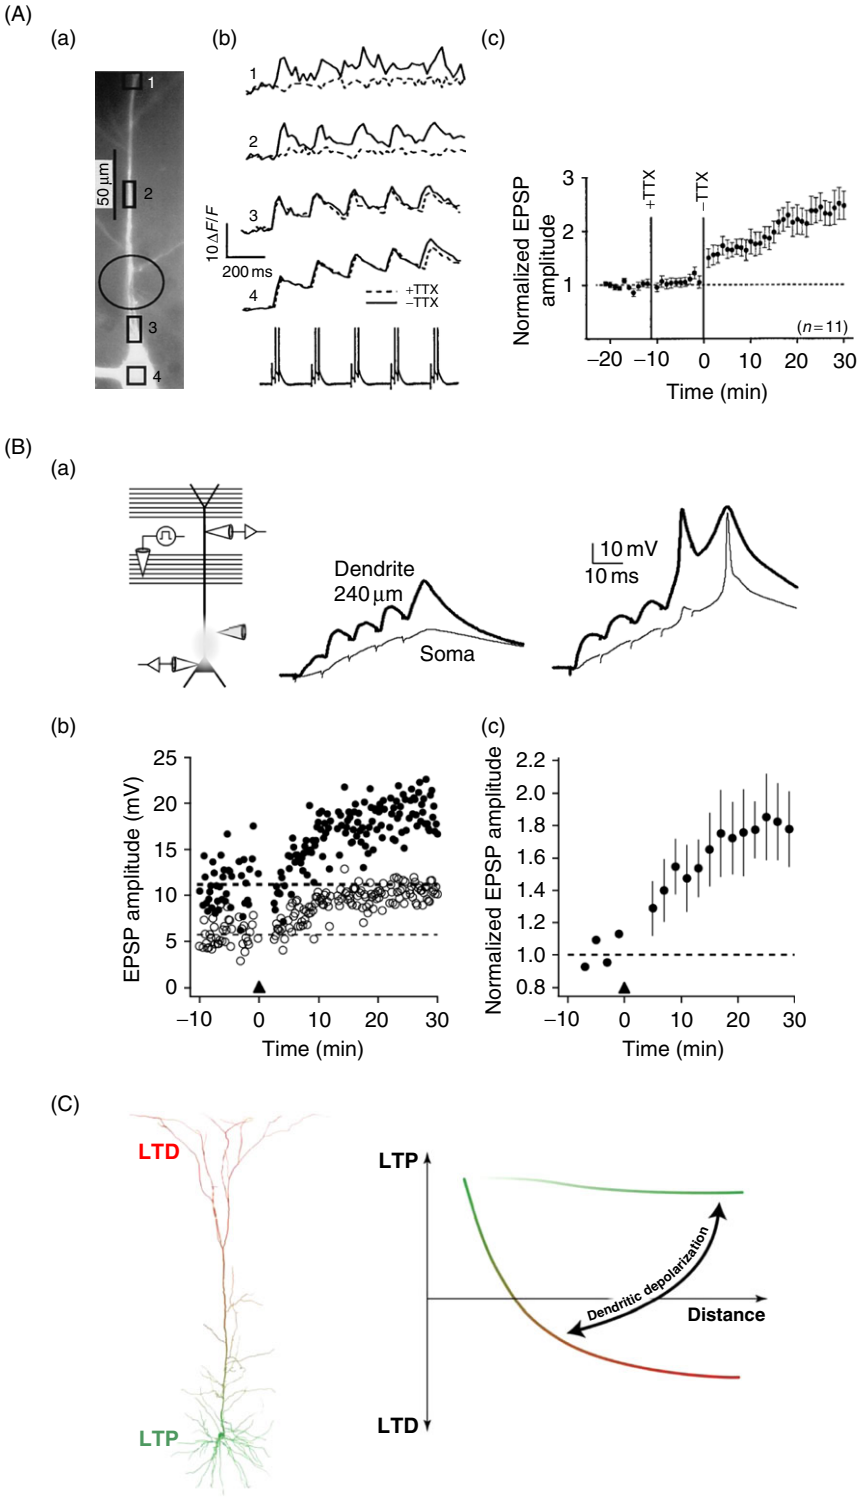
the result is often a burst of action potentials in the axon, which is likely to more powerfully promote the release of neurotransmitter from the axon terminals, compared to a single action potential. In Purkinje cells, however, the main function of the burst of action potentials may be the long pause in firing that follows the burst. Purkinje cells fire spontaneously and release the inhibitory transmitter GABA, so the pause in firing that follows the Ca^{2+} spike-induced burst may ultimately serve to activate the postsynaptic neurons in the deep cerebellar nucleus by releasing them from tonic inhibition.

A second possible function of dendritic excitability, besides promoting action potential firing in the axon, is to mediate neurotransmitter release from dendrites. The best-studied example of this is in the olfactory bulb, where reciprocal dendro-dendritic synapses are formed between mitral cells and granule cells. Both cell types have been shown to have excitable dendrites, which likely plays a key role in the activation of these synapses. Even in dendrites lacking structurally identifiable presynaptic specializations, dendrites can release substances that mediate local communication. For example, both pyramidal neurons and Purkinje cells have been shown to release endocannabinoids from their dendrites in response to dendritic depolarization. Events mediated by voltage-gated channels in dendrites (namely backpropagating action potentials and dendritic spikes) are likely to promote the release of these and other substances from dendrites. Notably, dendritic release may also be an outcome of the coincidence detection operations described above.

A third possible function of dendritic excitability is the induction or regulation of changes in synaptic strength such as Hebbian synaptic plasticity (Fig. 11.8). What kinds of dendritic events could provide the depolarization necessary for Hebbian plasticity? Backpropagating action potentials and dendritic spikes are both good candidates. For example, the backpropagating action potential has been proposed as an important signal for the induction of spike-timing-dependent synaptic potentiation and depression, because the activation of Ca_v channels (backpropagating action potential alone) and the relief of Mg^{2+} block of NMDA receptors (backpropagating action potential together with the binding of presynaptically released glutamate to the receptor) are sensitive to the relative timing of presynaptic and postsynaptic activation. Other forms of synaptic plasticity can occur in the absence of backpropagating action potentials. For example, dendritically initiated spikes have been shown to promote these forms of long-term potentiation (LTP) of excitatory synaptic strength even in the absence of axonal action potential firing. For some forms of plasticity, events mediated by dendritic excitability (backpropagating action potentials and dendritic spikes) are a requirement for the induction of synaptic plasticity. Therefore, these events are likely to serve as detectors of postsynaptic coincidence detection, thus mediating the property of synaptic cooperativity in LTP—that is, the requirement for multiple synaptic inputs to cooperate to produce the depolarization necessary for the induction of Hebbian LTP.

Although not as extensively studied, dendritic excitability may also contribute to other forms of plasticity, such as non-Hebbian synaptic plasticity, plasticity of inhibitory synapses, and plasticity of intrinsic membrane properties, including modulation of the very channels responsible for dendritic excitability. The latter mechanism could either work in a homeostatic manner or could enhance the probability of future dendritic spiking or synaptic plasticity. Finally, it should be noted that other processes might also regulate dendritic excitability. For example, modulatory neurotransmitters can regulate the activity of dendritic Na_v, Ca_v, and K_v channels, thus changing the excitable properties of the dendrite. This positions dendritic excitability as a mechanism that is both a regulator and a target of various forms of plasticity.

FIGURE 11.8 Dendritic excitability and synaptic plasticity. (A) Blocking backpropagating action potentials with dendritic application of TTX prevents the induction of LTP by pairing EPSPs with action potential firing. (a) CA1 pyramidal neuron filled with a Ca^{2+}-sensitive dye showing approximate location of TTX application (circle), strategically positioned to block action potential backpropagation without blocking action potential firing at the soma or synaptic transmission at more distal dendritic locations. (b) Ca^{2+}-sensitive fluorescence changes during pairing of EPSPs and action potentials (evoked by somatic current injection) in control (solid lines) and during application of TTX to the proximal dendrite (dashed lines). Numbered traces correspond to the locations of the numbered boxes in (a). Bottom trace is somatically recorded membrane potential during pairing. (c) Group data showing failure to induce LTP during dendritic TTX application, but not in the absence of TTX application. (B) Stronger stimulation can induce LTP in CA1 pyramidal neurons even when action potential backpropagation is blocked. (a) Paired somatic and dendritic recording during activation of presynaptic axons (no pairing with somatic current injection) and application of TTX to the soma and proximal dendrites to prevent action potential generation and backpropagation from the axon. Synaptic stimulation is strong enough to evoke dendritic spikes, which are attenuated at the soma. (b) Theta-burst synaptic stimulation induces LTP, which is observed in both the soma and the dendrite. (c) Group data showing LTP induction of somatic EPSP in experiments with backpropagating action potentials blocked. (C) Pairing of EPSPs and backpropagating action potentials in neocortical layer 5 pyramidal neurons induces either LTP or LTD, depending on the amplitude of the backpropagating action potentials. In proximal dendrites, where backpropagating action potentials are relatively large, LTP is induced. In distal dendrites, where backpropagating action potentials are smaller, LTD is induced. Depolarization of the distal dendrite amplifies backpropagating action potentials, however, resulting in induction of LTP instead of LTD. *Sources: (A) Magee and Johnston, 1997; (B) Golding et al., 2002; (C) Sjöström and Häusser, 2006.*



Dendritic Inhibition and Dendritic Excitability

One of the great mysteries of synaptic integration is why there are so many different types of inhibitory interneurons. Using classification mechanisms that depend on morphology, axon projections, physiological properties, and molecular markers, a great diversity of inhibitory cell types has been described. For example, more than 20 different types of inhibitory interneurons have been described in the CA1 region of the hippocampus alone. Interestingly, more than half of these types of interneurons

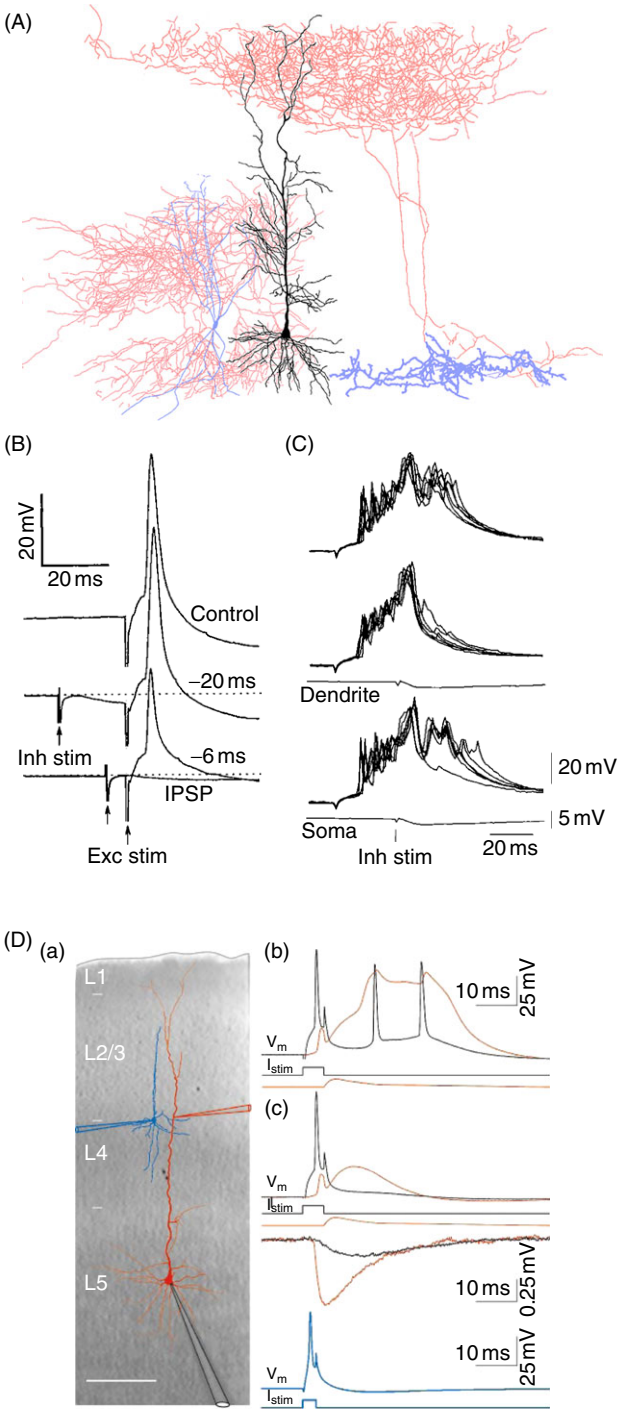


FIGURE 11.9 Functions of dendritic inhibition. (A) Compilation of inhibitory interneurons (dendrites blue, axon red) superimposed on a CA1 pyramidal neuron (black) to illustrate dendritic inhibition. (B) Effects of inhibition on backpropagating action potential in a CA1 pyramidal neuron. (C) Spikes evoked by current injection in a recording from a CA1 pyramidal neuron (top) are inhibited effectively by dendritic inhibition (middle), but not somatic inhibition (bottom). (D) (a) Simultaneous recording from a pyramidal neuron (red, soma and dendrite) and a neighboring inhibitory interneuron (blue). Scale bar is 200 µm. (b) BAC spike evoked by simultaneous somatic current injection to evoke an action potential and synaptic stimulation in layer 1 (somatic recording black; dendritic recording red). (c) BAC spike is blocked by activation of an action potential in the inhibitory interneuron (blue). IPSPs in the pyramidal neuron are also shown (i.e., with no current injection in pyramidal action potential or activation of layer 1 synapses). *Sources: (A) N. Spruston, McQuiston and Madison, 1999, Halasy et al., 1996; (B) Tsubokawa and Ross, 1996; (C) Miles et al., 1996; (D) Larkum et al., 1999.*

have axons that appear to innervate pyramidal neuron dendrites (Fig. 11.9A). What is the function of dendritic inhibition and why are the neurons that mediate it so diverse? At the moment, we have only limited insight into this problem, owing to the limited experimental data.

One of the most obvious functions of dendritic inhibition would be to selectively reduce the impact of excitatory synaptic inputs in the same dendritic compartment. For example, an interneuron that innervated the apical tuft of a pyramidal neuron might powerfully inhibit excitatory inputs to the tuft, while having little or no effect on excitatory synapses on basal dendrites. That said, the excitatory inputs that are affected by dendritic inhibition need not overlap directly with the inhibitory inputs. As noted above, for inhibition to be most effective, it should be on the path from the site of excitatory synapses to the axon.

Another likely function of dendritic inhibition is to regulate events mediated by dendritic excitability, such as backpropagating action potentials and dendritic spikes. Indeed, there is experimental evidence that these events can be attenuated by dendritic inhibition (Fig. 11.9B and 11.9C). Understanding the roles of different types of interneurons in this process is complex, however, because different varieties of dendritic spikes can be initiated in different dendritic compartments. To fully appreciate the role of dendritic inhibition, it will be necessary to understand not only the postsynaptic actions of each type of interneuron but also to understand when and why each interneuron type is active. For example, one study showed that feedback inhibition from one type of interneuron targets the proximal apical dendrites. During sustained firing, this form of dendritic inhibition outlasted somatic inhibition provided by a different type of interneuron. This cell-type-specific form of inhibition results from a combination of the intrinsic and synaptic properties of each type of interneuron. The ultimate goal is to understand when and why each cell type is activated in the intact brain and how this activity affects circuit function to mediate behavior and cognition.

STRUCTURE AND FUNCTION OF DENDRITIC SPINES

The dendrites of many neurons are covered with thousands of dendritic spines—small protuberances that form the primary sites of contact for excitatory synapses (and some inhibitory synapses) in many types of neurons. Ever since their discovery by Ramon y Cajal, the

function of spines has been a mystery. Today, we know a great deal more about the electrical and chemical properties of spines, but the reason for their existence remains elusive. We know for sure that dendritic spines are not essential for the basic function of excitatory synapses, since many neurons—most notably inhibitory interneurons—receive excitatory synapses directly onto their dendrites and lack dendritic spines. Even in some spiny neurons, some excitatory synapses are formed directly onto the dendrite, raising the possibility that excitatory synapses on spines and dendrites may have distinct functional properties. Certainly, the abundance of spines in the nervous system suggests strongly that they serve an important function.

Structure of Dendritic Spines

The typical dendritic spine is often described as having a "mushroom" shape, consisting of a narrow spine neck and a larger spine head (about one micron diameter). However, the structure of dendritic spines can be quite varied, even for spines on a single neuron (Fig. 11.10). Some spines have particularly long necks, which tends to correlate with smaller spine heads, while other spines have short, stubby necks and an unclear distinction between the neck and the head. In electron micrographs, spines are characterized by the presence of smooth endoplasmic reticulum and an actin cytoskeleton, as well as by the absence of microtubules, ribosomes, and mitochondria. In some cases a particularly extensive endoplasmic reticulum forms a structure called a "spine apparatus." One of the most distinctive features of dendritic spines is the postsynaptic density (PSD), which is an electron-dense region opposite the presynaptic terminal, thought to contain the postsynaptic machinery for synaptic function. Typically, PSDs are largest in mushroom-shaped spines and smaller in thin or stubby spines. As noted above, some spines have particularly large PSDs that are interrupted by a perforation. Strong correlations have been noted among the size of the spine head, the size of the PSD, and the number of AMPA-type glutamate receptors, indicating that there is a relationship between spine size and synaptic strength.

It has been suggested, and recently confirmed by experimental observations, that structural changes in dendritic spines can occur together with synaptic plasticity. This is a seemingly simple idea—stronger synapses need bigger spines, so growth of the spine is required for synaptic potentiation (e.g., LTP)—but complexities and open questions lurk beneath the surface of this idea. Can changes in spine structure alone mediate changes in synaptic strength, or are other molecular changes required as well? Are thin spines the initial precursors of mushroom spines and stubby spines the remnants of retracting spines, or does spine diversity reflect a diverse population of stable synapses? Indeed, conversion between the different types of spines has been observed *in vitro* and *in vivo*. A consensus from the *in vivo* studies is that some spines change over time, while other spines are extremely stable, reflecting the need for a balance between plasticity and stability in neural circuits.

Chemical and Electrical Compartmentalization in Spines

Conjecture regarding the function of dendritic spines has focused on two possibilities. The first is that spines function as a chemical compartment distinct from the dendritic shaft (Fig. 11.11A and 11.11B). This idea is suggested by the narrow constriction of the spine neck, which has been shown experimentally to limit the diffusion of substances out of the spine head. Even small molecules such as Ca^{2+} do not diffuse freely out of spines. As a result, during activation of NMDA receptors on spines, the intracellular Ca^{2+} concentration in the spine head can far exceed that of the dendritic shaft directly adjacent to the spine. Such observations, which have been greatly facilitated by the development of two-photon microscopy (Box 11.3), have been used to quantify the diffusion of small fluorescent molecules into and out of the spine. Two-photon, as well as conventional, light microscopy has also been used to study other chemical processes in spines. For example, the endoplasmic reticulum in spines has been shown to provide a source for Ca^{2+} release into the spine head, buffering of spine Ca^{2+} concentration, as well as a source for membrane proteins such as AMPA receptors, which are inserted into the spine-head membrane during LTP. Indeed, chemical compartmentalization in the spine head is likely to be crucially important for activity-dependent plasticity, such as LTP, which may depend initially on Ca^{2+} and subsequently on an orchestrated series of biochemical and cell biological processes in the spine head.

The other major concept central to the function of dendritic spines is electrical compartmentalization (Fig. 11.11B and 11.11C). Because they are so small, the input resistance of spines is higher than that of most dendrites. The value of spine input resistance depends primarily on the resistance of the spine neck, because the parallel resistance of the spine head is immeasurably large (on the order of thousands of gigaohms). One way of thinking about this is that there is very little membrane (and therefore very few channels) through which charge can flow out of the spine head. The spine neck, therefore, although thin, is by comparison a lower-resistance path out of the spine (and into it as well). Estimates of spine neck resistance are highly varied, ranging from approximately 50 megaohms (similar to the input impedance of large dendrites) to more than a gigaohm (similar to the

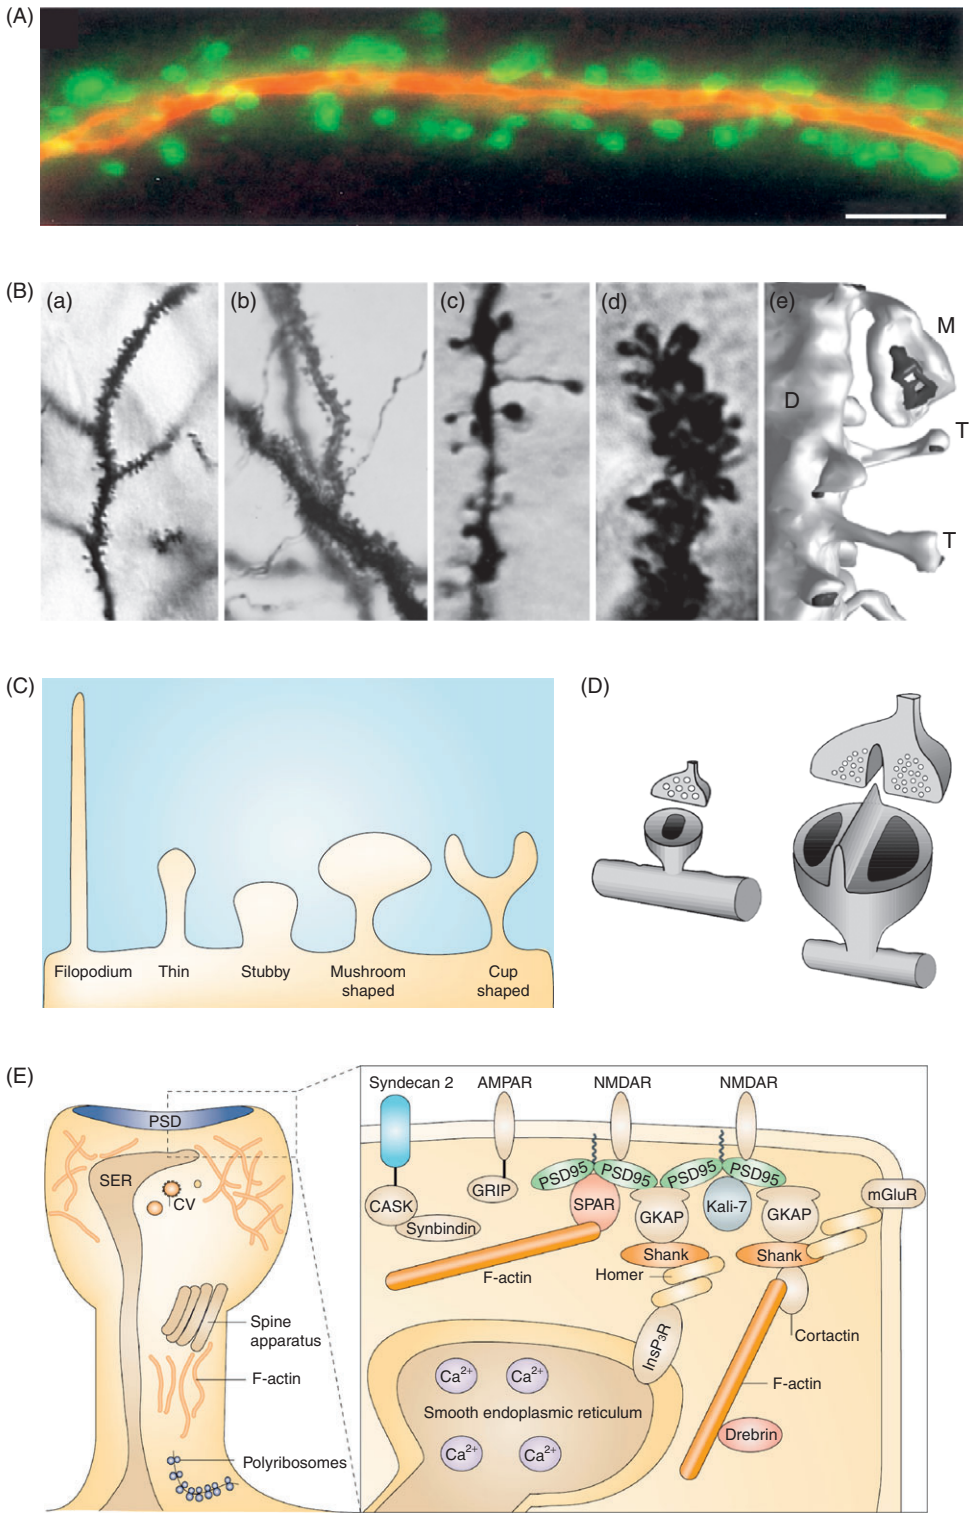

FIGURE 11.10 Spine diversity. (A) Dendritic spines expressing GFP-tagged actin (green) decorate a MAP2-labeled dendrite (red) of a cultured hippocampal neuron. Scale bar is 5 μm. (B) Dendritic spines at increasing magnification from: (a) neocortical pyramidal neuron, (b) hippocampal CA1 pyramidal neuron, (c) neocortical pyramidal neuron, (d) cerebellar Purkinje cell, (e) CA1 pyramidal neuron showing mushroom (M) and thin (t) pedunculated spines. (a–d) are light microscopy and (e) is an EM reconstruction. (C) Cartoons of different spine shapes. (D) Cartoons of small and large axo-spinous synapses. Note the "perforation" of the PSD in the large synapse. In CA1 pyramidal neurons, approximately 20% of synapses have perforated PSDs. These PSDs also have a higher density of AMPA receptors than nonperforated PSDs, suggesting that they are especially powerful synapses. (E) Cartoon illustrating the most abundant organelles and molecules in spines, including: smooth endoplasmic reticulum (SER), coated vesicles (CV), F-actin, and numerous other molecules associated with the postsynaptic density (PSD). *Sources: (A) Matus, 2000; (B) Fiala et al., 2008; (C) Hering and Sheng, 2001; (D) Geinisman, 2000; (E) Hering and Sheng, 2001.*

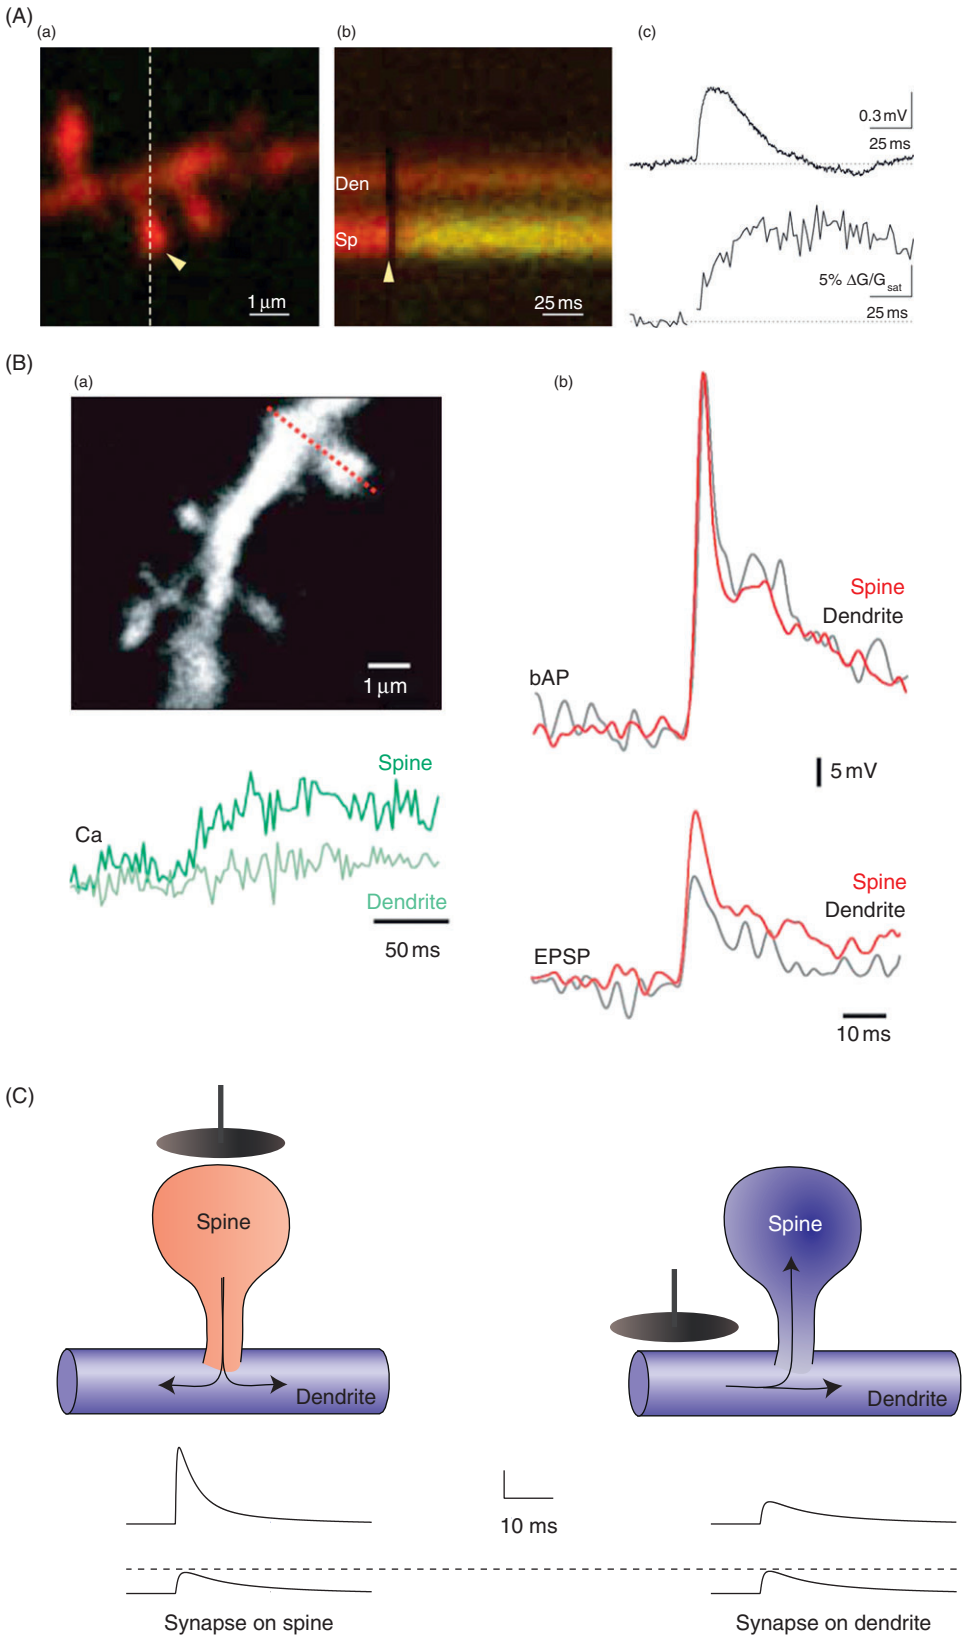

FIGURE 11.11 Chemical and electrical compartmentalization in spines. (A) (a) Image of a dendrite from a CA1 pyramidal neuron filled with a Ca^{2+}-insensitive dye (red) and a Ca^{2+}-sensitive dye (green). (b) Time series showing fluorescence changes along the line scan covering the spine (Sp) and the dendrite (Den). The yellow arrowhead indicates the position of a brief laser pulse to uncage MNI-glutamate at the position indicated in (a). (c) Somatically recorded EPSP (top) and Ca^{2+}-mediated fluorescence increase (bottom) in the spine in response to uncaging. (B) (a) Ca^{2+} transients (green traces below image) restricted to the spine in layer 5 pyramidal neuron. (b) Voltage-sensitive fluorescence changes in the spine (red traces) and dendrite (black traces) in response to a backpropagating action potential (bAP) and an EPSP. (C) Schematic diagram of the responses to a synapse on the spine head (left) and on the dendrite (right). Red indicates larger EPSP than blue. In B and C, note the attenuation from spine to dendrite, but not from dendrite to spine. *Sources: (A) Bloodgood and Sabatini, 2007; (B) Palmer and Stuart, 2009; (C) N. Spruston.*

input impedance of very small, terminal dendrites). This large range may reflect the range of spine-neck geometries: short, stubby spines likely have a relatively low resistance, while long, thin spines should have much higher resistances. Technical difficulties associated with estimating spine neck resistance may also contribute to this large range.

The spine can be considered electrically as a very high-resistance spine head connected to a relatively low-resistance dendrite via an intermediate-resistance spine neck. This electrical circuit consists of multiple impedance mismatches, which means that voltage drops are highly asymmetrical: voltage drops considerably from the spine head to the dendritic shaft, but it should hardly change at all when spreading in the other direction. Functionally, this means that when an excitatory synapse on a spine head is activated, the voltage in the spine head should be considerably larger than the voltage in the dendrite to which it is attached. On the other hand, voltages in the dendrite are expected to transmit reliably (i.e., without significant attenuation) into the spine head. This is biophysically similar to the situation described earlier for the dendrites: Dendritic spikes propagate poorly in the forward direction (from smaller dendrites into larger dendrites), but backpropagating action potentials propagate more reliably in the reverse direction (from larger dendrites into smaller dendrites).

The functional consequences of the electrical properties of spines are not known with certainty, but a few clear predictions can be made based on the electrical model described above. First, even though a single synapse produces very small EPSPs in the soma, the EPSP in the spine head is expected to be quite large, which could lead to activation of voltage-gated channels or relieve the Mg^{2+} block at activated NMDA receptors in the spine head. Indeed, Ca^{2+} imaging in spines has revealed Ca^{2+} entry through Ca_v channels and NMDA receptors, even in response to synaptic activation of a single spine. Second, the large voltage drop from the spine to the dendrite will limit the extent to which each synapse can influence its neighbors. For example, if the voltage drop were 10-fold, a 10 mV EPSP in the spine would only produce a 1 mV depolarization of neighboring spines. Third, voltage in the dendrite transmits reliably into spines. This makes it possible for a group of spines to influence one another, as well as for backpropagating action potentials or dendritic spikes to change the membrane potential in the spine. Indeed, this prediction has been validated by observations that backpropagating action potentials can readily activate Ca_v channels and relieve Mg^{2+} block of NMDA receptors in spines, a property that is crucially important for the ability of dendritic excitability to influence synaptic plasticity.

Another important question regarding the electrical properties of spines that has been considered ever since they were first discovered by Ramon y Cajal is whether changes in the spine neck can alter the coupling between the spine and the dendrite to change synaptic strength. Although this idea is appealing, the answer is probably "no." The spine neck is so short that it has negligible membrane resistance and capacitance. Thus, the amount of charge that is lost from the neuron as charge flows from the spine head to the dendrite is expected to be minuscule—certainly not large enough to significantly alter the size of the EPSP. This prediction is expected even for the highest-resistance spine necks, so lowering the neck resistance is not expected to increase the amount of charge reaching the dendrite. Changes in the spine neck can, however, have other effects. For example, lowering spine neck resistance would be expected to reduce the spine-head EPSP produced by activating the synapse on the spine, thus reducing the activation of voltage-gated channels in the spine head. Attempts to measure such effects, although difficult, have suggested that these effects are at best very small. Similarly, because of the high input impedance of the spine head, changes in the neck resistance are not likely to significantly affect the propagation of voltages from the dendrite into the spine.

Together, the available data and computer models suggest that the main electrical effect of spines is to amplify the local voltage at the synapse, perhaps allowing for more effective activation of Ca_v channels and relief of Mg^{2+} block at NMDA receptors. The resultant Ca^{2+} entry will elevate the Ca^{2+} concentration in the spine, influencing Ca^{2+}-sensitive biochemical processes in the spine head. Any resultant changes in spine structure are expected to have only minor effects on the electrical properties of spines, but the chemical compartmentalization provided by spines may facilitate biochemical and cell biological processes that influence synaptic strength such as addition of AMPA receptors and restructuring of the PSD.

COMPUTATIONS PERFORMED BY DENDRITES

Detailed analysis of synaptic integration in dendrites has been motivated by the implicit assumption that the ability of neural circuits to process and store information is dependent on the processing power of single neurons. This seems like a reasonable assumption when one considers the complexity of dendrites and their variability between different neuronal types. Ultimately, testing this assumption will require that dendrites be manipulated—likely through genetic means—to investigate how changes in their structure or ion channel expression affect neural circuit function and behavior. This is a great challenge, but one that is beginning to be possible owing to the development of sophisticated molecular genetic techniques. In the meantime, work has proceeded, using a

combination of anatomical, physiological, and computer-modeling approaches focused on developing working hypotheses about how the properties of dendrites may be used to perform neuronal "computations."

Boolean Operations and Dendritic Arithmetic

The properties of dendrites described in the previous sections allow dendrites to perform some basic Boolean operations such as AND, OR, or AND-NOT operations, thus potentially imparting onto neurons the ability to serve as basic computational elements.

One way that neurons could implement an AND operation is via the activation of two different types of presynaptic inputs targeting different dendritic domains (Fig. 11.12A)—in other words, simple coincidence detection. For example, CA1 pyramidal neurons receive inputs from CA3 (proximal inputs) and entorhinal cortex, (EC, distal inputs). These two inputs could be used to perform an AND operation (CA3 AND EC input causes CA1 spiking) or an OR operation (CA3 OR EC input causes CA1 spiking). It seems more likely to implement the AND operation, however, because EC inputs are quite far from the soma, with recordings and modeling studies suggesting that EC input is unlikely to trigger axonal action potential firing on its own. In this example, the AND operation may arise from the ability of the two inputs to interact nonlinearly in the dendrites by virtue of voltage-gated channels giving rise to dendritic spikes. Intriguingly, the observation that some

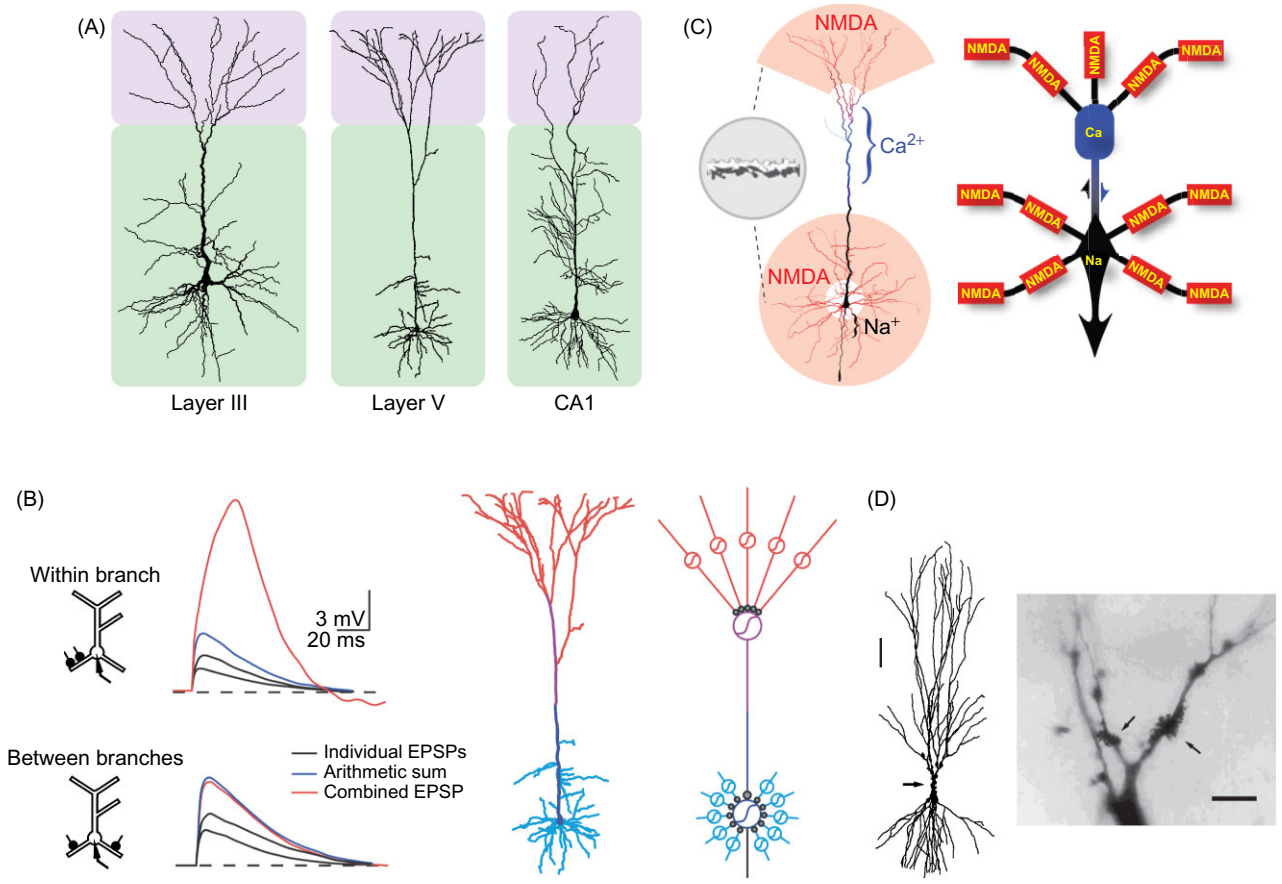

FIGURE 11.12 Compartmentalization of different dendritic inputs is important for dendritic computation. (A) Schematic diagram illustrating that the apical tuft (purple) and proximal apical/basal dendrites (green) receive separate synaptic inputs in a variety of types of pyramidal cells. (B) Summation of inputs onto a single dendritic branch (but not between branches) leads to a dendritic spike that remains below threshold for an action potential at the soma. It has therefore been proposed that each proximal apical and basal dendritic branch (blue) acts like a computational unit where synaptic inputs are summed (represented by sigmoidal functions in small circles) and multiple branches need to be activated to trigger an action potential (represented by sigmoidal function in large circles). Distal apical dendrites (red) may similarly sum inputs, which are further summed in a distal dendritic spike-initiation zone. (C) This model proposed in B has been further validated by experiments demonstrating summation of NMDA spikes in apical tuft dendrites to activate a distal Ca^{2+} spike-initiation zone. (D) CA3 pyramidal neurons receive strong excitatory synaptic input via the mossy fibers from dentate granule cells. These synapses contact elaborate dendritic spines (arrows) called thorny excrescences. Because of the large size of each mossy fiber synapse, they have been referred to as "detonator" synapses. Scale bars: 50 μm (left), 25 μm (right). *Sources: (A) Spruston, 2008; (B) Polsky et al., 2004, Spruston and Kath, 2004; (C) Larkum et al., 2009; (D) Gonzales et al., 2001.*

excitatory inputs selectively target distal dendrites and others target proximally is a common theme in many kinds of neurons (e.g., pyramidal neurons, dentate granule cells), suggesting that AND operations may be commonly implemented in this way.

Other mechanisms can also lead to AND operations in dendrites. For example, as discussed above, spikes generated in dendrites do not propagate reliably to the soma. Thus, dendritic spikes are often observed even in the absence of an axonal action potential. One idea that has been proposed is that pyramidal neurons might fire action potentials only when two or more dendritic branches are depolarized to threshold for a dendritic spike (Fig. 11.12B). For more distal synaptic inputs, such as those onto the apical tuft of layer 5 pyramidal neurons, NMDA spikes in multiple dendritic branches may be required in order to trigger an action potential in the axon (Fig. 11.12C). Thus, neurons can implement an AND operation using multiple dendritic branches. Another mechanism is the BAC spike observed in layer 5 pyramidal neurons (discussed above). BAC spikes implement an AND operation using excitatory input to the apical tuft combined with a backpropagating action potential (e.g., evoked by strong excitatory input to the basal dendrites).

Although the simplest possible outcome of a dendritic AND operation is generation of an action potential in the axon, other possible readouts may occur as well. In the case of a distal dendritic Ca^{2+} spike or BAC spike, the readout may be a burst of action potentials in the axon, or a large dendritic event that can influence synaptic plasticity even in the absence of an axonal spike. In Purkinje cells, activation of the climbing fiber alone always leads to a burst of action potentials, but when combined with parallel fiber activation, the AND operation may lead to more spikes in the burst, as well as plasticity at the activated parallel fiber inputs. Even individual dendritic spines can perform AND operations, as activation of glutamate receptors combined with a backpropagating action potential can lead to Ca^{2+} influx through NMDA receptors, thus influencing biochemical reactions in the spine, including those that can lead to synaptic plasticity.

Synaptic integration in dendrites may also give rise to OR operations. For example, hippocampal CA3 pyramidal neurons receive input from granule cells in the dentate gyrus via mossy fibers. The mossy fiber axons form large, specialized excitatory synapses on the main apical dendrite, very close to the soma (Fig. 11.12D). These synapses are sometimes called "detonator" synapses, because they produce large EPSPs that can cause the CA3 neuron to fire action potentials. On the other hand, CA3 neurons also form extensive collateral connections among themselves. Many of these synapses are also quite close to the soma, on basal and proximal apical dendrites, so they can also cause CA3 neurons to fire. Thus, CA3 neurons may respond to mossy fiber OR collateral input alone. CA3 neurons also receive excitatory input from EC onto the distal apical dendrites, however. Thus, like CA1 neurons, CA3 neurons could implement an AND operation as well (CA3 collateral AND EC input cause CA3 spiking). This anatomical arrangement suggests that neurons could implement both AND and OR operations, depending on which inputs are active in the dendritic tree.

Neurons can also use inhibition to implement AND-NOT Boolean operations. In this case, inhibition is viewed as vetoing the excitatory input. As discussed in previous sections, however, the effectiveness of inhibition depends not only on its strength but also on its location relative to active excitatory inputs. Thus, inhibition may perform a global AND-NOT operation if powerful inhibition is targeted to the soma or axon, or it may perform a more local AND-NOT operation if the inhibition is targeted to a particular dendritic domain. Many cortical pyramidal neurons receive feedback inhibition to the distal apical tuft, suggestive of a veto (NOT) of distal excitatory inputs.

Another mechanism by which neurons might implement Boolean operations is by using inputs from neuromodulatory systems. For example, a combination of excitatory synaptic input AND cholinergic input could be a condition for action potential firing, while excitatory input AND-NOT serotonergic input might be required. In these hypothetical scenarios, the cholinergic and serotonergic inputs could be excitatory and inhibitory, respectively, by acting on synaptic targets (e.g., enhancing or inhibiting glutamate release) or nonsynaptic targets (e.g., enhancing or inhibiting voltage-gated channels in the axon, soma, or dendrites).

Although these Boolean operations are relatively simple, very complex operations can be performed using them, as is the case for modern computers. Neural circuits can do this using large numbers of neurons, but as noted above, it may also be possible for one neuron to perform multiple (perhaps even many) Boolean operations. This can happen either separately or simultaneously. CA3 neurons may perform separate AND or OR operations, depending on the inputs they receive in any particular behavioral condition. On the other hand, action potential firing in some cases might represent a complex condition resulting from multiple, simultaneous operations, such as the following:

Distal excitation AND-NOT distal inhibition
AND
Proximal excitation AND dopaminergic modulation
AND-NOT
Axo-somatic inhibition

In this hypothetical scenario, some operations are on the same line to indicate local specificity of the effects,

while others are on separate lines to indicate the more global nature of the operation. As illustrated by this example, single neurons may implement complex operations that have traditionally been assigned to neural networks consisting of many neurons, each with much simpler properties. Thus, the presence of excitable dendrites that receive targeted inputs from distinct populations of excitatory, inhibitory, and modulatory synapses may confer complex computational power to single neurons.

In addition to performing Boolean operations, dendrites have also been described as performing arithmetic operations. The simplest example of this is summation. If a number of excitatory synaptic inputs are summed (spatially or temporally) to reach action potential threshold, this can be thought of as a simple addition. On the other hand, inhibitory inputs can reduce the depolarization from the summed excitatory inputs by providing a hyperpolarizing influence, which can be thought of as subtraction.

More complicated arithmetic—namely multiplication and division—can also be implemented in dendrites. For example, the AND operations described above can be thought of as multiplication because if either input is zero, the output is zero. On the other hand, shunting inhibition can be thought of as division because it reduces depolarization in proportion to the strength of the excitatory input (larger excitatory inputs produce larger driving forces for current flowing through the inhibitory shunt).

Dendrites and Neuronal Response Properties

Moving a step beyond the Boolean and arithmetic operations performed by dendrites (and the biophysical mechanisms used to implement them) requires a link between the function of a neuron (i.e., its response properties) and the properties of its dendrites. Such a link has been made in several cases, but in general the mechanisms are not well established. Two examples stand out, however, as illustrations of how dendrites can contribute to determining response properties.

The first example is the general case of visual motion detection, which has been studied in a variety of cell types with motion-sensitive receptive fields. Although several mechanisms have been described, what they all have in common is sequentially activated synaptic inputs targeting different dendritic positions in spatial order. Even in passive dendrites, it has been shown that sequential activation of excitatory synapses from distal (first) to proximal (last) is more effective than activation of the same synapses in reverse order (Box 11.1). The reason is that distal inputs have slower kinetics when they arrive at the soma, so they sum most effectively with proximal inputs (with faster kinetics) that arrive later. This mechanism is enhanced in dendrites by NMDA receptors, but for a different reason: distal dendrites have higher input impedance than proximal dendrites, so they produce large depolarizations that more effectively remove Mg^{2+} block at NMDA receptors, both at the distal synapses and at proximal synapses that are activated later. When synapses are activated in the reverse order (proximal before distal), the large dendritic depolarization associated with activation of distal synapses occurs too late to effectively remove the Mg^{2+} block at the proximal synapses activated earlier.

A second example of a well-understood mechanism of dendritic integration underlying a response property comes from the auditory system, where neurons involved in sound localization are responsive to interaural timing differences. These neurons respond best to coincident input from the two ears, with timing differences encoded by "delay lines" that allow for coincident arrival of inputs to the two ears even when sound arrives at the two ears with a slight delay. To respond optimally to two coincident inputs with very rigid timing requirements (microseconds), the EPSPs have to decay very rapidly, which requires very leaky dendrites. If the two inputs are located on the same dendrite, they will shunt each other (i.e., reduced driving force at one synapse resulting from depolarization via the other), so to effectively summate, the two inputs must be formed onto two different dendrites. Because these two dendrites are on opposite sides of the soma, the EPSP from one dendrite has little effect on the EPSP from the other dendrite, thus limiting the shunting effect. By contrast, a higher-intensity sound arriving at one ear would not be an effective stimulus for the neuron to fire because of the suppressive nonlinearity (shunting) caused by activating more synapses on the same dendrite.

The common denominator in these mechanisms is that in order for them to work, synaptic inputs have to be targeted to precise locations. It is not good enough for an axon carrying particular information (i.e., sound from the left ear) to find the correct postsynaptic neuron; it must also find the correct dendrite (i.e., left vs. right) on that neuron. Similarly, in pyramidal neurons, inputs clustered onto the same dendritic branch trigger dendritic spikes more readily than inputs that are distributed across multiple branches, suggesting that even more precise targeting may be required. Taking this a step further, clustering of inputs alone may not even be precise enough. For example, directional selectivity may require that certain synapses must find not only the correct dendrite but also the correct location on the dendrite (i.e., distal vs. proximal). The degree to which neural circuits are wired with this degree of precision is unknown. For example, do multiple axons carrying common information (e.g., a particular facial feature) selectively target the same dendrites or dendritic

compartments? Questions like these must be answered before we can truly understand how information is processed in dendrites.

SUMMARY

Neuronal dendrites are very complicated. This is obvious from a glance at their structure in the light microscope but is becoming even more apparent as the molecular composition and functional properties of different dendrites are investigated. In addition to the channels that give them a resting potential and allow them to engage in synaptic communication, they contain a host of voltage-gated channels expressed in exquisite patterns, differentially distributed across the dendrites of different neurons. In addition, synapses carrying information from different parts of the brain selectively target different dendritic domains. We have only begun to scratch the surface of the complexity that exists in neuronal dendrites, and there are many important questions left to answer, spanning multiple levels of organization and complexity. For example, at the cellular level: why are there at least 50 times more HCN channels in distal dendrites than in proximal dendrites of many pyramidal neurons? At the synaptic and circuit levels: why are there more than 20 different types of inhibitory interneurons in the CA1 region of the hippocampus alone, more than half of which target specific dendritic compartments? How precise is the specificity of this dendritic targeting, not only for inhibitory synapses but also for excitatory synapses? At the computational level: how do these cellular properties and synaptic circuitry come together with the structure of the dendritic tree to implement sophisticated cellular computation? At the systems level: why are distal and proximal synapses differentially modulated by modulatory neurotransmitters such as acetylcholine? How does such modulation alter the computations performed in dendrites as neurotransmitter levels change during various behavioral states? These and many other questions need to be answered, likely leading to even more questions. Elucidating the details of how synaptic integration works in elaborately branching dendritic trees will be critical for determining not only how neurons are built, but for what purpose. Ultimately, this challenge lies at the core of understanding how neurons are used to build circuits controlling sensation and action, perception, and cognition.

CHAPTER

12

Brain Energy Metabolism

All the processes described in this textbook require energy. Ample clinical evidence indicates that the brain is exquisitely sensitive to perturbations of energy metabolism. This chapter covers the topics of energy delivery, production, and utilization by the brain. Careful consideration of the basic mechanisms of brain energy metabolism is an essential prerequisite to a full understanding of the physiology and pathophysiology of brain function. Abnormalities in brain energy metabolism are observed in a variety of pathological conditions such as, for example, neurodegenerative diseases, stroke, epilepsy, and migraine. The chapter reviews the features of brain energy metabolism at the global, regional, and cellular levels and extensively describes recent advances in the understanding of neuro-glial metabolic cooperation. A particular focus is the cellular and molecular mechanisms that tightly couple neuronal activity to energy consumption. This tight coupling is at the basis of functional brain-imaging techniques, such as positron emission tomography (PET) and functional magnetic resonance imaging (fMRI).

ENERGY METABOLISM OF THE BRAIN AS A WHOLE ORGAN

Glucose Is the Main Energy Substrate for the Brain

The human brain constitutes only 2% of the body weight, yet the energy-consuming processes that ensure proper brain function account for approximately 25% of total body glucose utilization. With a few exceptions that will be reviewed later, glucose is the obligatory energy substrate of the brain. In any tissue, glucose can follow various metabolic pathways; in the brain, glucose is almost entirely oxidized to CO_2 and water through its sequential processing by glycolysis (Fig. 12.1), the tricarboxylic acid (TCA) cycle also referred to as the Krebs cycle (Fig. 12.2), and the associated oxidative phosphorylation, which yield, on a molar basis, between 30 and 36 ATPs per glucose, depending on the coupling efficiency of oxidative phosphorylation. Indeed, the oxygen consumption of the brain, which accounts for almost 20% of the oxygen consumption of the whole organism, is 160 mmol per 100 g of brain weight per minute and roughly corresponds to the value determined for CO_2 production. This O_2/CO_2 relation corresponds to what is known in metabolic physiology as a respiratory quotient of nearly 1 and demonstrates that carbohydrates, and glucose in particular, are the exclusive substrates for oxidative metabolism.

This rather detailed information of whole brain energy metabolism was obtained using an experimental approach in which the concentration of a given substrate in the arterial blood entering the brain through the carotid artery is compared with that present in the venous blood draining the brain through the jugular vein. If the substrate is utilized by the brain, the arteriovenous (A-V) difference is positive; in certain cases, the A-V difference may be negative, indicating that metabolic pathways resulting in the production of the substrate predominate. In addition, when the rate of cerebral blood flow (CBF) is known, the steady-state rate of utilization of the substrate can be determined per unit time and normalized per unit brain weight according to the following relation: CMR = CBF (A-V), where CMR is the cerebral metabolic rate of a given substrate.

This approach was pioneered by Seymour Kety and C. F. Schmidt in the late 1940s and was further developed in the 1950s and 1960s. In normal adults, CBF is approximately 57 ml per 100 g of brain weight per minute, and the calculated glucose utilization by the brain is 31 mmol per 100 g of brain weight per minute, as determined with the A-V difference method. This value is slightly higher than that predicted from the rate of oxygen consumption

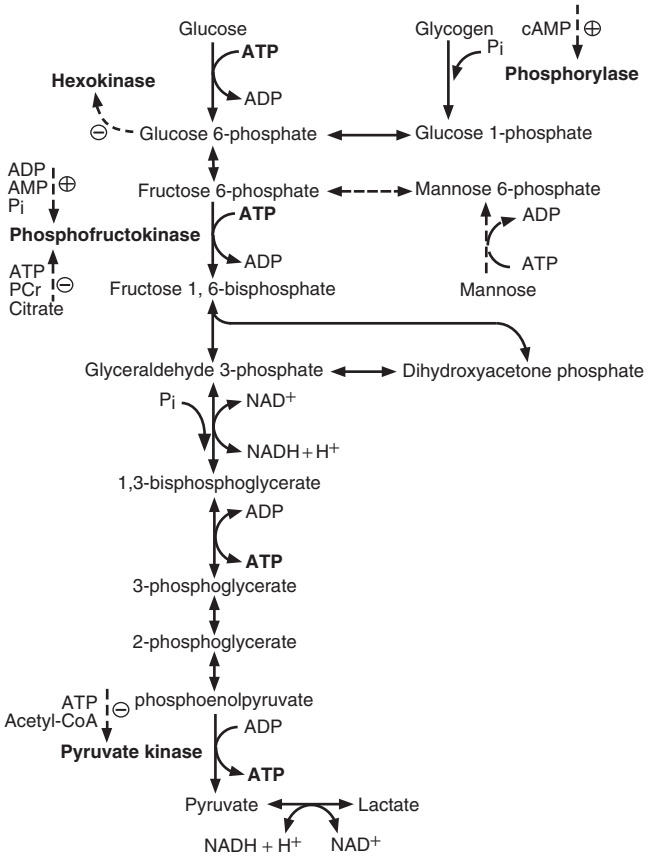

FIGURE 12.1 Glycolysis (Embden-Meyerhof pathway). Glucose phosphorylation is regulated by hexokinase, an enzyme inhibited by glucose 6-phosphate. Glucose must be phosphorylated to glucose 6-phosphate to enter glycolysis or to be stored as glycogen. Two other important steps in the regulation of glycolysis are catalyzed by phosphofructokinase and pyruvate kinase. Their activities are controlled by the levels of high-energy phosphates, as well as of citrate and acetyl-CoA. Pyruvate, through lactate dehydrogenase, is in dynamic equilibrium with lactate. This reaction is essential to regenerate NAD^+ residues necessary to sustain glycolysis downstream of glyceraldehyde 3-phosphate. PCr, phosphocreatine.

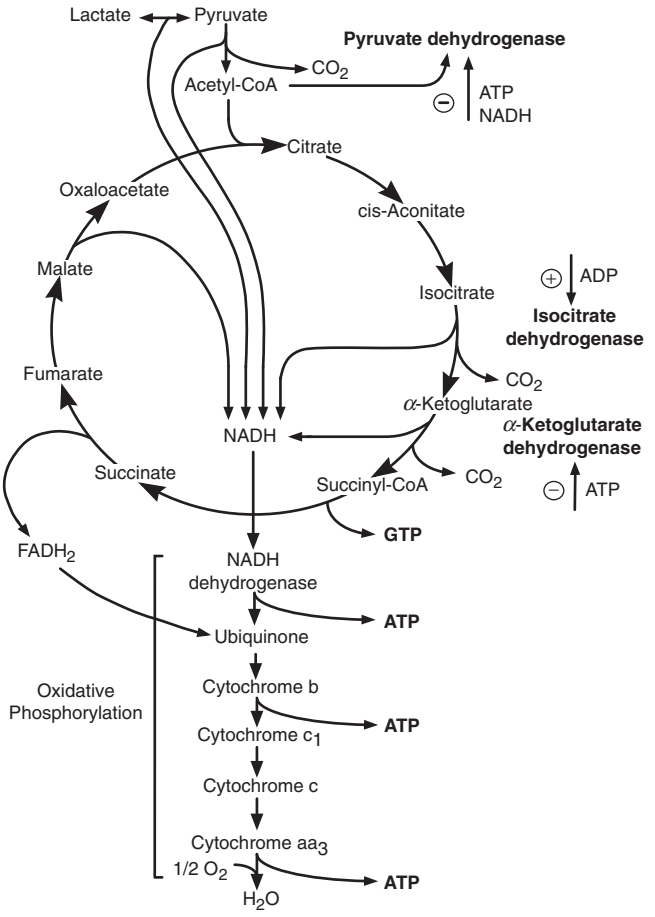

FIGURE 12.2 Tricarboxylic acid cycle (TCA cycle) and oxidative phosphorylation. Pyruvate entry into the cycle is controlled by pyruvate dehydrogenase activity that is inhibited by ATP and NADH. Two other important regulatory steps in the cycle are controlled by isocitrate and α-ketoglutarate dehydrogenases, whose activities are controlled by the levels of high-energy phosphates.

of the brain. Thus, in an organ such as the brain with a respiratory quotient of 1, the stoichiometry would predict that 6 mmol of oxygen are needed to fully oxidize 1 mmol of the six-carbon molecule of glucose; given an oxygen consumption rate of 160 mmol per 100 g of brain weight per minute, the predicted glucose utilization would be 26.6 mmol per 100 g of brain weight per minute (160:6), yet the actual measured rate is 31 mmol. What then is the fate of the excess 4.4 mmol? First, glucose metabolism may proceed, to a very limited extent, only through glycolysis, resulting in the production of lactate without oxygen consumption (Fig. 12.1); glucose can also be incorporated into glycogen (Fig. 12.1). Second, glucose is an essential constituent of macromolecules such as glycolipids and glycoproteins present in neural cells. Finally, glucose enters the metabolic pathways that result in the synthesis of three key neurotransmitters of the brain: glutamate, GABA, and acetylcholine (see Chapter 6).

Ketone Bodies Become Energy Substrates for the Brain under Particular Circumstances

Under particular circumstances, substrates other than glucose can be utilized by the brain. For example, breastfed neonates have the capacity to utilize the ketone bodies acetoacetate (AcAc) and D-3-hydroxybutyrate (3-HB) or free fatty acids, in addition to glucose, as energy substrates for the brain. This capacity is an interesting example of a developmentally regulated adaptive mechanism because maternal milk is highly enriched in lipids, resulting in a

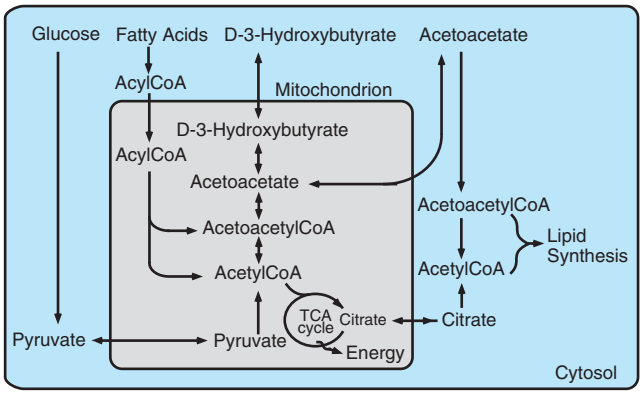

FIGURE 12.3 Relationship between lipid metabolism and the TCA cycle. Under particular dietary conditions, such as lactation in newborns or fasting in adults, the ketone bodies acetoacetate and D-3-hydroxybutyrate and circulating fatty acids can provide substrates to the TCA cycle after conversion to acetyl-CoA. Carbon atoms for lipid synthesis can be provided by glucose through citrate produced in the TCA cycle, a particularly relevant process for the developing brain.

lipid-to-carbohydrate ratio much higher than that present in postweaning nutrients. Indeed, lipids account for approximately 55% of the total calories contained in human milk, in contrast with 30–35% for a balanced postweaning diet. Acetoacetate, 3-HB, and free fatty acids can all be processed to acetyl-CoA, thus providing ATP through the TCA cycle (Fig. 12.3).

Another consideration regarding the lipid-rich diet provided during the suckling period relates to its contribution to the process of myelination. Evidence shows that brain lipids can be synthesized from blood-borne precursors such as ketone bodies. In addition, when suckling rats are fed a diet low in ketones, carbon atoms for lipogenesis can also be provided by glucose (Fig. 12.3). To summarize, ketone bodies are energy substrates, as well as precursors for lipogenesis during the suckling period; however, the developing brain appears to be metabolically quite flexible because glucose, in addition to its energetic function, can be metabolized to generate substrates for lipid synthesis.

Starvation and diabetes are two situations in which the availability of glucose to tissues is inadequate and in which plasma ketone bodies are elevated because of enhanced lipid catabolism. Under these conditions, the adaptive mechanisms described for breast-fed neonates become operative in the brain, allowing it to utilize AcAc or 3-HB as energy substrates.

Lactate and Pyruvate Serve as Instructive Cases

In addition to ketone bodies, lactate and pyruvate represent energy substrates alternative to glucose for neural cells. These two monocarboxylates can readily enter the cells through specialized monocarboxylate transporters (MCTs) and can be metabolized in the mitochondria through the TCA cycle and the oxidative phosphorylation to produce energy in the form of ATP (Fig. 12.2). *In vitro* and *ex vivo* data have provided extensive demonstration that lactate and pyruvate can sustain neuronal function—that is—synaptic activity, even in the absence of glucose (Schurr, 2006). In line with this, both monocarboxylates can protect neurons from cell damage/death in conditions of energy deprivation such as in hypoglycaemia.

It was initially thought that the permeability of the blood-brain barrier to monocarboxylates was limited, suggesting that circulating lactate or pyruvate could not represent significant alternative substrates to glucose for the brain *in vivo*. The demonstration of the expression of MCTs on intraparenchymal brain capillaries along with magnetic resonance spectroscopy (MRS) experiments have led to the reevaluation of the importance of circulating monocarboxylates, and in particular lactate, for brain energy metabolism. It is now estimated that plasma lactate (≈1.0 mM) is taken up by the human brain, where it is fully oxidized accounting for up to 8 to 10% of its energy requirements. This contribution may even be greater at supraphysiological lactate concentrations (i.e., following intravenous lactate infusion) with a near linear relationship. Increases in blood lactate concentration are observed in different physiological conditions such as during physical exercise, implying that lactate can readily be used by the brain as an alternative energy substrate in such specific conditions. In particular, during moderate-to-vigorous exercises, which results in blood lactate concentration up to 10 mM, the human brain takes up and oxidizes lactate to a considerably larger extent than under normal conditions (which could cover up to 20 to 25% of the total brain energy demand); this increase in lactate oxidation occurs at the expense of blood glucose utilization. Overall these data demonstrate that plasma lactate can be an energy substrate for the human brain. In addition, if formed within the brain parenchyma from glucose that has crossed the blood-brain barrier, lactate and pyruvate may in fact become the preferential energy substrates for activated neurons (see below).

Summary

Glucose is the obligatory energy substrate for brain, and it is almost entirely oxidized to CO_2 and H_2O. This simple statement summarizes, with few exceptions, over five decades of careful studies of brain energy metabolism at organ and regional levels. Under ketogenic conditions, such as starvation and diabetes and during breastfeeding, ketone bodies may provide an energy source for the brain. Lactate, formed from glucose within the brain parenchyma or imported from the circulation, is an adequate energy substrate as well.

TIGHT COUPLING OF NEURONAL ACTIVITY, BLOOD FLOW, AND ENERGY METABOLISM

A striking characteristic of the brain is its high degree of structural and functional specialization. Thus, when we move an arm, motor areas and their related pathways are activated selectively (see Chapter 27); intuitively, one can predict that as "brain work" increases locally (e.g., in motor areas), the energy requirements of the activated regions will increase in a temporally and spatially coordinated manner. Because energy substrates are provided through the circulation, blood flow should increase in the modality-specific activated area. In agreement with this prediction, a fascinating and robust feature of brain energy metabolism is the existence of such a tight coupling between energy demand and supply. Indeed, task-dependent increases in cerebral activity are invariably accompanied by changes in local cerebral blood flow and glucose utilization—these processes being referred to as neurovascular- and neurometabolic-coupling, respectively (Fig. 12.4A and Box 12.1).

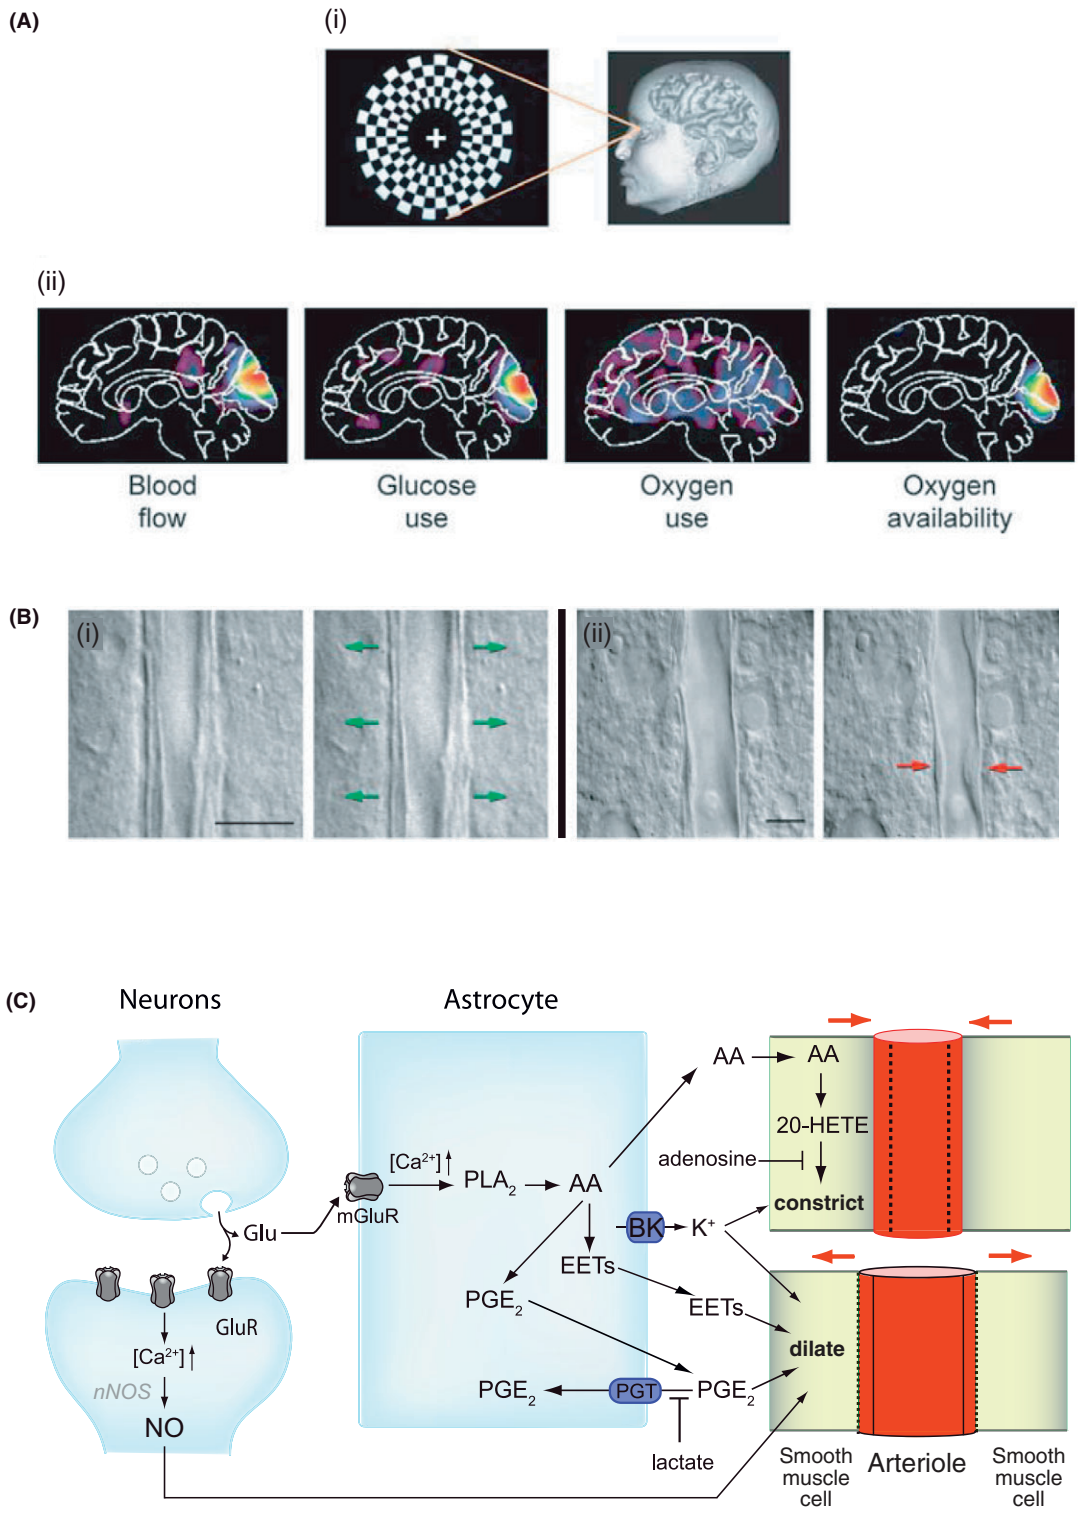
Which Mechanisms Couple Neuronal Activity to Blood Flow?

More than a century ago, the British neurophysiologist Charles Sherrington showed, in experimental animals, increases in blood flow localized to the parietal cortex in response to sensory stimulation. He postulated that "the brain possesses intrinsic mechanisms by which its vascular supply can be varied locally in correspondence with local variations of functional activity." With remarkable insight, he also proposed that "chemical products of cerebral metabolism" produced in the course of neuronal activation could provide the mechanism to couple activity with increased CBF (also known as functional hyperemia).

Since Sherrington's seminal work, a variety of vasoactive agents, including H^+, K^+, neurotransmitters (such as noradrenaline, serotonin, or vasoactive intestinal peptide [VIP]), adenosine, lactate, arachidonic acid metabolites, and nitric oxide (NO), released from different cellular compartments (i.e., neurons, astrocytes, pericytes, and smooth muscle cells) have been implicated in the activity-dependent increase in CBF. In conjunction with this, evidence suggests that the vascular tone is dynamically regulated, since both dilation and constriction of microvessels can be elicited in *ex vivo* preparations (Fig. 12.4B) (Attwell et al., 2010; Cauli et al., 2004; Petzold & Murthy, 2011). Although the exact physiological mechanisms underlying regulation of the vascular tone, and in particular functional hyperemia, are still incompletely understood, the importance played by neuron-to-astrocyte and glutamate signaling in this process is now widely demonstrated (Fig. 12.4C).

Nitric oxide has been recognized for a long time as an essential mediator for coupling neuronal activity to blood flow. NO is mainly formed locally by neurons under the action of glutamate (Fig. 12.4C), the principal excitatory neurotransmitter. Nitric oxide is a diffusible and potent vasodilator whose short half-life spatially and temporally restricts its domain of action. However, in several experimental models in which the activity of NO synthase, the enzyme responsible for NO synthesis, was inhibited, a certain degree of coupling was still observed, indicating that NO is only one of the regulators of local blood flow acting in synergy with others.

FIGURE 12.4 Neurovascular and neurometabolic coupling. (A) Differential regulation of blood flow (CBF), oxygen use ($CMRO_2$), and glucose use (CMRglu) during brain activation in humans. Stimulation of the human visual cortex was performed experimentally by presenting a visual stimulus in the form of a reversing annular checkerboard (i), and CBF, $CMRO_2$, and CMRglu were determined by PET (ii) (see Box 12.1). When compared with viewing a blank screen, visual stimulation produces marked changes in activity in visual areas of the brain, as shown in PET images using pseudo colors (from small increase, blue, to major increase, red). Increases in both blood flow and glucose use in the visual cortex could be observed that are unaccompanied by similar increases in oxygen use, suggesting that the metabolic needs associated with brain activation are met by glycolysis. As a result, the local availability of oxygen increases because the increased supply of oxygen by increased (arterial) blood flow exceeds the increased local demand for oxygen. Such an effect may account for the blood-oxygen-level-dependent (BOLD) signal of functional magnetic resonance imaging (fMRI). *Reproduced with permission from Raichle and Mintun (2006).* (B) Dynamic regulation of vascular tone. Single interneuron stimulation is sufficient to either dilate (i) or constrict (ii) neighboring microvessels in acute rat cortical slices. In (i) and (ii), images of blood vessels before (left) and after (right) electrical stimulation of the interneurons are shown. Scale bars, 10 μm. *Reproduced with permission from Cauli et al. (2004).* (C) Glutamate-dependent regulation of CBF. Neuronal activity-dependent glutamate release raises $[Ca^{2+}]_i$ in astrocytes by activating metabotropic glutamate receptors (mGluR). Ca^{2+} transients in astrocytes activate cytosolic phospholipase A_2 (PLA_2), thus producing arachidonic acid (AA). AA can generate different types of vasodilatory metabolites in astrocytes such as prostaglandins (PG), in particular PGE_2, and epoxyeicosatrienoic acids (EETs). In parallel, AA can diffuse to arteriolar smooth muscle cells, where it is converted to 20-hydroxyeicosatetraenoic acid (20-HETE) by ω-hydroxylase, which exerts a vasoconstricting effect. During brain activation, vasodilation is promoted by the increases in extracellular lactate and adenosine concentrations. Indeed, lactate favors PGE_2 accumulation in the extracellular space, and thus vasodilation, by decreasing the efficacy of the prostaglandin transporter (PGT) in astrocytes, whereas adenosine has an inhibitory effect on 20-HETE-mediated arteriolar constriction. In parallel to this, Ca^{2+} induces K^+ release from astrocytes through the activation of calcium-dependent potassium channels (BK), which in turn can promote either vasodilation or vasoconstriction, depending on the level of extracellular K^+. In postsynaptic neurons, glutamate activates ionotropic receptors, which trigger Ca^{2+} elevations, activation of the neuronal nitric oxide synthase (nNOS) and the release of the vasodilating nitric oxide (NO). Additional mechanisms are known to participate in CBF regulation but are not included in the present figure for clarity. A detailed description of all these mechanisms can be found elsewhere (see, for example, Attwell et al., 2010; Petzold & Murthy, 2011). *Modified with permission from Bélanger et al. (2011).*



More recent *in vitro* and *in vivo* experiments have provided evidence that astrocytes may play a key role in neurovascular coupling. Indeed, as will be elaborated in greater detail in the section(s) devoted to neurometabolic coupling (e.g., see Fig. 12.11), astrocytes occupy a strategic position between capillaries and the neuropil. Through receptors and reuptake sites for neurotransmitters, notably glutamate, they can sense synaptic activity and couple it to vascular response. In particular, calcium transients in astrocytes resulting from metabotropic

BOX 12.1

POSITRON EMISSION TOMOGRAPHY (PET) AND FUNCTIONAL MAGNETIC RESONANCE IMAGING (fMRI)

We have seen that neuronal activity is tightly coupled to blood flow and metabolism. With the advent of sophisticated imaging procedures such as positron emission tomography (PET) and functional magnetic resonance imaging (fMRI), it is now possible to detect the signals generated by the metabolic processes associated with neuronal activity, thus providing a unique opportunity to see the "brain at work." Indeed, local changes in blood flow, glucose utilization, and oxygen consumption can be monitored noninvasively under basal and activated conditions in human subjects. How is this possible?

For PET, a solution containing slightly radioactive molecules is injected into the circulation, and its sites of brain uptake can be visualized. The molecule is labeled radioactively with an unstable radionuclide possessing an excess number of protons; as a consequence of normal radioactive decay, the excess proton is converted to a neutron. In this process, a positron (a positively charged electron) is emitted and collides with an electron, releasing energy in the form of two photons with opposite trajectories. The photons are sensed by specialized detectors placed around the head; when two photons simultaneously reach two detectors positioned at 180 degrees of each other, the origin of the positron–electron collision can be localized with a millimeter resolution. Commonly used positron-emitting radionuclides are oxygen-15 (^{15}O), carbon-11 (^{11}C), and fluorine-18 (^{18}F). Blood flow is monitored with ^{15}O-labeled water and glucose utilization with ^{18}F-2-deoxyglucose. Oxygen consumption is visualized directly with ^{15}O. With the use of sophisticated algorithms to process data, the localization of activity to specific brain areas during a given task (sensory, motor, cognitive) can be achieved. Thus, the activity of neuronal ensembles, and of the associated glia, coupled to increased blood flow and glucose utilization results in a localized signal due to the augmented concentration of ^{15}O-labeled water (monitoring blood flow) and ^{18}F-2-deoxyglucose (assessing glucose utilization) in the activated area (see Fig. 12.4A).

PET is one of the ways in which brain work can be visualized. A now popular technique, fMRI relies on the magnetic signals detected in an activated brain region in relation to its degree of oxygenation. Depending on the degree to which it is saturated by oxygen, hemoglobin (by acting as a paramagnetic contrast agent) can alter the magnetic signal detected in a tissue exposed to the magnetic fields used for structural MRI. In other words, different MRI signals can be obtained depending on the oxyhemoglobin/deoxyhemoglobin ratio in a given brain area. Local activation of a brain area results in increased blood flow (see Fig. 12.4A). Although the precise mechanisms for the fMRI signals are still being discussed, it is currently thought that this phenomenon, by leading to a localized enrichment in oxyhemoglobin, alters the oxyhemoglobin/deoxyhemoglobin ratio, providing the blood-oxygen-level-dependent (BOLD) signal for fMRI. Functional MRI is a remarkably convenient and powerful technique: the signal acquisition time is extremely rapid (in the order of seconds), and the resolution equals that of PET (i.e., a few millimeters). In addition, fMRI is totally noninvasive and can thus be repeated frequently on the same subject, who can then serve as its own control. The model of neurometabolic coupling provided by the ANLS can account for the unexpected increases in oxyhemoglobin during activation, which is at the basis of the BOLD signal. Indeed, the Astrocyte-Neuron Lactate Shuttle (ANLS) predicts that a *transient nonoxidative* use of glucose occurs during the initial phases (1 to 2 seconds) of activation, resulting in lactate production by astrocytes. Since activity-dependent increase in CBF (neurovascular coupling) brings to the activated area oxygen-enriched (arterial) blood, while oxygen consumption does not increase commensurately because of the transient nonoxidative use of glucose in astrocytes (see Fig. 12.4A), it follows that the activated region will contain a higher ratio of oxy/deoxy hemoglobin at the basis of the BOLD signal. Recoupling with oxidative processing of lactate/pyruvate in neurons reestablishes the oxy/deoxyhemoglobin ratio, consistent with the transient nature of the kinetics for the BOLD signal.

glutamate receptor activation have been shown to induce the production and release of vasoactive agents from astrocytes which are associated with both dilation or constriction of blood vessels (Fig. 12.4C). These vasoactive agents include products of arachidonic acid (AA) metabolism such as (1) the two vasodilators epoxyeicosatrienoic acids (EETs) and prostaglandin E2 (PGE_2) formed within astrocytes, and (2) the vasoconstrictor 20-hydroxyeicosatetraenoic acid (20-HETE) that is produced in smooth muscle cells from AA released by astrocytes (Fig. 12.4C) (Attwell et al., 2010; Petzold & Murthy, 2011).

Interestingly, Gordon and collaborators demonstrated in rat brain slices that the balance between vasoconstriction

and vasodilation may be dictated by brain metabolism. They observed that neuronal activation leads to arteriolar dilatation under low-oxygen conditions, whereas in high-oxygen conditions the same stimulus induces the constriction of arterioles (see Attwell et al., 2010; Petzold & Murthy, 2011). The authors also demonstrated that the vasodilating effect observed in lower-oxygen conditions is mediated by the activation of glycolysis and an elevation of extracellular lactate and adenosine concentrations, which interfere with PGE_2 and 20-HETE metabolisms, respectively (Fig. 12.4C). This set of observations suggests that under resting conditions, when oxygen is not being rapidly consumed, astrocytic Ca^{2+} signals would induce a constricting tone, keeping cerebral blood flow at an appropriately lower level. In contrast, during activation, the drop in pO_2 due to oxygen consumption (see Attwell et al., 2010) and the rise in extracellular lactate and adenosine levels would promote astrocyte-mediated vasodilation. Another important vasoactive agent released by astrocytes, which is also coupled to elevation of calcium levels, is K^+. Indeed, activation of calcium-sensitive potassium (BK) channels leads to K^+ release into the extracellular space which triggers vasodilation, through hyperpolarization of smooth muscle cells (see Petzold & Murthy, 2011) (Fig. 12.4C). Interestingly, overactivation of BK channels produces supraphysiologic elevation of external $[K^+]$ (similar to those found in pathological conditions such as ischemia or spreading depression), which shifts vasodilation to vasoconstriction, suggesting that the ambient level of extracellular K^+ dictates the vascular tone.

In summary, several products of activity-dependent neuronal and glial metabolism such as NO, lactate, adenosine, prostanoids, and K^+ exert vasoactive effects and are thought to be major (but not exclusive when taken individually) mediators of hyperemia. Importantly, these mediators appear to act in concert to dynamically regulate, both spatially and temporally, the vascular tone to adapt energy demand and supply. Nitric oxide is undoubtedly a key element in coupling, particularly in view of the fact that glutamate, the principal excitatory neurotransmitter, triggers a receptor-mediated NO formation in neurons. In conjunction to this, astrocytes have emerged as essential intermediary processors in neurovascular coupling. Nevetheless, the complex mechanisms involved in the coupling of neuronal activation and increased CBF are not yet fully elucidated and still await firm functional confirmation *in vivo*.

Through the activity-linked increase in blood flow, more substrates—namely, glucose and oxygen—necessary to meet the additional energy demands are delivered to the activated area per unit time. The cellular and molecular mechanisms involved in oxygen consumption and glucose utilization are treated in later sections.

Blood Flow and Energy Metabolism Can Be Visualized in Humans

Modern functional brain-imaging techniques enable the *in vivo* monitoring of human blood flow and the two indices of energy metabolism: glucose utilization and oxygen consumption (Fig. 12.4A and Box 12.1) (Raichle & Mintun, 2006). For instance, with the use of PET and appropriate positron-emitting isotopes such as ^{18}F and ^{15}O, basal rates, as well as activity-related changes in local blood flow or oxygen consumption, can be studied using ^{15}O-labeled water or $^{15}O_2$, respectively (Fig. 12.4A). Local rates of glucose utilization [also defined as local cerebral metabolic rates for glucose (LCMRglu)] can be determined with ^{18}F-labeled 2-deoxyglucose (2-DG) (Fig. 12.4A). The use of 2-DG as a marker of LCMRglu was pioneered by Louis Sokoloff and associates at the National Institutes of Health, first in laboratory animals. The method is based on the fact that 2-DG crosses the blood-brain barrier, is taken up by brain cells, and is phosphorylated by hexokinase with kinetics similar to that for glucose; however, unlike glucose 6-phosphate, 2-deoxyglucose 6-phosphate cannot be metabolized further and therefore accumulates intracellularly (Fig. 12.5).

For studies in laboratory animals, tracer amounts of radioactive 2-DG are injected intravenously; the animal is subjected to the behavioral paradigms of interest and sacrificed at the end of the experiment. Serial thin sections of the brain are prepared and processed for autoradiography. This autoradiographic method provides, after appropriate corrections, an accurate measurement of LCMRglu with a spatial resolution of a few millimeters. Using this method, researchers have determined LCMRglu in virtually all structurally and functionally defined brain structures in various physiological and pathological states, including sleep, seizures, and dehydration, and after a variety of pharmacological treatments. Furthermore, glucose utilization increases in the pertinent brain areas during motor tasks or activation of pathways subserving specific modalities, such as visual, auditory, olfactory, or somatosensory stimulation. For example, in mice, sustained stimulation of the whiskers results in marked increases in LCMRglu in discrete areas of the primary sensory cortex called the barrel fields, where each whisker is represented with an extreme degree of topographical specificity (see Chapter 24). Basal glucose utilization of the gray matter as determined by 2-DG autoradiography varies, depending on the brain structure, between 50 and 150 mmol per 100 g of wet weight per minute in the rat.

In humans, LCMRglu determined by PET with the use of ^{18}F-2-DG is approximately 50% lower than that in rodents, and physiological activation of specific modalities increases LCMRglu in discrete areas of the brain that can be visualized with a spatial resolution of a few millimeters.

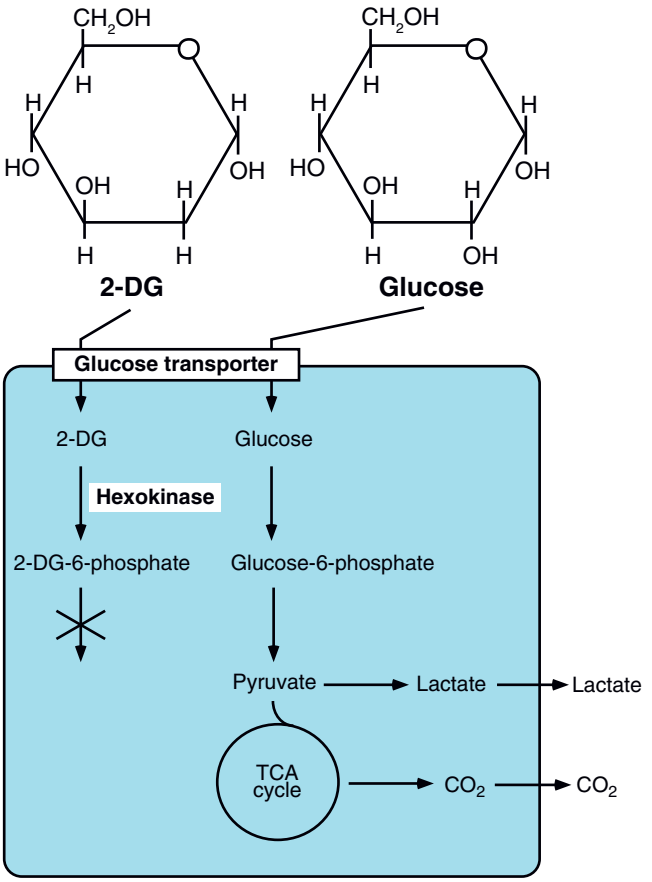


FIGURE 12.5 Structure and metabolism of glucose and 2-deoxyglucose (2-DG). 2-DG is transported into cells through glucose transporters and phosphorylated by hexokinase to 2-DG-6-phosphate without significant further processing or dephosphorylation back to glucose. Therefore, when labeled radioactively, 2-DG used in tracer concentrations is a valuable marker of glucose uptake and phosphorylation, which directly indicates glucose utilization.

For example, visual stimulations presented to subjects as checkerboard patterns reversing at frequencies ranging from 2 to 10 Hz selectively increase LCMRglu in the primary visual cortex and a few connected cortical areas. With the use of this stimulation paradigm, the combined PET analysis of local cerebral blood flow (LCBF) and local oxygen consumption ($LCMRO_2$), in addition to LCMRglu, has revealed a unique and unexpected feature of human brain energy metabolism regulation (Fig. 12.4A). The canonical view was that the three metabolic parameters were tightly coupled, implying that, if, for example, CBF increased locally during physiological activation, LCMRglu and $LCMRO_2$ would increase in parallel. In what is now referred to as the phenomenon of "uncoupling," physiological stimulation of the visual system increases LCBF and LCMRglu (both by 30 to 40%) in the primary visual cortex without a commensurate increase in $LCMRO_2$ (which increases only ≈5%) (Raichle & Mintun, 2006) (Fig. 12.4A), indicating that the additional glucose utilized during neuronal activation can be processed through glycolysis rather than through the TCA cycle and oxidative phosphorylation. The phenomenon of uncoupling has been confirmed in other cortical areas, although its magnitude may differ depending on the modality, and may actually be absent in certain cases. A glance at the metabolic pathways reveals that if glucose does not enter the TCA cycle to be oxidized, then lactate will be produced (Figs. 12.1 and 12.2).

Lactate, like several other metabolically relevant molecules, can be determined with the technique of magnetic resonance imaging (MRI) spectroscopy for ^1H, which provides a means of unequivocally identifying in living tissues the presence of molecules that bear the naturally occurring isotope ^1H. Consistent with the prediction that if during activation glucose is predominantly processed glycolytically, then lactate should be produced locally in the activated region, an activity-dependent transient increase in the lactate signal could be detected with ^1H MRI spectroscopy in different brain areas (Figley & Stroman, 2011, and references therein). Interestingly, recent evidence obtained in human visual cortex demonstrates that while ATP production positively correlates with $LCMRO_2$, task-induced CBF increase positively correlates with lactate production but negatively correlates with $LCMRO_2$ (see Figley & Stroman, 2011). This suggests that while energy demand is met through oxidative metabolism, CBF response is mediated by factors other than oxygen demand (see section above). These observations support the view that to face the local increases in energy demands linked to neuronal activation, the brain transiently resorts to an integrated sequence of glycolysis and oxidative phosphorylation (Magistretti & Pellerin, 1999). This transient uncoupling may vary in amplitude depending on the modalities of activation (Frackowiak et al., 2001) and is likely to occur in different cellular compartments—that is, astrocytes versus neurons (Figley & Stroman, 2011; Pellerin & Magistretti, 1994).

Summary

Studies at the whole organ level, based on the A-V differences of metabolic substrates, have revealed a great deal about the global energy metabolism of the brain. They have indicated that, under normal conditions, glucose is virtually the sole energy substrate for the brain and that it is entirely oxidized. New techniques that allow imaging of the three fundamental parameters of brain energy metabolism—namely, blood flow, oxygen consumption, and glucose utilization—provide a more refined level of spatial resolution and demonstrate that brain energy metabolism is regionally heterogeneous and is coupled tightly to the functional activation of specific neuronal pathways.

ENERGY-PRODUCING AND ENERGY-CONSUMING PROCESSES IN THE BRAIN

What are the cellular and molecular mechanisms that underlie the regulation of brain energy metabolism revealed by the foregoing studies at global and regional levels? In particular, what are the metabolic events taking place in the cell types that make up the brain parenchyma? How is it possible to reconcile whole organ studies indicating complete oxidation of glucose with transient activation-induced glycolysis at the regional level? These and other related questions will be addressed here and in the next sections.

Glucose Metabolism Produces Energy in the Form of ATP and Reducing Equivalents

Before we move on to an analysis of the cell-specific mechanisms of brain energy metabolism, it seems appropriate to briefly review some basic aspects of the energy balance of the brain. Because glucose, in normal circumstances, is the main energy substrate of the brain, the overview will be restricted to its metabolic pathways. Glucose metabolism in the brain is similar to that in other tissues and includes three principal metabolic pathways: (1) glycolysis occurring in the cytosol and associated with the pentose phosphate pathway and glucose storage in the form of glycogen (the latter only in astrocytes, see below), and (2) the TCA cycle and oxidative phosphorylation, which take place to the mitochondria. Because of the global similarities with other tissues, these pathways are simply summarized in Figures 12.1, 12.2, and 12.6, and only a few aspects specific to the nervous tissue will be discussed.

Glycolysis

Glycolysis (Embden-Meyerhof pathway) is the metabolism of glucose to pyruvate (Fig. 12.1). It results in the net production of only two molecules of ATP per glucose molecule; indeed, four ATPs are formed in the processing of glucose to pyruvate, whereas two ATPs are consumed to phosphorylate glucose to glucose 6-phosphate and fructose 6-phosphate to fructose 1,6-bisphosphate, respectively (Fig. 12.1). Under anaerobic conditions (meaning in the absence of oxygen), pyruvate is converted to lactate, allowing the regeneration of nicotinamide adenine dinucleotide (NAD^+), which is essential to maintain a continued glycolytic flux. Indeed, if NAD^+ were not regenerated, glycolysis could not proceed beyond glyceraldehyde 3-phosphate (Fig. 12.1). Another situation in which the end-product of glycolysis is lactate rather than pyruvate is when oxygen consumption does not match glucose utilization, implying that the rate of pyruvate production through glycolysis exceeds pyruvate oxidation by the TCA cycle (Fig. 12.2). This condition has been well described in skeletal muscle during intense exercise and in tumoral tissues, where it is referred to as the "Warburg effect". The occurrence of aerobic glycolysis in the nervous system is consistent with the transient uncoupling observed between glucose utilization and oxygen consumption that has been described in the human cerebral cortex during activation with the use of PET (Raichle & Mintun, 2006).

Tricarboxylic Acid Cycle

Under aerobic conditions, pyruvate is oxidatively decarboxylated to yield acetyl-CoA in a reaction catalyzed by the enzyme pyruvate dehydrogenase (PDH). Acetyl-coenzyme A condenses with oxaloacetate to produce citrate (Fig. 12.2). This is the first step of the TCA cycle, in which three pairs of electrons are transferred from NAD^+ to NADH—and one pair from flavin adenine dinucleotide (FAD) to its reduced form ($FADH_2$)—through four oxidation-reduction steps (Fig. 12.2). During the process of pyruvate oxidation, carbon atoms leave the TCA cycle in the form of CO_2. NADH and $FADH_2$ transfer their electrons to molecular O_2 through the mitochondrial electron transfer chain to produce 28-34 ATPs and H_2O in the process of oxidative phosphorylation. Thus, under aerobic conditions (i.e., when glucose is fully oxidized through the TCA cycle to CO_2 and H_2O), NAD^+ is regenerated enabling the TCA cycle to proceed further to generate ATP.

Pentose Phosphate Pathway

Although glycolysis, the TCA cycle, and oxidative phosphorylation are coordinated pathways that produce ATP, using glucose as a fuel, ATP is not the only form of metabolic energy. Indeed, for several biosynthetic reactions (anabolic reactions) in which the precursors are in a more oxidized state than the products, metabolic energy in the form of reducing power is needed in addition to ATP. This is the case for the reductive synthesis of free fatty acids from acetyl-CoA, which are components of myelin and of other structural elements of neural cells, such as the plasma membrane. In brain cells, as in other organs, the reducing power for anabolic reactions is provided by NADPH (the reduced form of nicotinamide adenine dinucleotide phosphate, $NADP^+$) which is mainly produced by glucose processing through the pentose phosphate pathway (PPP) (Fig. 12.6). The NADP/NADPH ratio is the single most important factor regulating the entry of glucose 6-phosphate into the PPP. Thus, when high reducing power is mobilized (see also below), NADPH levels decrease, and the pentose phosphate

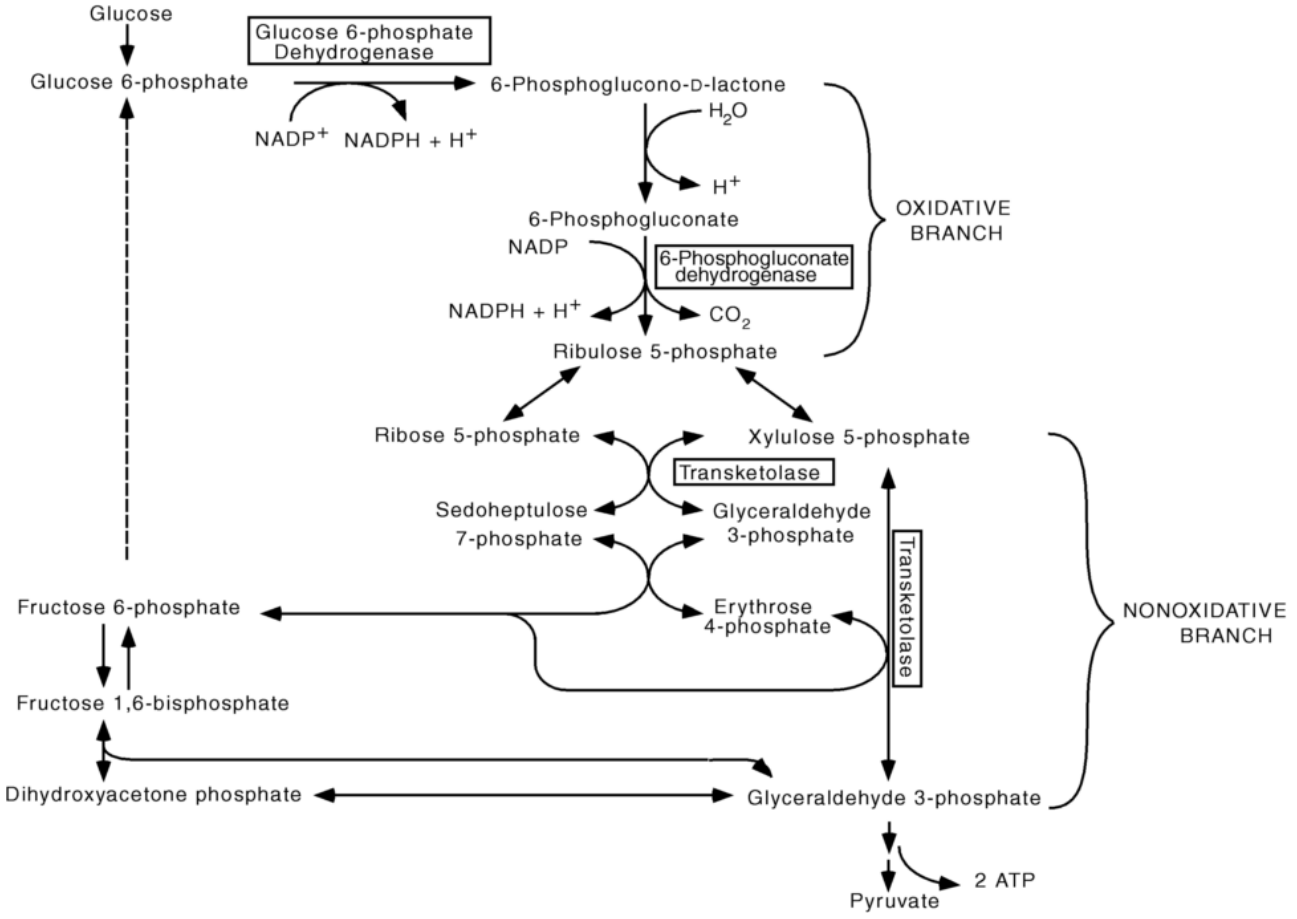

FIGURE 12.6 The pentose phosphate pathway. In the oxidative branch of the pentose phosphate pathway, two NADPH are generated per glucose 6-phosphate. The first rate-limiting reaction of the pathway is catalyzed by glucose 6-phosphate dehydrogenase; the second NADPH is generated through the oxidative decarboxylation of 6-phosphogluconate, a reaction catalyzed by 6-phosphogluconate dehydrogenase. The nonoxidative branch of the pentose phosphate pathway provides a reversible link with glycolysis by regenerating the two glycolytic intermediates glyceraldehyde 3-phosphate and fructose 6-phosphate. This regeneration is achieved through three sequential reactions. In the first, catalyzed by transketolase, xylulose 5-phosphate, and ribose 5-phosphate (which originate from ribulose 5-phosphate, the end product of the oxidative branch) yield glyceraldehyde 3-phosphate and sedoheptulose 7-phosphate. Under the action of transaldolase, these two intermediates yield fructose 6-phosphate and erythrose 4-phosphate. This latter intermediate combines with xylulose 5-phosphate, in a reaction catalyzed by transketolase, to yield fructose 6-phosphate and glyceraldehyde 3-phosphate. Thus, through the nonoxidative branch of the pentose phosphate pathway, two hexoses (fructose 6-phosphate) and one triose (glyceraldehyde 3-phosphate) of the glycolytic pathway are regenerated from three pentoses (ribulose 5-phosphate).

pathway is activated to generate new reducing equivalents. The pentose phosphate pathway is also tightly connected to glycolysis through two enzymes—transketolase and transaldolase—which recycle PPP metabolites to fructose 6-phosphate and glyceraldehyde 3-phosphate, two intermediates of glycolysis (Fig. 12.6).

Glucose Metabolism, Reactive Oxygen Species, and the Protective Role of Glutathione

In addition to anabolic reactions, NADPH is needed for the scavenging of reactive oxygen species (ROS). The superoxide radical anion (O_2^{-}.), hydrogen peroxide (H_2O_2), and the hydroxy radical (HO.) are three ROS, generated by the transfer of single electrons to molecular oxygen as by-products of several physiological cellular processes. A considerable contribution to the generation of ROS is the oxidative metabolism of glucose taking place in the mitochondrial electron transfer chain associated with oxidative phosphorylation. Other ROS-generating reactions include the activities of monoamine oxidase, tyrosine hydroxylase, nitric oxide synthase, and the eicosanoid-forming enzymes lipoxygenases and cyclooxygenases. Reactive oxygen species are highly damaging to cells because they can cause DNA disruption and mutations, as well as activation of enzymatic cascades, including proteases and lipases that can eventually lead to cell death.

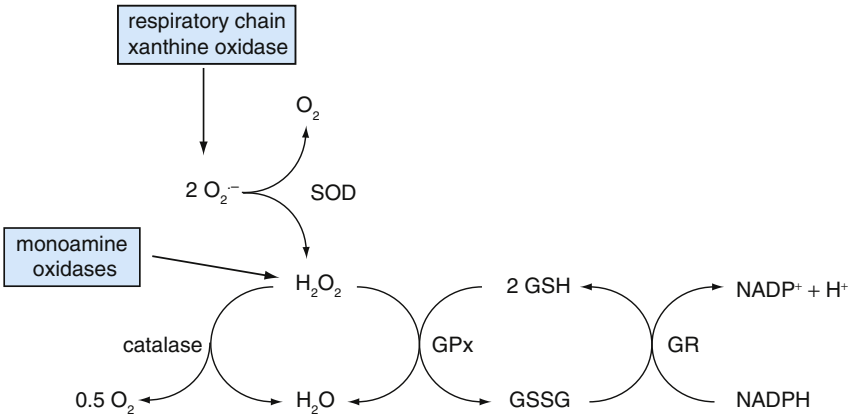

FIGURE 12.7 Enzymatic reactions for scavenging reactive oxygen species (ROS). The toxic superoxide anion ($O_2^{\cdot-}$) formed by a variety of physiological reactions, including oxidative phosphorylation (i.e., respiratory chain), is scavenged by superoxide dismutase (SOD), which converts the superoxide anion to hydrogen peroxide (H_2O_2) and molecular oxygen. Glutathione peroxidase (GPx) converts the still toxic hydrogen peroxide to water; reduced glutathione (GSH) is required for this reaction, in which it is converted to its oxidized form (GSSG). GSH is regenerated through the action of glutathione reductase (GR), a reaction requiring NADPH.

The coordinated activity of two molecules is essential in protecting cells against ROS-mediated damage, or oxidative stress: NADPH and glutathione. As we have seen, NADPH is produced through a particular arm of glucose metabolism, the PPP. Interestingly, therefore, glucose metabolism provides two forms of energy: high energy phosphates such as ATP and reducing power such as NAD(P)H, the latter contributing to the neutralization of ROS, the harmful by-products of the process (oxidative phosphorylation) that produces the former. It is, however, through its combined action with glutathione that NADPH contributes to ROS scavenging. Scavenging of ROS is ensured by the sequential action of superoxide dismutase (SOD) and glutathione peroxidase (Fig. 12.7). Thus, two superoxide anions formed by the aforementioned cellular processes are converted by SOD into H_2O_2, still a ROS. Glutathione peroxidase converts H_2O_2 into H_2O and O_2 at the expense of reduced glutathione (GSH), which is regenerated by glutathione reductase in the presence of NADPH (Fig. 12.7).

Glutathione is a tripeptide (GSH; γ-L-glutamyl-L-cysteinylglycine) synthesized through the concerted action of two enzymes: γGluCys synthase, which combines glutamate and cysteine to yield the dipeptide γGluCys, and glutathione synthase, which adds a glycine to the dipeptide to yield GSH (Fig. 12.8). The glutathione content and reducing potential are considerably higher in astrocytes compared to neurons; this fact, combined with the much higher oxidative activity of neurons versus astrocytes, makes neurons more vulnerable to oxidative stress as well as highly dependent on astrocytes for their protection. Indeed, among the numerous metabolic cooperations that exist between astrocytes and neurons (which will be developed in more detail in the next section), an important one with regard to oxidative stress defense mechanisms involves glutathione metabolism through the shuttling of GSH from astrocytes to neurons. Astrocytes release large amounts of GSH into the extracellular space; GSH is cleaved by the sequential action of ectoenzymes to Cys and Gly (Fig. 12.8). Cys and Gly are transported into neurons (note that neurons cannot take up GSH), providing two precursors for GSH synthesis. Glutamate, the third precursor of GSH, is also provided by astrocytes to neurons under the form of glutamine, from which glutamate is produced through the action of glutaminase, through the so-called glutamate-glutamine shuttle which will be described in the next section (Figs. 12.8 and 12.10).

Processes Linked to Neuronal Function Consume Energy

The main energy-consuming process of the brain is the maintenance of ionic gradients across the plasma membrane, a condition that is crucial for excitability. Indeed, neuronal signaling is based on the rapid flow of charges—carried by ions such as sodium, potassium, and calcium—across the membranes of the axon, dendrites, and soma. This is not expected to cost much *per se*, as the flow of ions follows favorable electrochemical gradients; however, reestablishing these constantly dissipated gradients, through the activity of ATP-consuming pumps such as the Na^+/K^+-ATPase, does indeed cost energy. As extensively reviewed in Chapters 5 and 10, two principal processes operate the signaling between neurons: the action potentials (AP) mainly carrying signals along the axon from the soma to the synapse (some APs, defined as backpropagating, are also generated in dendrites) and postsynaptic potentials (PSP), generated by synaptically released neurotransmitters acting at

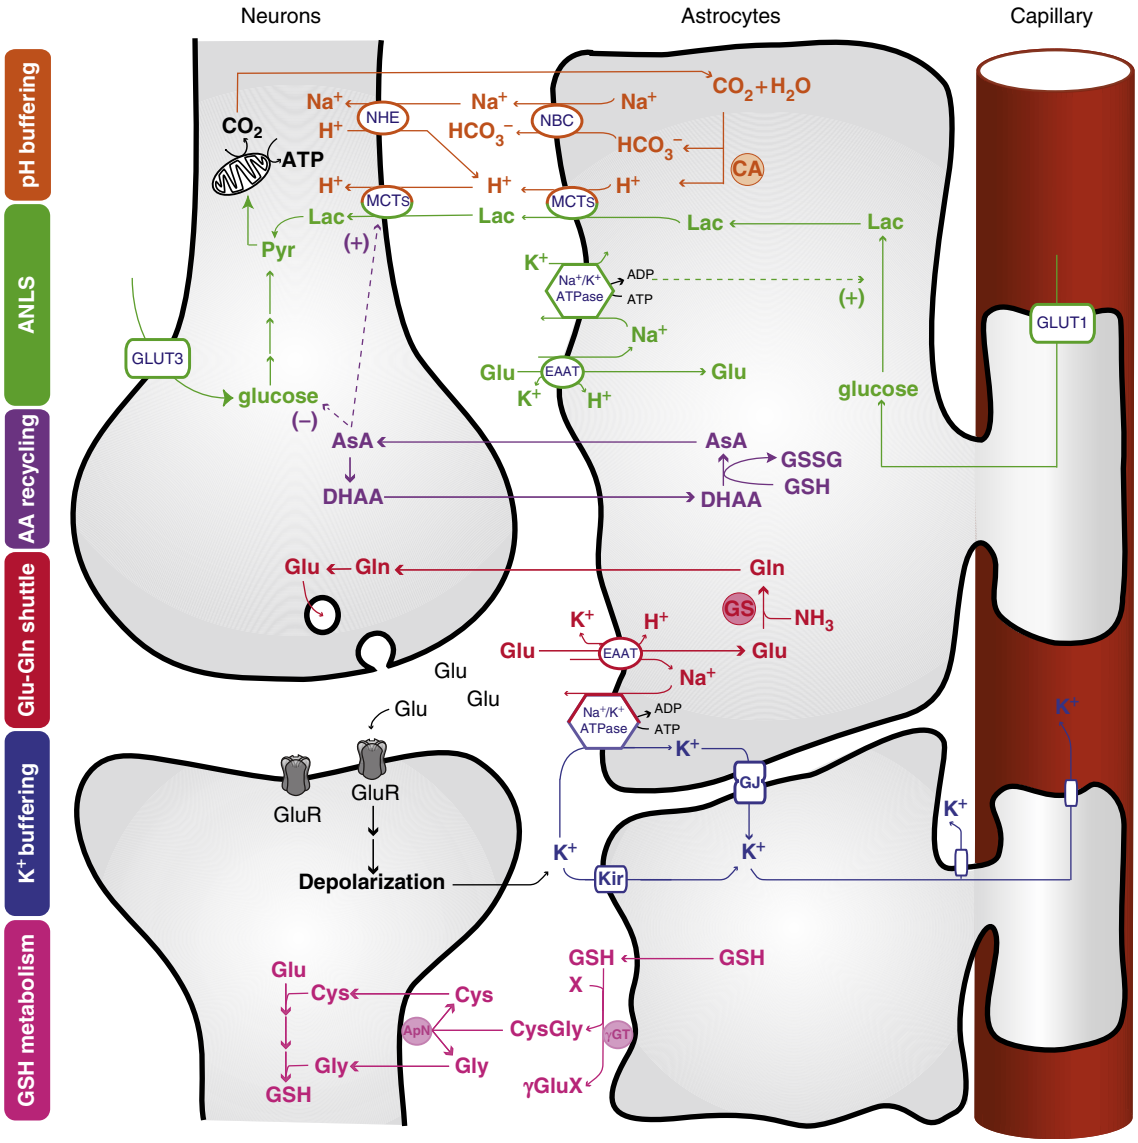

FIGURE 12.8 Central role of astrocytes in brain homeostasis. *Orange: pH buffering*. Abundant carbonic anhydrase (CA) in astrocytes converts CO_2 to H^+ and HCO_3^-. Two HCO_3^- are transported into the extracellular space along with one Na^+ via the Na^+-HCO_3^- cotransporter (NBC), thereby increasing the extracellular buffering power. Protons left in the glial compartment may drive the transport of lactate (Lac) outside of astrocytes and into neurons through monocarboxylate transporters (MCTs). Excess H^+ in neurons is extruded via sodium-hydrogen exchange (NHE). *Green: Astrocyte-neuron lactate shuttle (ANLS)*. Glutamate (Glu) uptake by astrocytes is accompanied by Na^+ entry, which is extruded by the action of the Na^+/K^+ ATPase. This triggers anaerobic glucose utilization in astrocytes and glucose uptake from the circulation through the glucose transporter GLUT1. The lactate produced is shuttled to neurons through MCTs, where it can be used as an energy substrate after its conversion to pyruvate (Pyr). Neurons can also take up glucose via the neuronal glucose transporter 3 (GLUT3). *Purple: Ascorbic acid recycling*. Astrocytes recycle oxidized ascorbic acid (dehydroascorbic acid; DHAA) back to ascorbic acid (AsA) using reduced glutathione (GSH) and forming oxidized glutathione (GSSG). AsA can be used directly in astrocytes or released and taken up by neurons for reactive oxygen species (ROS) scavenging. AsA may also act as a metabolic switch by inhibiting glucose consumption and stimulating lactate uptake in neurons. *Red: Glutamate-glutamine cycle.* Glutamate released into the synaptic cleft activates ionotropic glutamatergic receptor (GluR), producing a postsynaptic depolarization. Astrocytic excitatory amino acid transporters (EAATs) are responsible for the uptake of a large fraction of glutamate at the synapse. Glutamate is converted into glutamine (Gln) by glutamine synthase (GS) and shuttled back to neurons for glutamate resynthesis. *Blue: K^+ buffering*. Astrocytes buffer excess K^+ released into the extracellular space as a result of neuronal activity (for example, through inwardly rectifying K^+ channels, Kir). K^+ diffuses through the astrocytic network via gap junctions (GJ) down its concentration gradient and is released in sites of lower concentration. *Pink: Glutathione metabolism.* Astrocytes release glutathione (GSH) in the extracellular space, where it is cleaved by the astrocytic ectoenzyme γ-glutamyl transpeptidase (γGT). The resulting dipeptide CysGly is cleaved by the neuronal ectopeptidase aminopeptidase N (ApN), forming Cysteine (Cys) and Glycine (Gly), which serve as precursors for neuronal GSH synthesis. X represents an acceptor for the γ-glutamyl moiety (γGlu) in the reaction catalyzed by γGT. A detailed description of these neuron-astrocyte metabolic cooperations can be found elsewhere (see, for example, Bélanger & Magistretti, 2009, and references therein). *Reproduced with permission from Allaman et al. (2011).*

specific receptors present on dendrites and soma. Which of the AP and the PSP is more energetically costly? This question has been at the center of a long-standing debate in neuroscience. Early estimates in 1980s suggested that the energetic cost of signaling in the brain was dominated by PSPs. More recently, bottom-up energy budgets, in which the costs of each step of signaling were estimated, have proposed that APs and PSPs equally contribute to the energy consumption associated with neuronal activity in rodents (Attwell & Iadecola, 2002).

This is not just a question that excites neurophysiology *aficionados*: it has direct relevance for the interpretation of functional brain imaging signals because of the tight coupling between neuronal signaling and energy utilization. Experiments in which neuronal activity has been recorded while acquiring imaging data suggest that local field potentials, which reflect PSPs, best correlate with the imaging signal. In a series of elegant studies carried out in the rat hippocampus, Alle and colleagues have shown that the relative kinetic properties of sodium and potassium channels present on axons optimize the energy utilization necessary for APs generation. As described in Chapter 5, APs are produced by the sequential opening of voltage-sensitive sodium channels, resulting in a depolarization by allowing positive charges to flow from the extracellular space across the neuronal membrane; this is followed by the delayed opening of potassium channels (hence their name "delayed rectifiers") that elicits the exit of positive charges and contributes to the repolarization of the membrane. If the temporal overlap between the entry of sodium and the outflow of potassium is high, the system will be relatively inefficient, because a larger number of positive charges—that is, sodium ions—will have to enter the cell in order to achieve a given depolarization. This is because, in terms of positive charges, the exit of potassium will partially counterbalance the entry of sodium. On the contrary, a low temporal overlap will optimize conditions to achieve depolarization. Calculations based on the biophysical properties of neuronal membranes predict a minimum positive charge transfer (carried by sodium) per propagating action potential of 121 nanoCoulombs/cm^2.

In their classical modeling of the AP in the squid giant axon, Hodgkin and Huxley estimated that this minimum was to be 4 times higher in order to charge the membrane capacitance and elicit depolarization. In axons of the rat hippocampus, the sodium channel rapid activation and fast decay relative to the delayed onset of potassium currents result in optimal charge separation (i.e., minimal overlap of the inward and outward currents). Under these circumstances, charging the membrane capacitance requires 153 nanoCoulombs/cm^2, representing only 1.3 times the theoretical minimum. In previous energy budget estimates, a factor of 4 was used to approximate the sodium charge transfer per propagating AP (see Attwell & Iadecola, 2002), resulting in an overestimation of the actual number of picomoles of sodium ions flowing across the axonal membrane per surface unit per action potential. Since reestablishing intracellular sodium homeostasis is operated by the energy-consuming sodium-potassium ATPase, an overestimation of sodium transfer will result in an overestimation of the energy cost of APs by a factor of approximately 3 (4:1.3).

Comparison of the charge transfer due to excitatory PSPs mediated by the glutamate receptor activation indicates that the charge transfer involved in AP is about 6 times lower than that underlying PSPs—15 versus 96 picoCoulombs, respectively—with marginal contributions by backpropagating APs (3 pC) and depolarization of presynaptic terminals (1 pC). Translated into energy costs, these measurements indicate that PSPs dominate the energy requirements for neuronal signaling. Since glutamate synapses represent at least 80% of cortical synapses, these data support previous experimental results *in vivo* and *in vitro*, suggesting that glutamatergic neurotransmission is the major determinant of energy utilization by the brain (Hyder et al., 2006). As will be discussed in subsequent sections, coupling of glutamatergic transmission to local energy (glucose) delivery is mediated by glutamate signaling on astrocytes via glutamate transporters. This astrocyte-based coupling mechanism and the associated process of glutamate recycling represent only approximately 15% of the overall energy cost of glutamatergic neurotransmission (Hyder et al., 2006).

In addition to the maintenance of ionic gradients that are disrupted during activity, other energy-consuming processes exist in neurons. Thus, the permanent synthesis of molecules needed for communications, such as neurotransmitters, or for general cellular purposes consumes energy. Axonal transport of molecules synthesized in the nucleus to their final destination along the axon or at the axon terminal is yet another process fueled by cellular energy metabolism.

Summary

Exactly as in other tissues, the metabolism of glucose, the main energy substrate of the brain, produces two forms of energy: ATP and NADPH. Glycolysis and the TCA cycle produce ATP, whereas energy in the form of reducing equivalents stored in the NADPH molecule is produced predominantly through the pentose phosphate pathway. Reduced glutathione provides a major defense against oxidative stress. It is mainly synthetized in astrocytes, implying that neurons rely on astrocytes to provide them with GSH (through the shuttling of GSH) for protection against oxidative stress insults. Maintenance of the electrochemical gradients, particularly for Na^+ and K^+,

mainly dissipated by glutamate-mediated postsynaptic potentials is the principal energy-consuming process of neural cells.

GLUTAMATE METABOLISM: A COORDINATED SHUTTLE BETWEEN ASTROCYTES AND NEURONS

Astrocytes are known to play a major role in numerous functions of the central nervous system, including glutamate, ion and water homeostasis, defense against oxidative stress, energy storage in the form of glycogen, scar formation and tissue repair, modulation of synaptic activity via the release of gliotransmitters, and synapse formation and remodeling. Importantly, essential astrocytic functions involve strong metabolic cooperations with neighboring neurons. Such a metabolic interaction has been reviewed earlier in this chapter for GSH metabolism but is also operative for K^+ and pH buffering, ascorbic acid recycling, energy substrate delivery, and glutamate metabolism in the so-called glutamate-glutamine shuttle (Allaman et al., 2011; Bélanger & Magistretti, 2009) (Fig. 12. 8). The latter represents a key function of astrocytes, which play a critical role in the regulation of glutamate neurotransmission.

Indeed, synaptically released glutamate is removed rapidly from the extracellular space by a transporter-mediated reuptake system that is particularly efficient in astrocytes. This mechanism contributes in a crucial manner to the fidelity of glutamate-mediated neurotransmission. Indeed, glutamate levels in the extracellular space are low (<3 μM), allowing for optimal glutamate-mediated signaling after depolarization while preventing overactivation of glutamate receptors, which could eventually result in excitotoxic neuronal damage.

Five glutamate transporter subtypes have been cloned in various species, including humans. The excitatory amino acid transporter 1 (EAAT 1) and EAAT 2 subtypes (respectively GLAST and GLT-1 in rodents) are localized exclusively in astrocytes, whereas the EAAT 3 and 4 are predominantly localized in neurons, with a widespread distribution for EAAT 3 and a localized distribution to Purkinje neurons for EAAT 4. EAAT 5 is localized in rod photoreceptors and in bipolar cells of the retina. The density of EAAT 1 and 2 is particularly high on astrocytes that surround axon terminals and dendritic spines, consistent with the prominent role of these transporters in the reuptake of synaptically released glutamate. The driving force for glutamate uptake through the specific transporters is the transmembrane Na^+ gradient; indeed, glutamate is cotransported with Na^+ with a stoichiometry of one glutamate for three Na^+ ions. The selective loss of EAAT 2, the astrocyte-selective glutamate transporter, has been demonstrated in the motor cortex and spinal cord of patients who died of Amyotrophic Lateral Sclerosis, a neurodegenerative disease affecting motor neurons.

One may wonder how astrocytes dispose of the glutamate that they take up, because, unlike carbohydrates or lipids, amino acids cannot be stored. The predominant pathway in peripheral tissues for disposing of amino acids is the transfer of their α amino group to a corresponding α-keto acid; this reaction is catalyzed by aminotransferases (Fig. 12.9). In astrocytes, the α amino group of glutamate can be transferred to oxaloacetate to yield α-ketoglutarate (α-KG) and aspartate in a reaction catalyzed by aspartate amino transferase (AAT). The α-KG generated is an intermediate of the TCA cycle and is therefore oxidized further. Another transamination reaction catalyzed by alanine amino transferase (ALAT) transfers the α amino group of glutamate to pyruvate, resulting in the formation of alanine and α-KG.

Two other pathways exist in astrocytes to metabolize glutamate. First, glutamate can be converted directly into α-KG through an NAD-requiring oxidative deamination catalyzed by glutamate dehydrogenase (GDH) (Fig. 12.9). Glutamate, by entering the TCA cycle indirectly (through AAT or ALAT) or directly (through GDH), is an energy substrate for astrocytes. Second, the quantitatively predominant metabolic pathway of glutamate in astrocytes is its amination to glutamine, an ATP-requiring reaction in which an ammonium ion is fixed on glutamate (Figs. 12.9 and 12.10). This reaction is catalyzed by glutamine synthase (GS), an enzyme almost exclusively localized in astrocytes, and provides an efficient means of disposing not only of glutamate but also of ammonium (see Box 12.2). Glutamine is released by astrocytes and is taken up by neurons, where it is hydrolyzed back to glutamate by the phosphate-dependent

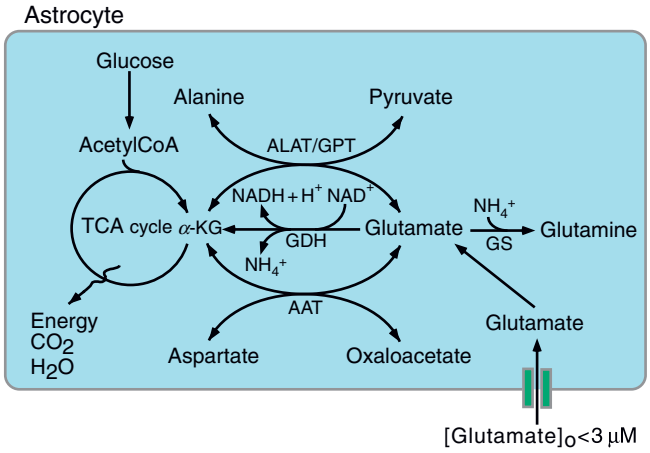

FIGURE 12.9 Metabolic fate of glutamate taken up by astrocytes. ALAT, alanine aminotransferase; GDH, glutamate dehydrogenase; GS, glutamine synthase; AAT, aspartate aminotransferase; GPT, glutamate dehydrogenase; α-KG, α-ketoglutarate.

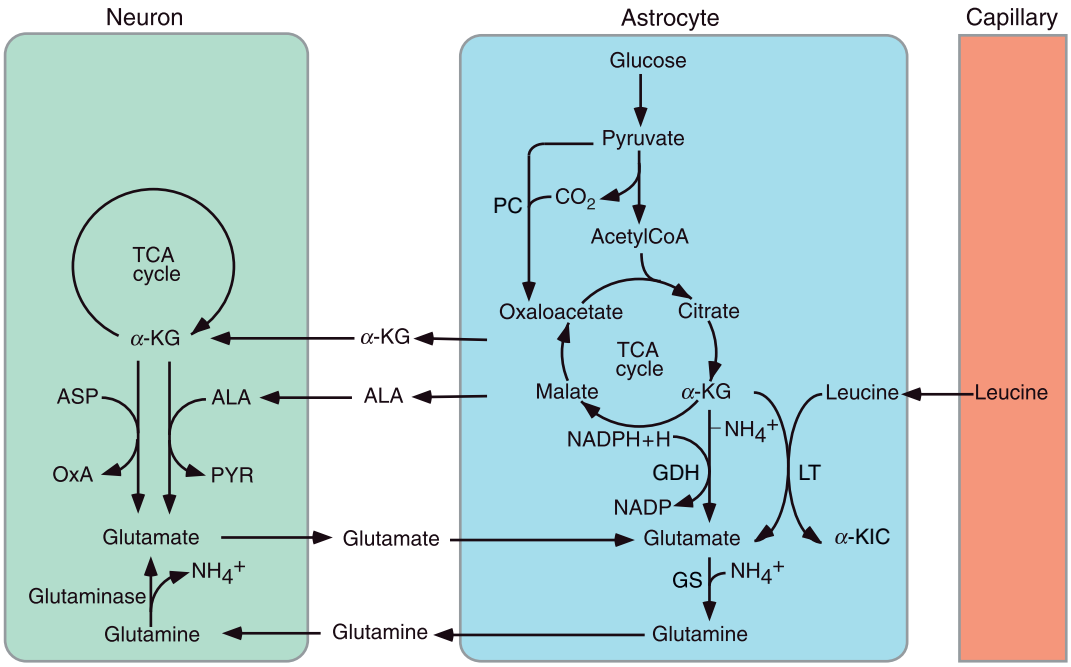

FIGURE 12.10 Metabolic intermediates are released by astrocytes to regenerate the glutamate neurotransmitter pool in neurons. Glutamine, formed from glutamate in a reaction catalyzed by glutamine synthase (GS), is released by astrocytes and taken up by neurons, which convert it into glutamate under the action of glutaminase. GS is an enzyme selectively localized in astrocytes. This metabolic cycle is referred to as the glutamate-glutamine shuttle. Other quantitatively less important sources of neuronal glutamate are alanine (ALA) and α-ketoglutarate (α-KG). In astrocytes, glutamate is synthesized *de novo* from α-KG through two different reactions catalyzed i) by glutamate dehydrogenase (GDH) and ii) by leucine transaminase (LT) producing glutamate and α-ketoisocaproate (α-KIC), in a transamination reaction in which leucine provides the amino group. Carbons "lost" from the TCA cycle as α-KG is converted to glutamate are replenished by oxaloacetate (OxA) formed from pyruvate (PYR) in a reaction catalyzed by pyruvate carboxylase (PC), another astrocyte-specific enzyme (anaplerotic cycle). ASP, aspartate.

BOX 12.2

HEPATIC ENCEPHALOPATHY

Hepatic encephalopathy is observed in patients with severe liver failure. The disease can be in one of two forms: an acute form, called fulminant hepatic failure, and a chronic form, called portosystemic encephalopathy. The neuropsychiatric symptoms of fulminant hepatic failure are delirium, coma, and seizures associated with acute toxic or viral hepatic failure. Patients having portosystemic encephalopathy may present personality changes, episodic confusion, or stupor and, in the most severe cases, coma. The current view on the pathophysiology of hepatic encephalopathy is that, due to liver failure, "toxic" substances that affect brain function accumulate in the circulation.

One of the substances thought to be responsible for neuropsychiatric "toxicity" is ammonia. The neuropathological findings are rather striking: astrocytes are the brain cells that appear to be principally affected. In the acute form, astrocyte swelling is prominent and likely to be the cause of the observed acute brain edema. In portosystemic encephalopathy, astrocytes adopt characteristic morphological features: in these cells, the nucleus is pale and enlarged, chromatin is marginated, and a prominent nucleolus is often observed. Lipofuscin deposits may be present, and the amount of the astrocyte-specific protein glial fibrillary acidic protein is decreased. Neurons appear structurally normal. All the foregoing histopathological changes have been reproduced *in vitro* by acutely or chronically applying ammonium chloride to primary astrocyte cultures. As mentioned earlier, detoxification of ammonium is an ATP-requiring, astrocyte-specific reaction catalyzed by glutamine synthase (see Figs. 12.9 and 12.10). It is therefore not surprising that excess ammonia perturbs energy metabolism; indeed, ammonia stimulates glycolysis, whereas it inhibits TCA cycle activity and decreases the glycogen content of astrocytes markedly. In addition, astrocytic accumulation of the osmotically active

BOX 12.2 *(cont'd)*

glutamine as a result of ammonia detoxification is thought to contribute at least partially to the swelling of astrocytes in hyperamonemic conditions.

In summary, while the precise pathophysiological mechanisms of the neuropsychiatric syndrome in hepatic encephalopathy are still unknown, this clinical condition provides a striking illustration of the fundamental importance of neuron–astrocyte metabolic interactions because structural and functional alterations apparently restricted to astrocytes result in severe behavioral perturbations.

enzyme glutaminase. This metabolic pathway is often referred to as the glutamate-glutamine shuttle (Figs. 12.8 and 12.10). It allows the removal of potentially toxic excess glutamate from the extracellular space, while returning to the neuron a synaptically inert (glutamine does not affect neurotransmission) precursor with which to regenerate the neuronal pool of glutamate.

However, not all glutamate is regenerated through the glutamate-glutamine shuttle because some of the glutamate released by neurons enters at the α-KG level, the TCA cycle in astrocytes; therefore, *de novo* synthesis is required to maintain the neuronal glutamate pool. Different pathways exist to synthesize glutamate both in astrocytes and neurons. In astrocytes, glutamate can be synthesized through amination of α-KG by two different pathways: GDH and leucine transaminase (LT) using leucine as a nitrogen donor (Fig. 12.10). Since these reactions take place in astrocytes, to replenish the neuronal pool, the astrocytes export glutamate as glutamine. Alternatively, neurons can take up α-KG and alanine from the extracellular space and convert them to glutamate and pyruvate in a transamination reaction catalyzed by ALAT (Fig. 12.10). In this case, as for the glutamate-glutamine shuttle, astrocytes provide the substrate(s) necessary for glutamate synthesis in neurons, since they are known to release significant amount of alanine an α-KG.

Note that because α-KG is used for glutamate synthesis, metabolic intermediates downstream of α-KG must be available to maintain a sustained flux through the TCA cycle in astrocytes (Fig. 12.10). This need is met by the activity of the enzyme pyruvate carboxylase (PC), which fixes CO_2 on pyruvate to generate oxaloacetate, which, by condensing with acetyl-CoA, maintains the flux through the TCA cycle. The carboxylation of pyruvate to oxaloacetate is referred to as an *anaplerotic* (Greek for "fill up") reaction. Interestingly, like glutamine synthase, PC is selectively localized in astrocytes. The fact that these two enzymes are localized in astrocytes in conjunction with the existence of a glutamate-glutamine shuttle stresses the essential role of astrocytes for maintaining the neuronal glutamate pool used for neurotransmission (Fig. 12.10).

Summary

A key function of astrocytes is to remove synaptically released glutamate. A large proportion of glutamate is transformed to glutamine through an energy-requiring process that also allows for the detoxification of ammonium. Glutamine released by astrocytes regenerates the neuronal glutamate pool. Some of the glutamate is also regenerated from astrocytic-derived metabolites either in astrocytes or neurons providing another indication of the crucial function that astrocytes play in maintaining the neuronal glutamate pool at levels that ensure the maintenance of synaptic transmission.

BRAIN ENERGY METABOLISM AT THE CELLULAR LEVEL

Glia and Vascular Endothelial Cells, in Addition to Neurons, Contribute to Brain Energy Metabolism

Neurons exist in a variety of sizes and shapes and express a large spectrum of firing properties (see Chapter 3). These differences are likely to imply specific energy demands; for example, large pyramidal cells in the primary motor cortex, which must maintain energy-consuming processes such as ion pumping over a large membrane surface or axonal transport along several centimeters, are likely to have considerably larger energy requirements than local interneurons. However, it is now clear that other cell types of the nervous system—glia and vascular endothelial cells—not only consume energy but also play a crucial role in the flux of energy substrates to neurons. Arguments for such an active role for nonneuronal cells—in particular, glia—are both quantitative and qualitative. Glial cells make up approximately half of the brain volume. A conservative figure is a 1:1 ratio between the number of astrocytes, one of the predominant glial cell types (see Chapters 1 and 3), and neurons. Higher ratios have been described, depending on the regions, developmental ages, or species. Indeed, the astrocyte-to-neuron ratio increases with the size of the brain and is thus high in humans. It is therefore

clear that glucose reaching the brain parenchyma provides energy substrates to a variety of cell types, only some of which are neurons.

Even more compelling for the realization of the key role that astrocytes play in providing energy substrates to active neurons are the cytological relations that exist among brain capillaries, astrocytes, and neurons. These relations, which are illustrated in Figure 12.11, are as follows. First, through specialized processes, called end feet, astrocytes surround brain capillaries. This implies that astrocytes contribute to the first cellular barrier that glucose entering the brain parenchyma encounters and make them a likely site of prevalent glucose uptake and energy substrate distribution. More than a century ago, the Italian histologist Camillo Golgi and his pupil Luigi Sala sketched such a principle. In addition to perivascular end feet, astrocytes bear processes that ensheathe synaptic contacts and express receptors and uptake sites with which neurotransmitters released during synaptic activity can interact (in particular glutamate, see previous sections) (Chapters 6 and 7). These features endow astrocytes with an exquisite sensitivity to detect increases in synaptic activity. In addition to this, and as previously described, astrocytes establish with neurons numerous metabolic cooperations that play a central role in brain homeostasis (Fig. 12.8). In summary, because of the foregoing structural and functional characteristics, astrocytes are ideally suited to couple local changes in neuronal activity with coordinated adaptations in energy metabolism (Fig. 12.11).

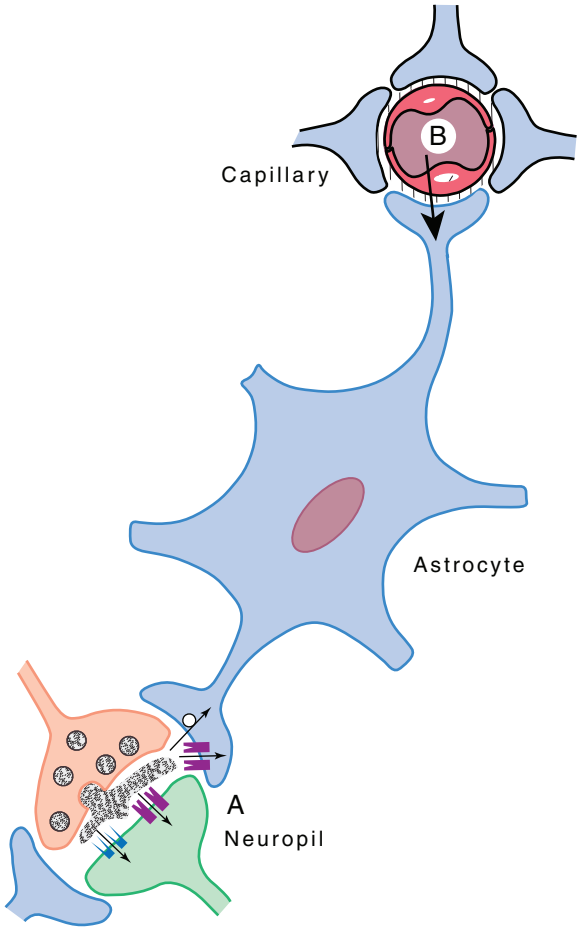

FIGURE 12.11 Schematic representation of cytological relations existing among intraparenchymal capillaries, astrocytes, and the neuropil. Astrocyte processes surround capillaries (end feet) and ensheathe synapses. In addition, receptors and uptake sites for neurotransmitters are present on astrocytes. These features make astrocytes ideally suited to sense synaptic activity (A) and to couple it with uptake and metabolism of energy substrates originating from the circulation (B).

A Tightly Regulated Glucose Metabolism Occurs in All Cell Types of the Brain, Neuronal and Nonneuronal

Given the high degree of cellular heterogeneity of the brain, understanding the relative role played by each cell type in the flux of energy substrates has largely depended on the availability of purified preparations, such as primary cultures enriched in neurons, astrocytes, or vascular endothelial cells. Such preparations have some drawbacks because they may not necessarily express all the properties of the cells *in situ.* In addition, one of the parameters of energy metabolism *in vivo*—namely, blood flow—cannot be examined in cultures. Despite these limitations, *in vitro* studies in primary cultures have proved very useful in identifying the cellular sites of glucose uptake and its subsequent metabolic fate—particularly, glycolysis and oxidative phosphorylation—thus providing illuminating correlations of two parameters of brain energy metabolism that are monitored *in vivo*: glucose utilization and oxygen consumption.

Glucose Transporters in the Brain

Glucose is a highly hydrophilic molecule that enters cells through a facilitated transport mediated by specific transporters. Twelve genes, encoding glucose transporter proteins, have been identified and cloned so far; these are designated GLUT1 to GLUT12. Glucose transporters belong to a family of rather homologous glycosylated membrane proteins with 12 transmembrane-spanning domains, and both amino and carboxyl terminals are exposed to the cytoplasmic surface of the membrane. In the brain, seven transporters are expressed predominantly in a cell-specific manner: GLUT1 (two isoforms), GLUT2-5, and GLUT8 (Fig. 12.12).

GLUT 1 and 3 represent the two major cerebral GLUTs. Two isoforms of GLUT1 with molecular masses of 55 and 45 kDa, respectively, are detected in the brain, depending on their degree of glycosylation. The 55-kDa form of

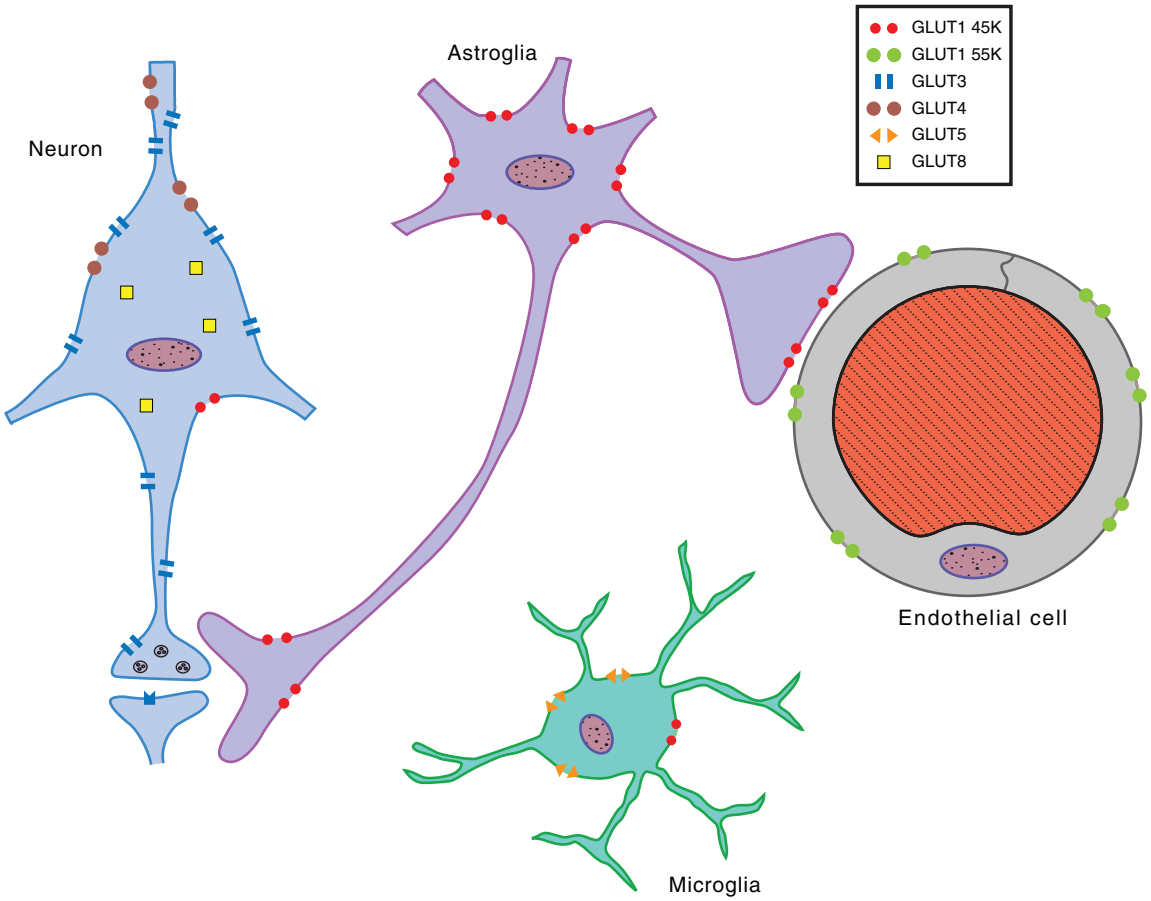

FIGURE 12.12 Cellular distribution of the principal glucose transporters in the nervous system. The 55-kDa form of GLUT1 is localized in brain microvessels, choroid plexus, and ependymal cells, whereas the 45-KDa form is localized predominantly in astrocytes. GLUT3 is specifically expressed in neurons. GLUT 4 and 8 are expressed in a subset of neurons, where their expression appears to predominate on the cell body and proximal dendrites. GLUT5 (which presents a higher affinity for fructose than glucose) is localized selectively to microglial cells. Another glucose transporter, GLUT2, has been localized selectively in astrocytes of discrete brain areas, such as certain hypothalamic and brainstem nuclei, which participate in the regulation of feeding behavior and in the central control of insulin release (not shown).

GLUT1 is essentially localized in brain microvessels, choroid plexus, and ependymal cells. In the brain *in situ*, the 45-kDa form of GLUT1 is localized predominantly in astrocytes. Under culture conditions, all neural cells, including neurons and other glial cells, can express GLUT1; however, this phenomenon appears to be due to the capacity of GLUT1 to be induced by cellular stress. As opposed to GLUT1, the glucose transporter specific for neurons is GLUT3; it is widely expressed across the different neuronal types. Its cellular distribution appears to predominate in the neuropil.

It is clear that glucose uptake into the brain parenchyma is a highly specified process regulated in a cell-specific manner by glucose transporter subtypes. Figure 12.12 summarizes this process: Glucose enters the brain through 55-kDa GLUT1 transporters localized on endothelial cells of the blood-brain barrier, thus representing the first barrier for the transport of circulating glucose into the brain parenchyma. Uptake into astrocytes is mediated by 45-kDa GLUT1 transporters, whereas GLUT3 transporters mediate this process in neurons.

Cell-Specific Glucose Uptake and Metabolism

With respect to their different physiological roles, astrocytes and neurons express different metabolic phenotypes (Fig. 12.8). As previously reviewed, specific functions of astrocytes, in particular with regard to astrocyte-neuron metabolic interactions, rely on the selective expression of key proteins (e.g., PC, EAAT1 and 2 or GS). Such differences in metabolic profiles also operate for glucose metabolism. Indeed, cell type–specific expression patterns of key genes regulating energy metabolism have been shown (see, for example, Bélanger et al., 2011, and references therein) for glucose (see above) and MCTs, for genes involved in the regulation of the transfer of NADH into the mitochondria (i.e., malate-aspartate shuttle and glycerol phosphate shuttle), and for metabolic fluxes of

glucose, including mitochondrial activity, of glycogen synthesis or glycolysis. For example, glucose storage in the form of glycogen is exclusively found in astrocytes (see below), in part because the glycogen synthesis machinery is kept inactive in neurons through proteasomal-dependent mechanisms (see Bélanger et al., 2011). Adaptation of energy metabolism to increased energy demand also presents differences between the two cell types. For instance, in a series of elegant studies Moncada, Bolanos, and their collaborators observed that, in contrast to astrocytes, neurons are unable to prevent nitrosative stress damages through upregulation of glycolysis due to the virtual absence of a key regulator of glycolysis in this cell type. Further stressing the specificity in their metabolic profile, manipulations that drive neurons to increase glucose utilization or to synthetize glycogen affect their survival (see Bélanger et al., 2011). In summary, neurons and astrocytes preferentially use different (but complementary) metabolic pathways with regard to glucose metabolism under physiological conditions.

As we have seen, glucose utilization can be assessed with radioactively labeled 2-DG. To determine the cellular site of basal and activity-related glucose utilization, this technique has been applied to homogeneous cultures of astrocytes or neurons. For quantitative purposes and to allow comparisons with *in vivo* studies, these *in vitro* experiments, in which radioactive 2-DG is used as a tracer, must be conducted in a medium containing a concentration of glucose near that measured *in vivo* in the extracellular space of the brain (0.5 to 2 mM). The basal rate of glucose utilization is higher in astrocytes than in neurons, with values of about 20 and 6 nmol per milligram of protein per minute, respectively (Magistretti & Pellerin, 1999). These values are of the same order as those determined *in vivo* for cortical gray matter (10–20 nmol mg^{-1} min^{-1}) with the 2-DG autoradiographic technique. In view of this difference and of the quantitative preponderance of astrocytes compared with neurons in the gray matter, these data reveal a significant contribution by astrocytes to basal glucose utilization as determined by 2-DG autoradiography or PET *in vivo.* High-resolution microautoradiographic imaging has indicated an approximately even distribution of 2-DG in neurons and astrocytes.

The contribution of astrocytes to glucose utilization during activation appears to be even more striking. *In vitro,* activation can be mimicked by exposure of the cells to glutamate, the principal excitatory neurotransmitter (Chapter 6), because, during activation of a given cortical area, the concentration of glutamate in the extracellular space increases considerably due to its release from the axon terminals of activated pathways. L-glutamate stimulates 2-DG uptake and phosphorylation by astrocytes in a concentration-dependent manner, with an EC_{50} of 60 to 80 μM (Pellerin & Magistretti, 1994). Unlike other actions of glutamate, stimulation of glucose utilization in astrocytes is mediated not by specific glutamate receptors, but by glutamate transporters as well. As previously described, glutamate uptake into astrocytes is mediated by cell specific transporters using transmembrane Na^+ gradient as a driving force (Fig. 12.8).

Glutamate-Stimulated Uptake of Glucose by Astrocytes Is a Source of Insight into the Cellular Bases of ^{18}F–2–DG PET *in Vivo*

The glutamate-stimulated uptake of glucose by astrocytes is a source of insight into the cellular bases of the activation-induced local increase in glucose utilization visualized with ^{18}F-2-DG PET *in vivo.* As we have seen, focal physiological activation of specific brain areas is accompanied by increases in glucose utilization; because glutamate is released from excitatory synapses when neuronal pathways subserving specific modalities are activated, the stimulation by glutamate of glucose utilization in astrocytes provides a direct mechanism for coupling neuronal activity to glucose utilization in the brain (Fig. 12.13). The intracellular molecular mechanism of this coupling requires Na^+, K^+-ATPase because ouabain completely inhibits the glutamate-evoked 2-DG uptake by astrocytes (Pellerin & Magistretti, 1994). The astrocytic Na^+, K^+-ATPase responds predominantly to increases in intracellular Na^+ (Na^+_i), for which it shows a K_m of about 10 mM. In astrocytes, the Na^+_i concentration ranges between 10 and 20 mM, so Na^+, K^+-ATPase is set to be activated readily when Na^+_i rises concomitantly with glutamate uptake (Magistretti & Chatton, 2005) (Fig. 12.14). These observations indicate that a major determinant of glucose utilization is the activity of Na^+, K^+-ATPase. In this context, one should note that, *in vivo*, the main mechanism that accounts for activation-induced 2-DG uptake is the activity of Na^+, K^+-ATPase. It is important here to briefly consider the relative participation of the neuronal and astrocytic Na^+, K^+-ATPases in glucose utilization. When glutamate is released from depolarized neuronal terminals, it is taken up predominantly into astrocytes. The stoichiometry of glutamate reuptake being one molecule of glutamate cotransported with three Na^+ ions, the increase in intracellular astrocytic Na^+ concentration associated with glutamate reuptake massively activates the pump. Thus, although the tonic activity of the Na^+, K^+-ATPase is needed to maintain the transmembrane neuronal and glial ionic gradients and accounts for basal glucose utilization, on a short-term temporal scale (from milliseconds to seconds), when glutamate is released from depolarized axon terminals of modality-specific afferents, the astrocytic Na^+, K^+-ATPase is briskly activated, due to the massive increase (by at least 10 mM) in intracellular Na^+ associated with glutamate reuptake, providing the signal for the activation-dependent glucose utilization.

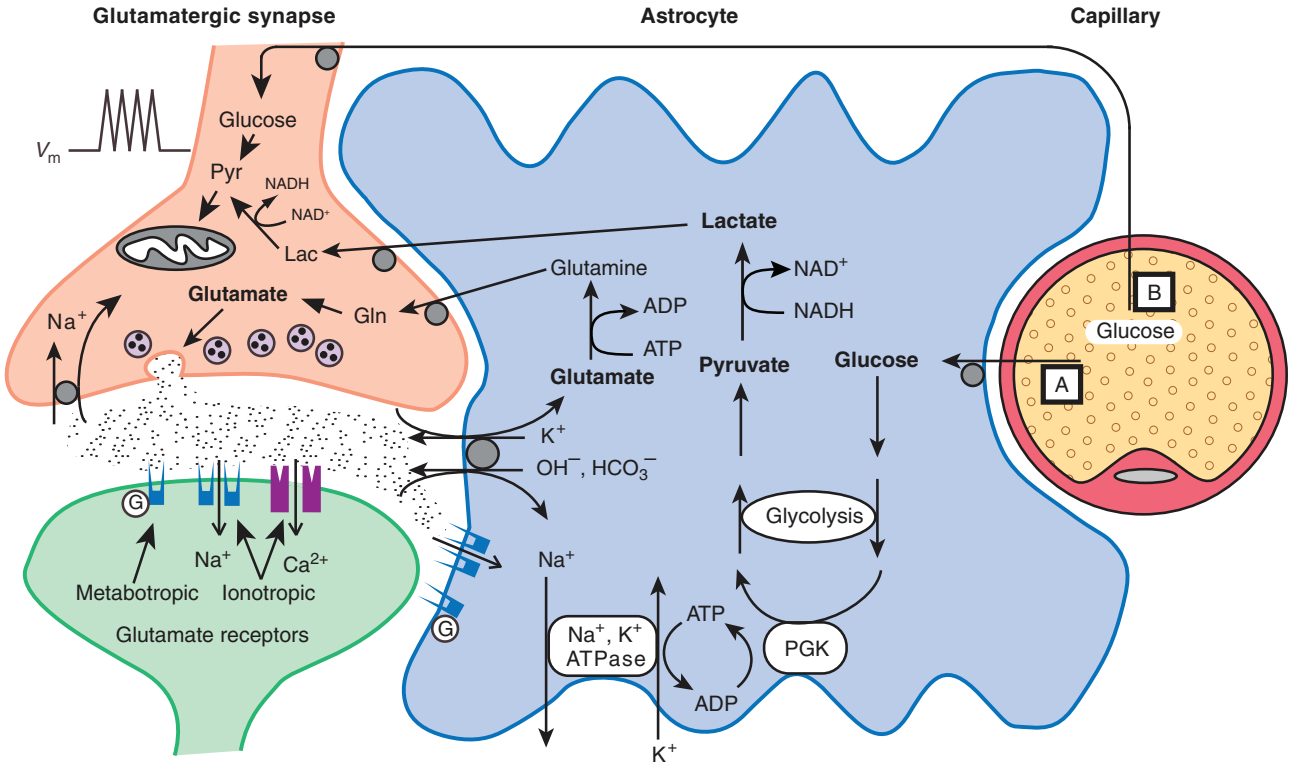

FIGURE 12.13 Schematic representation of the mechanism for glutamate-induced glycolysis in astrocytes during physiological activation. At glutamatergic synapses, presynaptically released glutamate depolarizes postsynaptic neurons by acting at specific receptor subtypes. The action of glutamate is terminated by an efficient glutamate uptake system located primarily in astrocytes. In fact, glutamate is taken up predominantly into astrocytes. Glutamate is cotransported with Na^+, resulting in an increase in the intra-astrocytic concentration of Na^+, leading to an activation of the astrocytic Na^+, K^+-ATPase. Activation of Na^+,K^+-ATPase stimulates glycolysis (i.e., glucose utilization and lactate production). The stoichiometry of this process is such that for one glutamate molecule taken up with three Na^+ ions, one glucose molecule enters astrocytes, two ATP molecules are produced through glycolysis, and two lactate molecules are released. Within the astrocyte, one ATP fuels one "turn of the pump," while the other provides the energy needed to convert glutamate to glutamine by glutamine synthase (see Fig. 12.10). Once released by astrocytes, lactate can be taken up by neurons and serve as an energy substrate (For graphic clarity, only lactate uptake into presynaptic terminals is indicated. However, this process could also take place at the postsynaptic neuron). This model, which summarizes *in vitro* experimental evidence indicating glutamate-induced glycolysis, is taken to show cellular and molecular events occurring during activation of a given cortical area (arrow labeled A, activation). Direct glucose uptake into neurons under basal conditions is also shown (arrow labeled B, basal conditions). Pyr, pyruvate; Lac, lactate; Gln, glutamine; G, G protein; PGK, phosphoglycerate kinase. *Modified with permission from Pellerin and Magistretti (1994).*

How does activation of Na^+, K^+-ATPase cause increased glucose utilization? The mechanism was explained by pioneering studies on erythrocytes by Joseph Hoffmann and colleagues at Yale University, which have been confirmed in a number of other cell systems, including brain and vascular smooth muscle. The increase in pump activity consumes ATP (Fig. 12.14), which is a negative modulator of phosphofructokinase, the principal rate-limiting enzyme of glycolysis (Fig. 12.1). Thus, when ATP concentration is low, phosphofructokinase activity is stimulated, resulting in increased glucose utilization. The activity of hexokinase, the enzyme responsible for glucose and 2-DG phosphorylation (Fig. 12.5), is also increased under these conditions. This explains why the increase in glucose utilization, associated with the stimulation of Na^+,K^+-ATPase, can be monitored with 2-DG, which is not processed beyond the hexokinase step.

A compartmentalization of glucose uptake during activation has also been unequivocably found by Marco Tsacopoulos and colleagues in the honeybee drone retina (Tsacopoulos & Magistretti, 1996). In this highly organized, crystal-like nervous tissue preparation, photoreceptor cells form rosette-like structures that are surrounded by glial cells. In addition, mitochondria are exclusively present in the photoreceptor neurons. Light activation reveals an increase in radioactive 2-DG uptake in the glial cells surrounding the rosettes but not in the photoreceptor neurons. An increase in O_2 consumption is nevertheless measured in photoreceptor neurons. After activation of photoreceptors by light, glucose is probably taken up predominantly by glial cells, which then release a metabolic substrate to be oxidized by photoreceptor neurons.

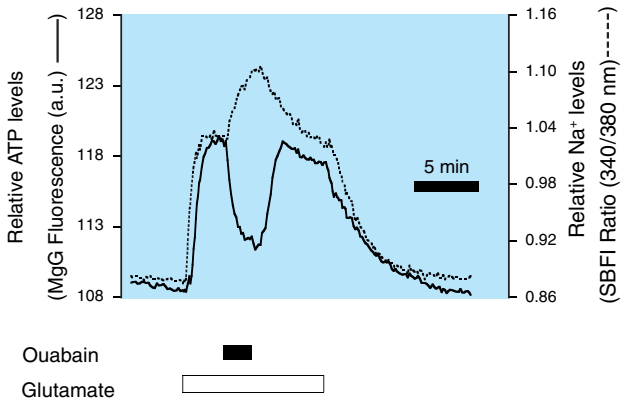

FIGURE 12.14 Temporal coincidence in the increase in sodium concentration and ATP consumption triggered by glutamate in astrocytes. These processes, which are dependent on the activity of the Na^+,K^+-ATPase as they are ouabain-sensitive, are the effectors of the glutamate-stimulated glycolysis in astrocytes (see also Fig. 12.13). *Modified with permission from Magistretti and Chatton (2005).*

In summary, as indicated in the operational model described in Figure 12.13, upon activation of a particular brain area, glutamate released from excitatory terminals is taken up by a Na^+-dependent transporter located on astrocytes. The ensuing local increase in intracellular Na^+ concentration activates Na^+,K^+-ATPase, which in turn stimulates glucose uptake by astrocytes. The key role of glial glutamate transporters in activity-dependent glucose uptake by the brain has been demonstrated *in vivo* (see Bélanger et al., 2011, and references therein). This model delineates a simple mechanism for coupling synaptic activity to glucose utilization; in addition, it is consistent with the notion that the signals detected during physiological activation in humans with ^{18}F-2-DG PET and autoradiography in laboratory animals may predominantly reflect uptake of the tracer into astrocytes. Recently, in the well-studied whisker-to-barrel somatosensory pathway, Buzsaki and colleagues have demonstrated a selective increase in glucose uptake into astrocytes during activation. The model originally proposed by Pellerin and Magistretti (1994) does not question the validity of the 2-DG-based techniques; rather, it provides a cellular and molecular basis for these functional brain-imaging techniques (Magistretti & Pellerin, 1999).

Lactate Released by Astrocytes Is a Metabolic Substrate for Neurons

The fact that the increase in glucose uptake during activation can be ascribed predominantly, if not exclusively, to astrocytes indicates that energy substrates must be released by astrocytes to meet the energy demands of neurons. As indicated earlier, lactate and pyruvate are adequate substrates for brain tissue *in vitro* (Schurr, 2006). In fact, synaptic activity can be maintained *in vitro* in cerebral cortical slices with only lactate or pyruvate as a substrate. Lactate is quantitatively the main metabolic intermediate released by cultured astrocytes at a rate of 15 to 30 nmol per milligram of protein per minute. For lactate (or pyruvate) to be a metabolic substrate for neurons, particularly during activation, two additional conditions must be fulfilled: (1) that indeed during activation lactate release by astrocytes increases, and (2) lactate uptake by neurons must be demonstrated. Both mechanisms have been indeed demonstrated. Mimicking activation *in vitro* by exposing cultured astrocytes to glutamate results in a marked release of lactate and, to a lesser degree, pyruvate (Pellerin & Magistretti, 1994). This glutamate-evoked lactate release shows the same pharmacology and time course as glutamate-evoked glucose utilization and indicates that glutamate stimulates the processing of glucose through glycolysis. *In vivo* ^{1}H MRI studies in humans that show a transient lactate peak in different brain areas during physiological stimulation (Figley & Stroman, 2011, and references therein) are consistent with the notion of activation-induced transient glycolysis. Finally, MCTs have been demonstrated on neurons and astrocytes in addition to capillaries.

Thus, a metabolic compartmentation whereby glucose taken up by astrocytes and metabolized glycolytically to lactate is then released in the extracellular space to be utilized by neurons is consistent with biochemical and electrophysiological observations (Bélanger et al., 2011; Hyder et al., 2006; Tsacopoulos & Magistretti, 1996). This array of *in vitro* and *in vivo* experimental evidence, known as the Astrocyte-Neuron Lactate Shuttle (ANLS), is summarized in the model of cell-specific metabolic regulation illustrated in Figure 12.13.

Studies of the well-compartmentalized honeybee drone retina and of isolated preparations of guinea pig retina containing photoreceptors attached to Mueller (glial) cells corroborate the existence of such metabolic fluxes between glia and neurons. In addition to the glial localization of glucose uptake during activation, glycolytic products have been shown to be released. In particular, during activation, glial cells in the honeybee drone retina release alanine produced from pyruvate by transamination; the released alanine is taken up by photoreceptor neurons and, after reconversion into pyruvate, can enter the TCA cycle to yield ATP through oxidative phosphorylation (Fig. 12.2). In the guinea pig retina, lactate, formed glycolytically from glucose, is released by Mueller cells to fuel photoreceptor neurons (Tsacopoulos & Magistretti, 1996).

In addition to plasma lactate, which is imported into the brain to a limited extent or during specific conditions (see above), lactate formed *within* the brain parenchyma (e.g., through glutamate-activated glycolysis in astrocytes) can thus fulfill the energetic needs of neurons. Lactate, after conversion into pyruvate by a reaction catalyzed by lactate dehydrogenase (LDH), can provide, on a molar

basis, 14 to 17 ATPs through oxidative phosphorylation. Conversion of lactate to pyruvate does not require ATP, and, in this regard, lactate is energetically more favorable than the first obligatory step of glycolysis in which glucose is phosphorylated to glucose 6-phosphate at the expense of one molecule of ATP (Fig. 12.1). In addition, lactate may contribute to the redox potential of neurons, since through its conversion to pyruvate, it generates NADH, hence providing energy in the form of reducing equivalents useful for a variety of metabolic reactions but also for ROS scavenging after its conversion to NADPH (Fig. 12.7). Another metabolic fate for lactate has been shown *in vitro* and *in vivo* by MRS. Thus, once converted to pyruvate in neurons, lactate may enzymatically yield glutamate and thus be a substrate for the replenishment of the neuronal pool of glutamate. Because this reaction is not associated with oxygen consumption, part of the uncoupling between glucose utilization and oxygen consumption described in certain paradigms of activation may be explained by the processing of glucose-derived lactate into the glutamate neuronal pool; another reason for such an uncoupling may be the use of glucose for non-energy-yielding processes such as its incorporation into certain macromolecules (glycoproteins and glycolipids).

Very recent evidence demonstrates that in addition to its role as an energy substrate, astrocytic-derived lactate also participates in the control of neuronal activity. For instance, effects of lactate on neuronal excitability have been observed for glucose-sensing and orexin neurons in the hypothalamus, as well as GABAergic neurons in the subfornical organ (see Bélanger et al., 2011, and references therein). Although the mechanism(s) of action of lactate in this context are not yet fully characterized, they appear to critically involve ATP-sensitive K^+ channels (K_{ATP}) (see Bélanger et al., 2011, and references therein). In this case, increased ATP concentration, produced by lactate oxidation, would trigger the closure of K_{ATP} channels leading to membrane depolarization and neuronal activation, providing a mechanism that links lactate release by astrocytes, lactate utilization by neurons, and modulation of neuronal excitability (see Chapter 5). These observations add another level of interaction between astrocytes and neurons with regards to energy metabolism.

Glycogen, the Storage Form of Glucose, Is Localized in Astrocytes

Glycogen is the single largest energy reserve of the brain; it is mainly localized in astrocytes, although ependymal and choroid plexus cells, as well as certain large neurons in the brainstem, contain glycogen. When compared to the contents in liver and muscle, the glycogen concentration in the brain is exceedingly small, about 100 and 10 times inferior, respectively.

Glycogen Metabolism Is Coupled to Neuronal Activity

Glycogen turnover in the brain is extremely rapid, and glycogen levels are finely coordinated with synaptic activity. For example, during general anesthesia, a condition in which synaptic activity is markedly attenuated, glycogen levels rise sharply. Interestingly, however, the glycogen content of cultures containing exclusively astrocytes is not increased by general anesthetics; this observation indicates that the *in vivo* action of general anesthetics on astrocyte glycogen is due to the inhibition of neuronal activity, stressing the existence of a tight coupling between synaptic activity and astrocyte glycogen. Accordingly, reactive astrocytes, which develop in areas where neuronal activity is decreased or absent as a consequence of injury, contain high amounts of glycogen.

Certain Neurotransmitters Regulate Glycogen Metabolism in Astrocytes

Glycogen levels in astrocytes are tightly regulated by various neurotransmitters. Several monoamine neurotransmitters—namely, noradrenaline, serotonin, and histamine—are glycogenolytic in the brain, in addition to certain peptides, such as VIP and pituitary adenylate cyclase activating peptide (PACAP), and adenosine and ATP. The effects of all these neurotransmitters are mediated by their cogent specific receptors coupled to second messenger pathways that are under the control of adenylate cyclase or phospholipase C. These observations show that neuronal signals (e.g., certain neurotransmitters) can exert receptor-mediated metabolic effects on astrocytes in a manner similar to peripheral hormones on their target cells. However, the action of this type of neurotransmitter is temporally specified and spatially restricted to activated areas. Indeed, brain glycogenolysis in laboratory animals has also been demonstrated *in vivo* after physiological activation of modality-specific pathways (see Bélanger et al., 2011, and references therein). These observations indicate that the physiological activation of specific neuronal circuits results in the mobilization of glial glycogen store.

The initial rate of glycogenolysis activated by VIP and noradrenaline measured in *in vitro* or *ex vivo* preparations is between 5 and 10 nmol per milligram of protein per minute, a value that is remarkably close to glucose utilization of the gray matter, as determined by the 2-DG auto-radiographic method. This correlation indicates that glycosyl units mobilized in response to glycogenolytic neurotransmitters can provide quantitatively adequate substrates for the energy demands of the brain parenchyma. While glycogen mobilization may also fulfill the astrocytes' own metabolic needs, glycogen breakdown typically results in lactate production and release in the

extracellular space. Consistent with its role as a neuronal energy substrate, glycogen-derived lactate was demonstrated to preserve axonal function in conditions of energy deprivation. It was also observed that astrocytic glycogen mobilization is required to sustain neuronal activity during intense stimulation in a mouse optic nerve preparation (see Bélanger et al., 2011, and references therein). Furthermore, recent data indicate a critical role of glycogen metabolism in higher brain functions. Thus, glycogen-derived lactate, and its transfer to neurons, is necessary for the establishment of long-term memory formation and for the maintenance of long-term potentiation (LTP) *in vivo* (see Bélanger et al., 2011).

Summary

Under basal conditions, glucose uptake and metabolism occur in every brain cell type. Glucose uptake is mediated by specific transporters that are distributed in a cell-specific manner. Astrocytes play a critical role in the utilization of glucose coupled to excitatory synaptic transmission. The molecular mechanisms of this coupling are stoichiometrically directed: for each synaptically released glutamate molecule taken up with three Na^+ ions by an astrocyte, one glucose molecule enters the same astrocyte, two ATP molecules are produced through glycolysis, and two lactate molecules are released and consumed by neurons to yield 14-17 ATPs through oxidative phosphorylation. Neuronal signals—for example, certain neurotransmitters—can exert receptor-mediated glycogenolysis in astrocytes in a manner similar to peripheral hormones on their target cells. However, this type of effect by neurotransmitters is temporally specified and spatially restricted within activated areas, possibly to provide additional energy substrates (i.e., lactate) in register with local increases in neuronal activity. This glycogen-derived lactate is critical for the expression of synaptic plasticity.

THE ASTROCYTE-NEURON METABOLIC UNIT

From a strictly energetic viewpoint, the brain can be seen as an almost exclusive glucose-processing machine producing H_2O and CO_2. However, the metabolism of glucose in the brain is specified temporally, spatially, and functionally. Thus, glucose metabolism increases with exquisite spatiotemporal precision in register with neuronal activity. The site of this increase is not the neuronal cell body; rather, it is the neuropil, where presynaptic terminals, postsynaptic elements, and astrocytes ensheathing synaptic contacts are localized. This cytological relation between astrocytes and neurons is also manifested by a functional metabolic partnership that operates as one of the major elements at the basis of neurovascular and neurometabolic coupling (Fig. 12.15). In response to a neuronal signal (glutamate), glucose is taken up by perivascular astrocytes (neurometabolic coupling) through a

glutamate transporter-mediated mechanism and released as a glucose-derived metabolic substrate for neurons (lactate), and vasoactive agents are released by astrocytes and neurons to increase CBF (neurovascular coupling) involving receptor-mediated mechanisms (Fig. 12.15).

Glucose also provides the carbon backbone for regeneration of the neuronal pool of glutamate. This process results from a close astrocyte-neuron cooperation. Indeed, the selective localization of PC in astrocytes, indicating the need to replenish the TCA cycle with carbon backbones, strongly suggests that glucose-derived metabolic intermediates are used for glutamate (and other amino acid) synthesis. The newly synthesized glutamate is not provided as such by astrocytes to neurons; rather, it is converted to glutamine by GS, another enzyme localized selectively in astrocytes. Glutamate, taken up by astrocytes during synaptic activity, undergoes the same metabolic process, also being released as glutamine (the glutamate-glutamine shuttle).

Summary

In conclusion, the axon terminal of glutamatergic neurons, which are the main communication lines in the nervous system, and the astrocytic processes that surround them should be viewed as a metabolic unit in which the neuron furnishes the activation signal (glutamate) to the astrocyte and the astrocyte provides not only the precursors needed to maintain the neurotransmitter pool (i.e., mainly glutamine), but also the energy substrate (lactate) (Fig. 12.16). The efficacy of the predominant excitatory synapse in the brain, the glutamatergic synapse, cannot be maintained without a close astrocyte-neuron interaction. Furthermore, evidence is accumulating that indicates that dysfunctions of this neuron-astrocyte metabolic cooperation are likely to be involved in pathological conditions, in particular neurodegeneration (Allaman et al., 2011; Bélanger & Magistretti, 2009).

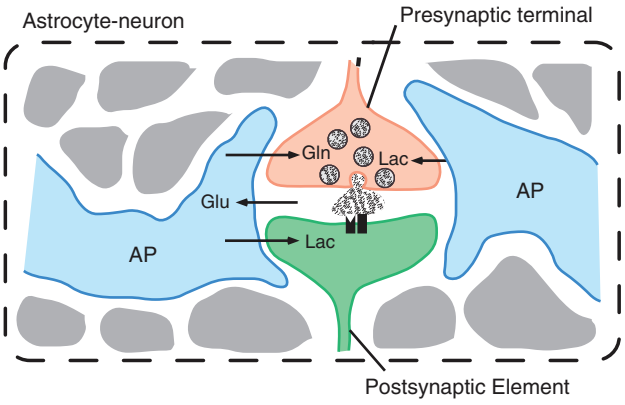

FIGURE 12.16 The astrocyte-neuron metabolic unit. Glutamatergic terminals and the astrocytic processes that surround them can be viewed as a highly specialized metabolic unit in which the activation signal (glutamate, Glu) is provided by the neuron to the astrocyte, whereas the astrocyte provides the precursors needed to maintain the neurotransmitter pool (i.e., mainly glutamine, Gln), as well as the energy substrate (lactate, Lac). AP, astrocyte process.

CHAPTER

13

Neural Induction and Pattern Formation

This chapter describes some of the key events that take place in the early stages of vertebrate nervous system development, during which the neural tube, placodes, and neural crest are formed, setting up the *structural ground plan* on which the functioning nervous system is built. The first part of the chapter describes how these embryonic structures are specified by inductive tissue interactions and how the processes of morphogenesis shape the early nervous system. The second part describes how the nervous system is patterned along its different axes, such that neural precursor cells acquire the ability to give rise to hundreds of different types of neuron, each forming in its appropriate position in the adult nervous system. These processes begin when neural tissue first appears and progress to finer and finer levels of cellular organization.

NEURAL INDUCTION

Embryonic Origins of the Nervous System

The progenitor cells that form the entire vertebrate nervous system can be traced back in development to an epithelial cell layer, the *ectoderm*, that covers the outside of the embryo during *gastrulation* (Fig. 13.1). Ectodermal cells give rise to different derivatives depending on position along the dorsoventral (DV) axis of the embryo. The dorsal-most ectoderm thickens to form the *neural plate*, a structure shaped like a tennis racquet with the head lying anteriorly. During a complex morphogenetic process called *neurulation*, the flat neural plate rolls up into a tube that sinks into the interior of the embryo and becomes overlain by epidermal ectoderm. This *neural tube* is the anlage of the central nervous system (CNS). As the neural plate folds and closes, *neural crest* cells detach from its lateral margins and migrate away, later condensing to form the major part of the peripheral nervous system (PNS). The ectodermal cells lying more ventral around the edge of the cranial neural plate constitute a domain where various sensory structures such as the ear, nose, and cranial sensory ganglia will arise from isolated patches of thickened ectoderm called *placodes*. Finally, ectodermal cells on the ventral side of the embryo give rise to the outer layer of the skin, the epidermis. The first step in forming the nervous system, therefore, is the establishment of these different regions of ectoderm, a process involving inductive interactions that were discovered early in the last century. Only quite recently, however, has the mechanism of *neural induction* been revealed at the molecular level.

Neural Induction and the Spemann Organizer

In the 1920s, Hilde Mangold, a PhD student in Hans Spemann's laboratory at the University of Freiburg, performed transplantation experiments on newt embryos and frequently obtained conjoined twins after grafting a small piece of the dorsal blastopore lip (DBL, where mesodermal cells start to involute during gastrulation) from a donor embryo to the opposite side of a host (Spemann & Mangold, 1924). Unlike others who had performed similar experiments before, Spemann and Mangold used differently pigmented newt species as donors and hosts, allowing them to determine the fate of the grafted cells. They noticed that the grafted DBL made only a small contribution to the secondary embryonic axis, most of which was derived from the host embryo, and concluded that DBL cells must have induced surrounding tissue in a spatially organized fashion to form an accurately patterned embryo (Fig. 13.2). Based on this inducing activity, Spemann called the DBL the *organizer*. For this groundbreaking discovery he was awarded with the 1935 Nobel Prize in Medicine (Mangold had died earlier in a domestic accident). Since

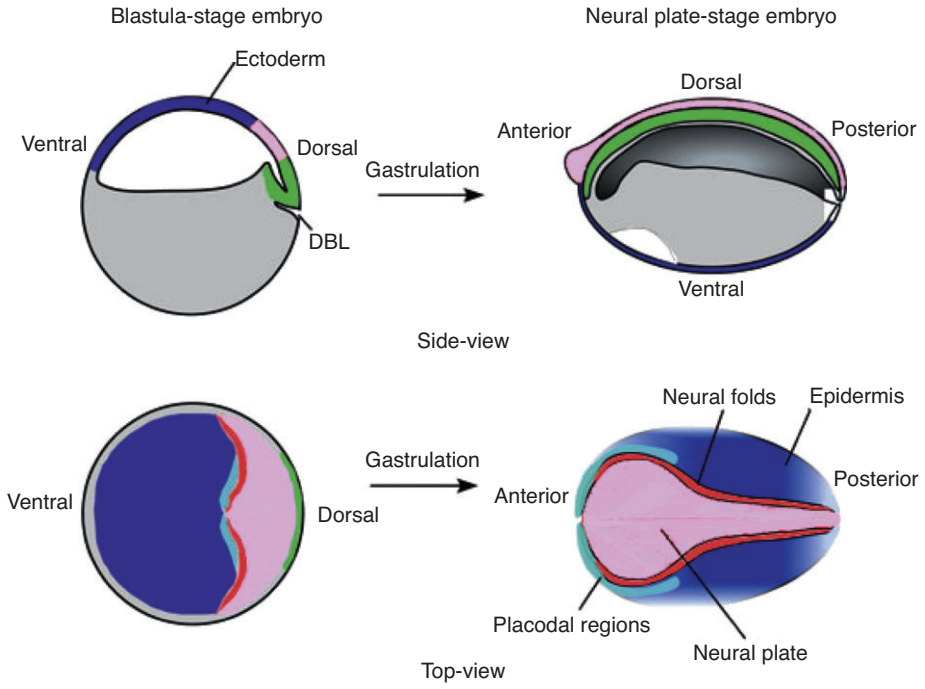

FIGURE 13.1 Ectoderm is subdivided into different fates during gastrulation. Shown is a cross-sectional side view, and top view of an amphibian embryo before (blastula-stage) and after gastrulation (neural plate-stage). During gastrulation, the gray and green (dorsal mesoderm) regions of the blastula involute, and the ectoderm (blue/red) at the top spreads over the outside of the embryo, and extends along the anterior-posterior axis. As this process occurs, signals emanating from the dorsal and ventral sides of the embryo specify different fates, so that dorsal ectoderm (red) becomes neural tissue while ventral ectoderm (blue) becomes epidermis.

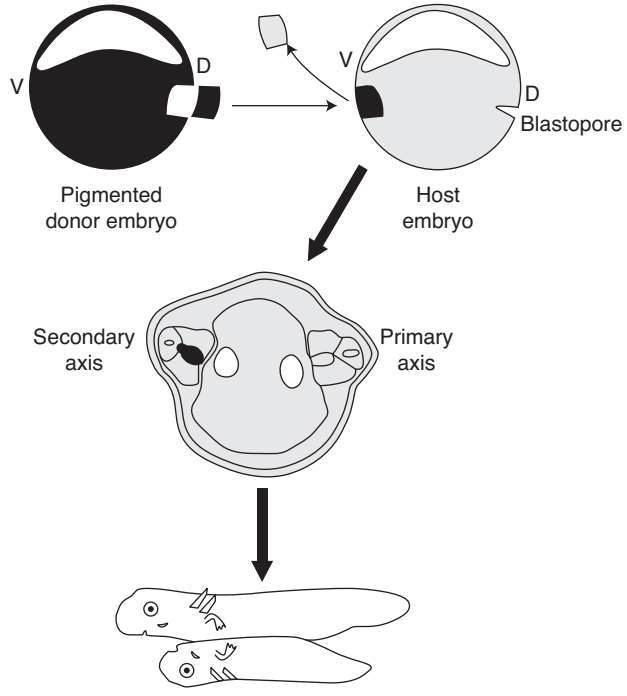

FIGURE 13.2 Organizer transplant experiment of Mangold and Spemann. Tissue around the DBL was removed from one embryo (black) and placed into the ventral side of another (light gray). The transplanted DBL, if large enough, will cause a complete second dorsal axis to form on the host embryo, resulting in twinning. Cross section through the tadpoles shows that the second dorsal axis contains a complete nervous system. Importantly, by using differently pigmented embryos, one can show that the majority of the nervous system in this new dorsal axis is not derived from the transplanted tissue, but rather from host tissue, fated to give rise to ventral tissues in the absence of a graft.

then tissues that are topologically and functionally equivalent to the organizer have been identified in fish (where this region is also called the *shield*), in chick, mouse and rabbit (where it is referred to as the *node*) and, more recently, even in some invertebrates.

Importantly, the secondary axis induced in Spemann and Mangold's experiment contained a complete nervous system that was accurately patterned along its anteroposterior (AP) and DV axes and consisted predominantly of host tissue, indicating that the organizer has both neural-inducing and neural-patterning activity. This observation prompted a quest for the molecules mediating these inductions, in particular for the neural inducer. However, subsequent findings that dead organizer tissue (killed by boiling, freezing, or chemical fixation) as well as many heterologous substances such as methylene blue or even grains of sand were able to induce neural tissue in newt ectoderm led to disillusionment among embryologists, and by the 1960s Spemann's organizer concept had lost much of its impetus. It took another 30 years, the emergence of molecular cloning, and the introduction of a different amphibian model system, for there to be a renaissance of the organizer and an understanding of its mechanism of action.

The Molecular Nature of Organizer Factors and the Default Model for Neural Induction

From the 1950s onward, the African frog *Xenopus laevis* became a popular model organism for biological research.

The ectoderm of the Anuran *Xenopus* turned out to be less easily neuralized than that of the Urodeles used by Spemann and others. A piece of ectoderm isolated from a *Xenopus* embryo before the onset of gastrulation (a so-called "animal cap" explant) will differentiate into epidermis when cultured in the absence of any external factors. In the 1980s, embryologists started to apply the newly developed toolkit of molecular biology to questions of embryonic patterning, and, for the first time, genes that are expressed in specific tissues of an embryo could be identified and visualized by *in situ* hybridization. Rapidly, an increasing number of factors specifically expressed in the organizer were found, and several of those acted as neural inducers when overexpressed in frog embryos by mRNA injection, but how they functioned molecularly remained to be established.

The first step toward an understanding of the molecular mechanism of neural induction came from experiments using a truncated form of an Activin receptor that functioned as a dominant-negative because it lacked the intracellular domain essential for signal transduction. Activin, a member of the transforming growth factor β (TGFβ) superfamily, had previously attracted attention as an inducer of mesoderm in both animal cap explants and entire embryos. Expression of the truncated receptor resulted in neural induction in animal cap explants that would normally form epidermis. This was the first indication that the *inhibition* of a signaling pathway, rather than its activation, could underlie neural induction. It also led to the re-evaluation of an experiment performed by Grunz and Tacke (1989) a few years before, where neural tissue was induced in animal caps that had been dissociated into single cells and reaggregated several hours later: the dissociation of ectodermal cells may have diluted an antineuralizing factor that is normally present in intact ectoderm.

Finally it was demonstrated that bone morphogenetic proteins (BMPs), also members of the TGFβ superfamily, were likely candidates to mediate this antineuralizing signal: (1) they are widely expressed in the embryo before and throughout gastrulation (but their expression becomes downregulated in the neural plate); (2) addition of BMP4 protein to dissociated animal caps prevents neuralization and promotes epidermis formation; (3) overexpression of BMPs by mRNA microinjection results in embryos with a reduced neural plate and expanded epidermis; and (4) the dominant-negative Activin receptor that induced neural induction in animal caps also blocks BMP signaling. The last piece in the puzzle was added when several of the neural-inducing factors secreted by the organizer were found to be inhibitors of BMP signaling: Noggin, Chordin, Follistatin, and Cerberus all bind to BMPs with high affinity, thereby preventing them from activating their receptors, whereas *Xenopus* Nodal-related 3 (Xnr3) inhibits BMP signaling by an as yet unknown mechanism. Taken together, these observations led to the idea that Spemann's organizer induces neural tissue in the dorsal ectoderm by inhibiting BMPs, whereas ventral ectoderm develops into epidermis as it remains exposed to BMPs. An important aspect of this *default model* for neural induction (Muñoz-Sanjuán & Brivanlou, 2002) is that ectoderm will inherently (by default) form neural tissue unless it is exposed to antineuralizing signals—a notion that could explain why so many "neural inducers" were found in the period following Spemann and Mangold's discovery (Fig. 13.3).

The interplay between BMPs and their inhibitors is not limited to the ectodermal germ layer. BMPs were also found to ventralize, whereas organizer-derived BMP inhibitors dorsalize the mesoderm. Thus, a main function of the organizer is to create a sink for BMPs that normally establish ventral identity. Surprisingly, this molecular mechanism appears to be conserved far beyond the deuterostome superphylum, as the formation of the ventral nerve cord in the fruit fly *Drosophila melanogaster* depends on the inhibition of Decapentaplegic (a fly BMP) by the Chordin ortholog Short gastrulation (Bier, 1997).

Due to the extensive redundancy of BMP inhibitors secreted by the organizer, the genetic evidence for their requirement is comparably weak. For example, a loss-of-function mutation in the zebrafish ortholog of *chordin* causes only a moderate reduction in the size of the neural plate (Schulte-Merker, Lee, McMahon, & Hammerschmidt, 1997). Similarly, mice lacking either *Chordin* or *Noggin* function (see Box 13.1) display a relatively normal CNS. The simultaneous deletion of two BMP inhibitors in *Chordin/Noggin* double knockout mice leads to severe head and forebrain defects, but neural tissue is still induced in these embryos (Bachiller et al., 2000). Only the depletion of three BMP inhibitors—Chordin, Noggin, and Follistatin—by injection of morpholino antisense oligonucleotides directed against the mRNAs of these genes into *Xenopus* embryos resulted in a dramatic loss of neural tissue and dorsal mesoderm, indicating a strict requirement for organizer-derived BMP inhibitors (Khokha, Yeh, Grammer, & Harland, 2005). Conversely, the simultaneous depletion of four BMPs using the same experimental strategy leads to a dramatic expansion of neural at the expense of epidermal tissue in *Xenopus* (Reversade & De Robertis, 2005).

The default model for neural induction has also received support from work in embryonic stem (ES) cells. There are different ways of converting ES cells into neurons, but the depletion of growth factors is one of these. Furthermore, addition of BMP protein to ES cell cultures is known to block neural and promote epidermal differentiation, highly reminiscent of its role in vertebrate embryos. Recently, a zinc finger transcription factor, Zfp521, was shown to be strictly required for neural differentiation of ES cells, where it functions by recruiting

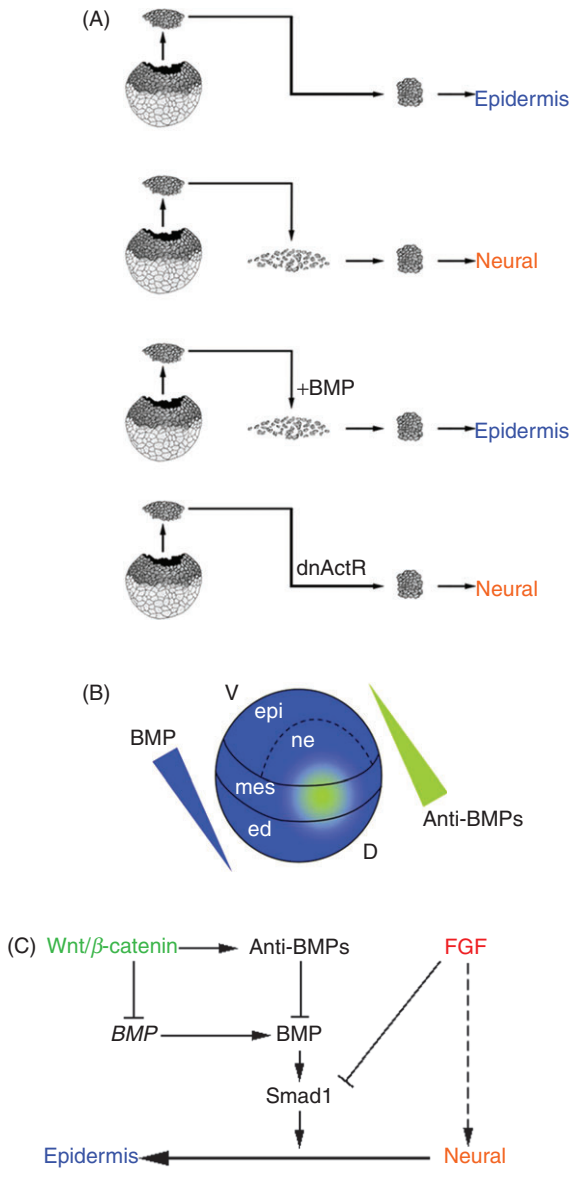

FIGURE 13.3 The BMP signaling pathway and its role in DV patterning of the ectoderm. (A) Experiments in *Xenopus* embryos that led to the default model: culture of animal cap explant results in epidermis differentiation; dissociation for several hours followed by reaggregation of animal cap tissue results in neural induction; the presence of BMPs during dissociation prevents neural induction and promotes epidermis formation; the expression of a dominant-negative Activin receptor results in neural induction even without dissociation. (B) Schematic model for DV patterning of the amphibian embryo. Spemann's organizer (green) on the dorsal (D) side of the embryo produces BMP antagonists that counteract the activity of BMPs (blue) on the ventral side (V). This results in a BMP activity gradient that patterns the DV axis of the embryo. Ventral ectoderm develops into epidermis (epi) under the influence of BMPs, whereas the neural plate (neurectoderm, ne) is induced on the dorsal side through BMP inhibition; mes, mesoderm; ed, endoderm. (C) The default model for neural induction including recent modifications: BMPs induce epidermal fate and inhibit neural induction via Smad1 activity; BMP inhibitors act as neural inducers by blocking BMPs; FGFs act as neural inducers by counteracting Smad1 and via BMP-independent mechanisms; Wnt/β-catenin signaling predisposes ectoderm for neural induction by both preventing the transcription of *Bmp* genes and inducing the expression of BMP inhibitors.

the transcriptional co-activator p300 to the promoters of multiple early neural genes. Forced expression of Zfp521 neuralizes ES cells even in the presence of BMPs. This discovery highlights the importance of intracellular factors in executing the effects of extracellular signals that drive cell fate changes, such as neural induction (Kamiya et al., 2011).

Challenges to the Default Model and Additional Pathways Involved in Neural Induction

Although the fundamentals of the default model have been widely accepted, several recent studies have added complexity to our current view of neural induction. For example, the analysis of fish, frog, and mouse embryos in which Nodal signaling is impaired has cast doubt on the importance of Spemann's organizer in neural induction. Nodal, a TGFβ molecule similar to Activin, is essential for mesoderm and endoderm induction and thus for organizer formation. Surprisingly, Nodal-deficient embryos still form a relatively well-patterned CNS, suggesting that the organizer is dispensable for neural induction. One possible explanation for this phenotype could be that these embryos not only lack an organizer but also most nonorganizer mesoderm and endoderm, which is a likely source of antineuralizing signals. However, BMPs that are expressed in the ectoderm should be sufficient to prevent neural induction in embryos that lack Nodal. Work in frog embryos demonstrated that the Wnt/β-catenin signaling pathway that is known to establish dorsal identity at very early stages of development can induce neural tissue by (1) repressing the transcription of *bmp4* and (2) inducing the expression of *chordin*, *noggin*, *follistatin*, *Xnr3*, and *cerberus* in the dorsal part of the embryo, even in the absence of an organizer. This activity of Wnt/β-catenin signaling occurs before the onset of gastrulation, possibly priming the dorsal ectoderm for neural induction by later signals from the organizer (Baker, Beddington, & Harland, 1999; Wessely, Agius, Oelgeschläger, Pera, & De Robertis, 2001).

In chick embryos, misexpression of *Chordin* fails to induce ectopic neural tissue in regions outside of the presumptive neural plate, whereas misexpression of *Bmps* fails to block neural induction, calling the role of BMPs and their inhibitors into question. Fibroblast growth factors (FGFs) are expressed in the precursors of the chick organizer and have been shown to be both required and sufficient to induce early neural marker genes, leading to a model where FGF signaling initiates neural induction before the onset of gastrulation by inducing a labile early neural character and the BMP inhibitors secreted by the organizer stabilize neural fate in such "primed" ectodermal cells at later stages. How FGFs induce neural tissue remains somewhat controversial.

BOX 13.1

TRANSGENIC MICE AND ENGINEERED MUTATIONS

Rapid and complementary advances in the fields of molecular biology and experimental embryology have combined to offer neuroscience researchers unprecedented power to manipulate the mammalian genome. The technologies used for these manipulations have been worked out primarily in the laboratory mouse and fall into two basic classes: those used for transgenic mice and those used for embryonic stem cell chimeric mice.

Transgenic mice are created by the injection of a cloned DNA fragment into the male pronucleus of a recently fertilized mouse embryo. The fragment will integrate into the host genome and be passed through subsequent mitoses to all the cells of the adult, including the gametes. The integrated DNA fragment, now known as a "transgene," usually is engineered to contain a promoter and associated regulatory sequences, a structural gene, and a 3′ polyadenylation signal. Transgenes add to the genome. As a genetic element, the chromosomal site of integration is random, and there is no wild-type allele on the sister chromosome. As an expressed locus, the transgene message is made over and above the endogenous gene expression pattern. This technique can be used as both an analytical and an experimental tool. Used as an analytical tool, the potency of a certain genetic element to direct cell- or tissue-specific gene expression can be determined by using the element to regulate marker genes such as β-galactosidase or green fluorescent protein. The genetic elements that regulate the temporal and spatial expression pattern of *Hox* genes in hindbrain, tyrosine hydroxylase in adrenergic neurons, and L7 in Purkinje cells, have all been explored by this means. Used as an experimental tool, transgenes can exploit a genetic element with known specificity to deliver a gene product to an ectopic cell site or developmental time. Thus, the PDGF promoter has been used to drive the expression of human β-amyloid precursor protein, the L7 promoter has been used to deliver diphtheria toxin to differentiating Purkinje cells, and the β-actin promoter has been used to deliver *Hox-A1* to inappropriate sites in the developing embryo.

Embryonic stem cells (ES cells) are stable cell lines derived from the inner cell mass of the preimplantation embryo. They are totipotent, which means that if they are introduced into a host embryo, they can contribute to all cell types in the resulting chimera (including gametes). The use of homologous recombination in ES cells allows changes to be engineered in specific genetic loci in culture. By using modified cells to create chimeras, changes can be introduced into the mouse germline and propagated as new mutations. The mutations can be insertions, deletions, modifications, or any combination of the three. When the engineered insertion/deletion disables the normal allele, the resulting mutation often is referred to by the slang term "knockout." These techniques alter the genome. As a genetic element, the engineered locus replaces a specific gene locus, and there is a normal wild-type allele on the sister chromosome. Used in this way, a knockout mutation can be used to model an inherited disease. Lesch-Nyhan (HPRT-null), ataxia-telangectasia (ATM-null), and fragile-X mental retardation syndrome (FMR1-null) have all been modeled in this way. As an expressed locus, the knockout transcript is made instead of the wild-type gene product. This technique can thus be used to create a modified locus such that the targeted gene is mutated rather than destroyed, in the same way an endogenous transcript of one gene can be replaced with that of a different one. Thus, sequences encoding *Engrailed-2* have been inserted into the *Engrailed-1* locus in such a way that the *Engrailed-1* transcript is lost (a null mutation) and *Engrailed-2* is made in its place.

These are only some of the ways in which the powerful new technologies of transgenic and knockout mice are providing powerful genetic tools for use in neuroscience research.

In chick, FGF signaling induces the intracellular protein Churchill that activates Smad-interacting protein 1 (Sip1). Sip1 inhibits Smad proteins, the intracellular transducers of TGFβ signals, and could therefore block both mesoderm-inducing Nodal signaling and antineuralizing BMP signaling (Stern, 2006).

Smad1, the main transducer of the BMP signaling pathway, has phosphorylation sites for mitogen-activated protein kinase (MAPK), which is activated by FGFs as well as some other neural inducing factors such as insulin-like growth factor (IGF) and hepatocyte growth factor (HGF). Phosphorylation of Smad1 by MAPK inactivates its signaling function, providing a further explanation for the neural-inducing activity of FGFs. However, some effects of FGFs, such as the induction of early markers of neural progenitors of the *Sox* gene family, are thought to occur independently from BMP signaling.

The De Robertis laboratory has recently discovered that Smad1 is phosphorylated by glycogen synthase kinase 3 (GSK3), which targets it for proteasomal degradation. Since Wnt signaling inhibits GSK3 activity, Wnts may inhibit neural induction by stabilizing Smad1. Indeed, an antineuralizing and epidermis-inducing effect of Wnts has been reported in some chick and frog studies. At first

sight, this seems to be at odds with the idea that Wnt signaling predisposes dorsal ectoderm for neural induction before gastrulation; however, the timing of the Wnt signal likely plays a key role in these differential effects. Intriguingly, MAPK phosphorylation primes Smad1 for phosphorylation by GSK3, suggesting that the neural-inducing MAPK signal initiates its own termination. This study provides a beautiful example as to how a single molecule can integrate three signaling pathways—BMP, FGF, and Wnt—to generate a temporally controlled output (De Robertis, 2006; Fuentealba et al., 2007).

Summary

Classical transplantation experiments showed that Spemann's organizer is able to induce an ectopic neural plate when grafted to the ventral side of a host embryo. Molecular studies have revealed that BMPs block neural induction and that the organizer expresses various BMP inhibitors that function as neural inducers, leading to the default model for neural induction, which suggests that ectodermal cells will become neural as long as they are not exposed to antineuralizing signals. However, complexity was added to this model with the finding that FGF and Wnt signaling establish an early neural potential before the onset of gastrulation, highlighting the necessity to view neural induction as a multistep process. The characterization of transcription factors such as Smad1 and Zfp521 has started to draw attention to the importance of intracellular factors in integrating extracellular signals and in coordinating the temporal progression of neural induction.

EARLY NEURAL PATTERNING

The first step in establishing the morphological and cellular complexity of the mature CNS is the establishment of polarity along the anterior-posterior (AP) and dorsal-ventral (DV) axes of the neural plate. At later stages, the neural plate is parcellated into subdivisions on both of these principal axes to give rise to a multitude of different cell types in a spatially organized manner; these then become wired up in a stereotyped fashion and subserve distinct tasks in functional neural networks.

Classical Models for Early Neural Patterning—Establishment of AP and DV Axes

The ectopic CNS induced in Spemann's organizer experiment was patterned along its AP and DV axes, indicating that the organizer is not only able to induce neural fate, but also to mediate neural patterning. Spemann noted that inductions by the organizer differ depending on the developmental stage of the donor embryo. When he transplanted the DBL from an embryo at early gastrula stage, the graft induced a complete secondary embryonic axis; however, when he transplanted the DBL from a late gastrula donor, the graft only induced ectopic trunk and tail structures (Fig. 13.4A). A possible explanation for this

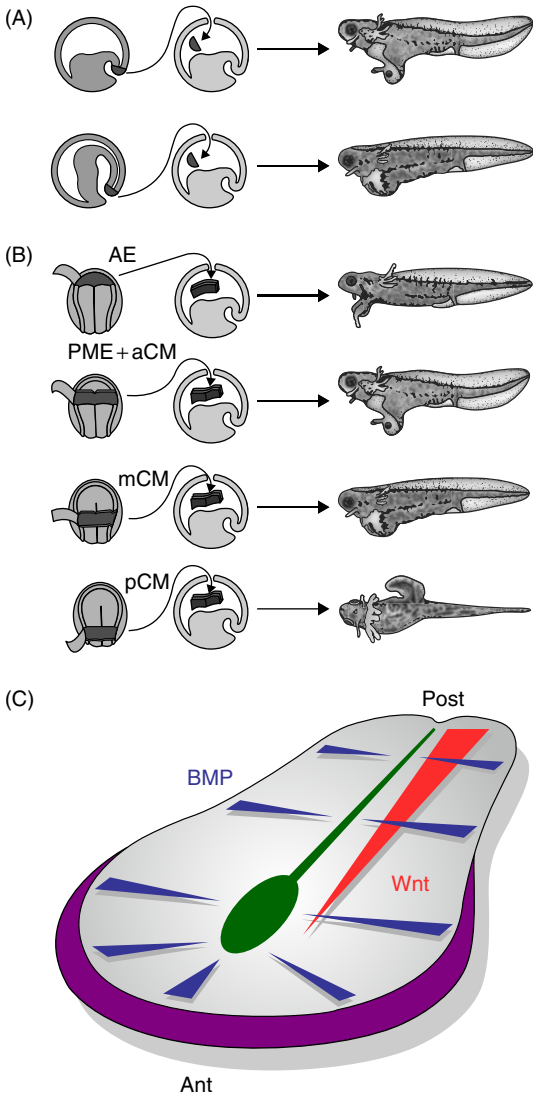

FIGURE 13.4 Models for early AP patterning of the CNS. (A) A graft of the DBL at early gastrula stages (EGO) results in the induction of a complete secondary axis, whereas a late gastrula DBL graft (LGO) only results in trunk and tail induction. (B) Anteriormost sections of the AME that contain mostly AE induce only very anterior ectopic structures; sections containing PME and anterior CM induce heads, whereas more posterior sections induce trunks and tails, leading to the idea of regionally specific inductions. (C) Model for pattern formation in the early neural plate: graded Wnt signaling (red) specifies the anteroposterior axis, whereas graded BMP signaling (blue) specifies the mediolateral axis of the neural plate. These gradients are shaped by the expression of BMP inhibitors in the AME (green) and of Wnt inhibitors in the anterior AME and in the ANB (purple).

observation is that the early gastrula organizer (EGO) contains a population of cells that release a head-inducing signal and that this subpopulation of organizer cells is lost from the late gastrula organizer (LGO).

During gastrulation, cells in the organizer region involute through the DBL, move toward the future anterior end of the embryo, and stretch out to form the axial mesendoderm (AME), which, from anterior to posterior, consists of the anterior endoderm (AE), prechordal mesendoderm (PME), and chordamesoderm (CM). Later on, the AE gives rise to the foregut, thyroid gland, and liver; the PME gives rise to the prechordal plate that underlies the presumptive forebrain region; and the CM gives rise to the notochord, a rod-shaped structure that acts as a signaling center involved in neural tube polarization (see following). The parts of the neural plate/tube that are found above the PME and CM are also referred to as prechordal and epichordal CNS, respectively.

Hilde Mangold's husband Otto dissected pieces of dorsal mesoderm that contained different AP segments of the AME from an early neurula stage embryo and tested their inductive potential by grafting them to gastrula stage host embryos. The anteriormost pieces (containing AE) only induced very anterior structures such as balancers and parts of the oral apparatus; tissue containing PME or anterior CM frequently induced ectopic head structures, including forebrain, eyes, otic vesicles, and midbrain; and tissue containing posterior CM predominantly induced trunk and tail structures, including spinal cord (Fig. 13.4B). Taken together, Spemann's and O. Mangold's experiments suggested that the EGO can induce a full embryonic axis because it contains progenitors of AE, PME, and CM, whereas the LGO can only induce trunk and tail structures because AE and PME progenitors have left the organizer region by that stage. Spemann proposed that inductions by the organizer are *regionally specific* due to the existence of functionally separable head, trunk, and tail organizers. The recent analysis of gene expression in the organizer supports the idea that AE, PME, and CM precursors are unevenly distributed within the EGO—even before a visible DBL has formed (Zoltewicz & Gerhart, 1997).

In the 1950s, Spemann's model had lost its popularity, and embryologists searched for alternative explanations for how the emerging CNS is patterned. Nieuwkoop and his colleagues in Utrecht implanted folds of ectodermal tissue at different AP levels into the prospective neural plate of *Xenopus* embryos. They found that folds implanted at the forebrain level tend to differentiate exclusively into anterior neural structures, whereas folds implanted more posteriorly tend to differentiate into posterior neural tissue at their base, close to the host's neural plate, and into anterior neural tissue more distally. At the time, the idea that tissues could be patterned by morphogens, diffusible factors that induce multiple different cell fates as a function of their dose, had become very popular. Nieuwkoop proposed that a planar signal that travels within the neural plate induces posterior identity in a dose-dependent, morphogen-like fashion. This posteriorizing factor—which was called *the transformer* by Nieuwkoop—is absent from the anterior end of the neural plate where the forebrain forms and gradually increases posteriorly, specifying midbrain, hindbrain, and spinal cord, depending on its dose.

Molecular Basis of Early AP Patterning

The first candidate for Nieuwkoop's transformer was retinoic acid (RA). The teratogenic activity of RA had been known for a long time, but when molecular markers for different regions of the nervous system became available in the 1980s, these effects were tested in a quantitative fashion. Treatment of frog embryos with increasing doses of RA resulted in a progressive loss of head structures and a concomitant upregulation of posterior neural marker genes at the expense of anterior markers. As a small, diffusible molecule that can easily cross cell membranes, RA was an attractive candidate to posteriorize the neural plate in a morphogen-like fashion. RA is synthesized by enzymes of the retinaldehyde dehydrogenase family, and only one member of this family, Raldh2, is expressed in early embryos. In *Raldh2* knockout mice as well as *raldh2* mutant zebrafish, markers of early AP neural regionalization are expressed normally, although patterning defects in the hindbrain become evident at later stages of neural development (see following). Thus, RA is unlikely to be the endogenous transformer, and its neural patterning function appears to be limited to the hindbrain (Maden, 2007).

In addition to their early role in neural induction, FGFs have been proposed also to posteriorize neural tissue. Overexpression of FGFs results in headless frog and fish embryos and treatment of neuralized animal caps with increasing doses of FGF protein results in a progressive induction of posterior neural markers. No genetic loss-of-function in mouse or zebrafish embryos has supported a requirement for FGFs in neural posteriorization, but this could be due to the severe early defects that various FGF mutants display. However, expression of a truncated, dominant-negative FGF receptor in frog embryos results in dramatic posterior truncations, indicating that FGFs are indeed required for posterior development. Yet, these embryos lack not only the posterior CNS but also all other posterior tissues, raising the question as to whether the effects on posterior neural development are direct or a secondary consequence of a lack of a posteriorizing factor secreted from, for example, the posterior mesoderm. Nevertheless, MAPK activity can be detected in the posterior neural plate of gastrulating *Xenopus* embryos using an antibody that specifically recognizes the activated form of this FGF transducer (Mason, 2007).

In higher vertebrates such as mice and chicks the posterior neuraxis is only formed late during gastrulation and is progressively laid down as the node regresses. Thus, AP patterning of the CNS is more protracted in these embryos than in frog and fish and requires a more complex spatiotemporal coordination. Experiments in chick embryos showed that FGF8, which is expressed in the regressing node, maintains a pool of stem cells that is required for posterior axis extension (Diez del Corral & Storey, 2004; Mathis, Kulesa, & Fraser, 2001). Thus, it is possible that the role of FGF signaling is to determine when cells leave the node and that those cells that remain in the stem zone acquire more posterior identities as they are exposed to another posteriorizing factor, the transformer, for longer.

Signaling factors of the Wnt family are currently the best candidates to mediate neural posteriorization in a manner consistent with Nieuwkoop's transformer. These secreted glycoproteins can activate a variety of signaling pathways of which the Wnt/β-catenin pathway is arguably best understood. Overexpression of Wnts antagonizes anterior development and promotes posterior development in frog, fish, chick, and mouse embryos. Treatment of neuralized animal caps with different doses of Wnts results in a stepwise posteriorization and implanting Wnt-expressing cells into the anterior neural plate of gastrulating *Xenopus* embryos results in the outgrowth of a mini-neuraxis around the implanted cells, indicating that they act as an organizer of posterior development. Finally, a graded activation of the Wnt signaling pathway can be detected along the AP axis of the neural plate by quantifying the nuclear localization of β-catenin, a hallmark of Wnt activity (Kiecker & Niehrs, 2001).

Several factors expressed by Spemann's organizer were found to be Wnt inhibitors, and these remain expressed in the anterior but are absent from the posterior AME during gastrulation. Cerberus is a multifunctional inhibitor that sequesters BMPs, Nodal, and Wnts and is expressed in the AE; Dickkopf1 (Dkk1) blocks the Wnt/β-catenin pathway at the level of receptor activation and is expressed in the PME; and Frzb1 sequesters Wnts by direct binding and is expressed in the PME and in the anterior CM. The strongest evidence that Wnt inhibition from the organizer is required for anterior neural development comes from the genetic knockout of *Dkk1* in mice that results in embryos lacking both forebrain and midbrain. A comparable phenotype is observed in frog embryos following injection of a neutralizing antibody directed against Dkk1 (Niehrs, 2004).

Thus, tissues attributed with head organizer activity by Spemann and Mangold (EGO, PME, and anterior CM) express Wnt antagonists, whereas trunk/tail organizers (LGO, posterior CM) do not. This leads us to a reconciliation of Spemann and Mangold's model of regionally specific inductions and Nieuwkoop's gradient-based model: the head organizer expresses Wnt inhibitors that help to establish a posteriorizing gradient of Wnt activity along the AP axis of the neural plate; anterior neural tissue is induced in the prechordal neural plate where levels of Wnt signaling are lowest. Just as an electron can act both as a wave and as a particle, AP patterning is regulated by organizers or gradients, depending on the experimental approach.

Other Tissues Involved in AP Patterning

An extraembryonic tissue, the anterior visceral endoderm (AVE), underlies the presumptive anterior neural plate in mouse embryos and becomes displaced anteriorly by the extending AME during gastrulation. The AVE expresses a range of factors that are also expressed in the organizer, suggesting that it could play a role in neural induction and/or patterning. In fact, when initial attempts in grafting the mouse EGO or LGO failed to induce heads it was suggested that head and tail organizer activity might be split between the AVE and the node in mouse embryos. However, later studies demonstrated that the mouse node is able to induce a complete secondary axis upon transplantation at mid-gastrula stage. The mouse AVE and its chick equivalent, the anterior hypoblast, are not sufficient to stably induce anterior neural markers when grafted to ectopic locations; yet the AVE can suppress posterior neural marker genes and the anterior hypoblast transiently induces early neural markers, suggesting that they may act permissively to prime the anterior neural plate for later signals from the organizer that stabilize the early labile anterior neural fate. Notably, the AVE expresses the BMP/Nodal/Wnt inhibitor Cerberus and the Wnt inhibitor Dkk1 that are likely to mediate the function of the AVE.

A single row of cells at the anterior border of the neural plate (ANB) of the zebrafish gastrula embryo is also involved in establishing anterior neural identity, as its surgical removal results in a loss of anterior character and, conversely, transplantation of ANB cells to more posterior locations leads to an ectopic induction of anterior neural fates (Houart, Westerfield, & Wilson, 1998). The ANB was found to express a Wnt inhibitor related to Frzb1, Tlc, whose activity mimics ANB function. Thus, tissues other than the anterior AME can exert head organizer function—but their unifying feature is the expression of Wnt inhibitors that counteract the posteriorizing influence of Wnts.

Early DV Patterning

Whereas Wnt inhibitors are only expressed in the anterior AME, the BMP inhibitors secreted by the EGO remain expressed along the entire AP extent of the AME. Since the AME underlies the neural plate along its midline, it can act

as a sink for BMPs expressed in the ectoderm surrounding the neural plate. Experiments in zebrafish have suggested that a low/medial-high/lateral gradient of BMP activity is established across the neural plate that specifies different mediolateral neural fates in a morphogen-like fashion depending on the BMP dose (Barth et al., 1999).

Summary

Classical models for early AP neural patterning suggested the presence of qualitatively distinct head, trunk, and tail organizers or the quantitative activity of a posteriorizing morphogen. Both models are now reconciled by the emerging molecular mechanism of this process: Wnts posteriorize the neural plate in a dose-dependent fashion, and tissues with head organizer activity protect the anterior neural plate from this posteriorizing influence by secreting Wnt inhibitors, thereby generating an AP gradient of Wnt activity across the neural plate. FGFs and RA also contribute to neural posteriorization. A gradient of BMP activity is established by the interplay between BMPs from the ectoderm and BMP inhibitors from the AME that patterns the mediolateral axis of the neural plate. Thus, quasi-orthogonal BMP and Wnt gradients establish a near Cartesian coordinate system within the neural plate and neural cells become allocated to a specific fate according to their position within this grid (Fig. 13.4C). However, it is clear that a mechanism solely based on global gradients can only establish a crude initial pattern. We will see later that additional mechanisms are required to refine this initial pattern.

Early Neural Morphogenesis

Striking morphological changes in cellular and tissue structure accompany the processes of neural induction and neurulation. At the cellular level, ectoderm cells lose their cuboidal shape and elongate into the pseudostratified morphology that is characteristic of neural precursor cells along the entire axis of the embryo. At a tissue level, the neuroepithelium of the neural plate undergoes the complex morphogenetic movements of neurulation to form the neural tube, which invaginates, dives into the embryo, pinches off from the surrounding ectoderm, and forms a separate tissue. Due to the geometric changes underlying this process, the initial mediolateral polarity of the neural plate becomes translated into the ventrodorsal polarity of the neural tube. Neurulation is an exceedingly complex process and prone to failure for multiple reasons. Indeed, a failure to close the neural tube has devastating downstream consequences on neural development and is the cause of neural tube defects (NTDs), one of the most common classes of human birth defects, occurring in approximately one in 1000 live births.

In higher vertebrates, neurulation can be divided into two phases that differ in their morphogenetic movements: a primary phase involving the brain and most of the spinal cord and a secondary phase involving more posterior regions of the spinal cord. While we are far from understanding the tissue mechanics that underlie neurulation, some progress has been made in characterizing specific cellular behaviors within subregions of the neuroepithelium. Among the earliest of these are the convergent-extension (CE) movements during gastrulation and neurulation that drive elongation of the embryo along its AP axis (Fig. 13.5A). CE is driven by organized cell intercalation much like the behavior of movie-goers when they exit a theater using only a central aisle (Keller, 2002). In a similar manner, neural plate cells intercalate along the mediolateral axis of the neural plate, resulting in a narrowing of the ML axis and simultaneous extension of the AP axis of the embryo.

CE is known to require planar cell polarity (PCP) signaling, a pathway originally identified in *Drosophila* where PCP mutations cause defects in the planar organization of bristles on the wing (Wang & Nathans, 2007). Proteins of the PCP pathway localize asymmetrically to opposite

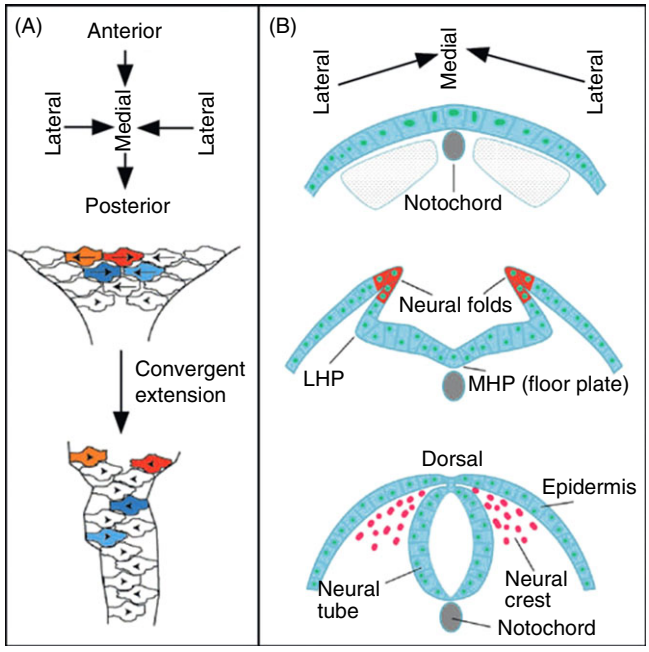

FIGURE 13.5 Morphogenesis of the neural plate and tube. (A) The formation of the neural plate and tube requires an organized intercalation of cells along the medial-lateral axis (convergence), which extends the neural anlage along the anterior-posterior axis (extension). The polarized cell behaviors that drive this process require the PCP pathway. (B) Neurulation of the neural plate into a tube requires several hinge points along the DV axis, including one at the forming ventral midline (MHP) which becomes the floor plate, as well as more dorsal ones (LHP). These hinge points allow the neural plate to buckle and the neural folds to elevate and fuse at the dorsal midline. At the same time, the neural crest cells form (red) and emigrate.

sides of cells within the plane of an epithelium, where they influence the planar orientation of the cytoskeleton. Vertebrate orthologs of these proteins are required during CE to organize the cytoskeleton of migrating cells along the mediolateral axis of the neural plate in a manner that orients polarized cell rearrangements. Consequentially, experimental interference with PCP signaling or mutations of PCP pathway genes disable CE, resulting in an abnormally wide neural plate, a subsequent failure to elevate the neural folds at the edges, and an open neural tube.

CE movements are far more pronounced in the posterior neural plate compared to anterior regions, resulting in the distinctive elongation of the hindbrain and spinal cord. Thus, patterning and morphogenesis are intimately linked during CNS development and experimental perturbation of one typically also affects the other. For example, the implantation of Wnt-expressing cells into the anterior neural plate of a frog embryo results in an induction of posterior neural fate, but also in the outgrowth of a mini-neuraxis (see above).

As CE extends the neural plate along the AP axis, other localized cell behaviors along the DV axis contribute to the buckling of the plate into a tube. Hinge points form at the midline of the neural plate as well as at more dorsal positions (Fig. 13.5B) by apical constriction of actin microfilaments in neuropithelial cells that produces a wedge-shaped morphology. Accordingly, mutations in various proteins that regulate microfilament dynamics are commonly associated with NTDs in the mouse. Shaping of the neural tube also requires localized regions of apoptosis, the lack of which can lead to NTDs. Finally, the neural tube closes with the fusion of the neural folds, forming the dorsal midline of the neural tube. The neural folds give rise to the neural crest, a population of migrating neural progenitors. Mutations in the mouse that alter neural crest formation and emigration are also capable of producing NTDs. Even with this short summary one can appreciate that integrating these various aspects of cell behavior into a unifying mechanical model of neurulation is a formidable task—although one that is required for a better understanding of the etiology of several human birth defects.

Summary

The formation of the vertebrate nervous system is accompanied by striking changes in cell and tissue morphology. Neural tube formation involves the complex morphogenetic process of neurulation that requires coordinated changes in cell shape, cell migration, cell death, and cell–cell contacts. One prominent cell behavior during neural plate and tube formation is CE that depends on PCP signaling and narrows the neural anlage mediolaterally and extends it along the AP axis by cell intercalation.

REGIONALIZATION OF THE CENTRAL NERVOUS SYSTEM

Following the establishment of polarity and the delineation of prechordal and epichordal regions of the neural plate, the AP axis becomes further regionalized into smaller domains, as revealed by the expression of developmental control genes. This process of progressive regional refinement involves two general classes of mechanism—the partitioning of the neuroepithelium into small modules or segments in which development can proceed with a degree of autonomy, as seen in the hindbrain, and the establishment of local organizers as sources of diffusible factors (morphogens), as seen at the junction between the midbrain and hindbrain and at specific locations in the forebrain. In both cases, a conspicuous and important feature is the setting up of narrow boundary regions that either partition the segments or provide a specialized signaling function, or both. We will illustrate these patterning mechanisms by reference to selected examples. Our intention is to outline general principles rather than to provide a comprehensive review of nervous system patterning.

Hindbrain Segmentation

Shortly after neural tube closure, a series of seven varicosities appear along the AP axis of the hindbrain region. Although transient, these *rhombomeres* are true segments with defined sets of precursor cells allocated to an axially repeated set of similar modules (Lumsden & Keynes, 1989). Thus, the earliest formed neurons are laid out in stripes that match the morphological repeat pattern, with neurogenesis starting within the confines of alternate, even-numbered rhombomeres, and only appearing later in odd-numbered rhombomeres—a "two-segment repeat" pattern (Fig. 13.6). Later in development, these segmental origins become obscured as the neuronal nuclei condense and migrate bodily to new positions.

Segmentation is a strategy for specifying the pattern of developing structures that has been adopted independently by many animal phyla, offering the advantages that organizational fields remain small and specializations of cell type and pattern can be generated as individual segmental variations on the repetitive theme. In a segmented system, precise boundaries can be set for both cellular assemblies and realms of gene action.

The neural tube cannot become segmented in the same way as the mesoderm, where physically separate somites are formed, because the tube has to retain epithelial continuity, not least as a conduit for extending axons. Rather, the process must involve some mechanism that restricts cell mingling. Vital dye and genetic marking experiments have revealed such a *cell lineage restriction* mechanism in the hindbrain: clonal descendants of marked cells disperse

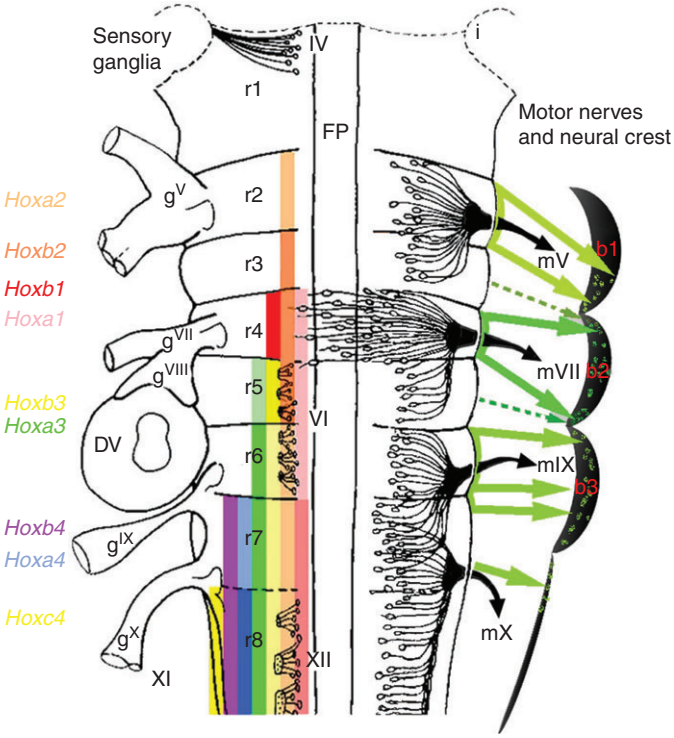

FIGURE 13.6 Distribution of motor neuronal types in the chick embryo hindbrain in relation to rhombomeres. Shown on the right side are branchiomotor neurons, forming in r2 + r3 (Vth cranial nerve, trigeminal), r4 + r5 (VIIth nerve, facial), and r6 + r7 (IXth nerve, glossopharyngeal), and contralaterally migrating efferent neurons of the VIIIth nerve (vestibuloacoustic), which are in the floor plate (FP) of r4 at the stage shown. Shown on the left side are somatic motor neurons, forming in r1 (IVth nerve, trochlear), r5 + r6 (VIth nerve, abducens), and r8 (XIIth nerve, hypoglossal). Cranial nerve entry/exit points and sensory ganglia associated with r2 (trigeminal), r4 (geniculate, vestibuloacoustic), r6 (superior), and r7 (jugular) are shown, as is the otic vesicle (ov). Colored bars represent the AP extent of *Hox* gene expression domains; note that one of these, *Hoxb1*, is expressed at a high level only in r4. *Modified from Lumsden and Keynes (1989).*

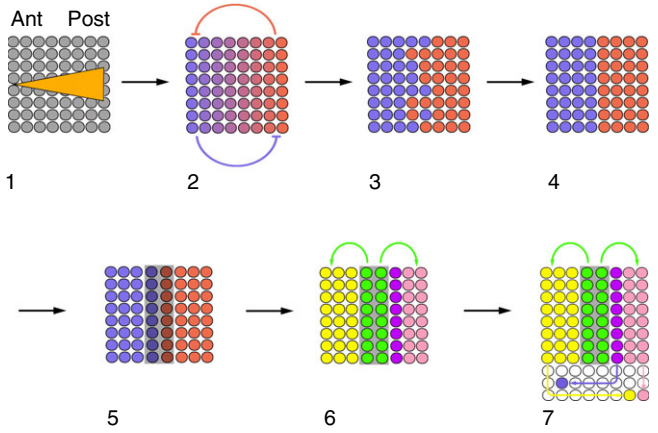

FIGURE 13.7 Model for neural boundary formation. 1. An initially uniform sheet of cells is polarized by a global signaling gradient (yellow)—for example, by a posterior-to-anterior gradient of WNTs. 2. This results in a coarse prepattern of transcription factor expression, with blue induced at low WNT signal level and red at a higher level. 3. Mutual cross-repression between blue and red factors establishes two distinct populations of cells separated at a fuzzy interface. 4. Cell sorting processes, depending on affinity molecules regulated by the red and blue transcription factors, act by minimizing contact between red and blue cells; a sharp, straight interface results. 5. Interaction between red and blue cells at the interface induces a boundary cell phenotype and boundary-specific markers are expressed (shaded area). 6. The boundary cells then express a signal molecule (green) that spreads laterally. Asymmetric responses by receiving cells to the green morphogen may depend either on prepatterned difference in competence (blue cells become yellow, and red cells become either both mauve and pink), and on morphogen concentration (mauve at high level, pink at lower level). The diffusion of a morphogen from a local source also governs the timing and spatial extent of responses. Later (7), postmitotic cells may migrate to new positions in the non-lineage-restricted mantle layer. *From Kiecker and Lumsden (2005).*

widely within the neuroepithelium, but the spreading cell clone always remains within a single rhombomere, confined at its boundaries (Fraser, Keynes, & Lumsden, 1990; Jimenez-Guri et al., 2010). The vertebrate hindbrain thus shares with insects the phenomenon of modular construction using cell-tight developmental compartments, where lineage restriction prevents cells wandering from one rhombomere to another and blurring the resulting pattern.

What mechanism is responsible for segregating hindbrain cells into compartments? One possibility is that cells of adjacent rhombomeres express surface molecules that favor affinity between the cells within a rhombomere but reduce affinity for cells in adjacent rhombomeres. Consistent with this, cultured cell aggregate experiments have shown that cells from even-numbered rhombomeres mix evenly with cells from other evens (as do odds with odds), whereas odd and even cells segregate from each other (Wizenmann & Lumsden, 1997). Thus, rhombomeres may partition according to an adhesion differential, obeying a two-segment repeat rule. Candidate molecules for mediating reduced intercellular affinity or adhesion at rhombomere boundaries include the Eph family of receptor tyrosine kinases and their ephrin ligands (Xu, Mellitzer, Robinson, & Wilkinson, 1999). Eph receptors are expressed in odd-numbered pre-rhombomeres, whereas their ligands are expressed in evens. This mutually exclusive pattern means that ligand–receptor interaction can only occur at forming boundaries, where it results in sharpening of the initially fuzzy interface between the adjacent domains (Fig. 13.7). Little is known about how the segmental pattern of the hindbrain is initially set out. Among the few known candidate regulators of segmental pattern is the zinc finger protein Krox20, an upstream transcriptional regulator of Eph receptors, which is expressed in two stripes in the neural plate that later become rhombomere (r)3 and r5.

Summary

Shortly after closure, the hindbrain neural tube becomes subdivided by transverse boundaries to form rhombomeres, a series of repetitive elements or metameres that have compartment properties. The existence of compartmental organization in the hindbrain suggests that cells become specified in segmental groups during their confinement in the ventricular zone and that they initially share a common identity, or ground state. First a row of similar boxes is formed and then the boxes are assigned individual identities according to their positional value.

Definition of AP Pattern by Differential Homeobox Gene Expression

Central to the illumination of vertebrate CNS pattern formation has been the discovery that developmental control genes related to genes with a known patterning role in the *Drosophila* embryo are expressed in spatially restricted domains of the neural plate and tube. These regulatory genes, many of which encode homeodomain-containing transcriptional control proteins, include the *Hox* genes, which specify positional value along the AP body axis of the fly embryo. In both flies and vertebrates the *Hox* genes have a clustered chromosomal organization in which the relative position of a gene in the cluster reflects its boundary of expression along the AP axis. In vertebrates, the *Hox* genes are expressed in overlapping, or nested, domains along the AP axis of the early embryo, with those at the 3′ ends of the cluster being expressed most anteriorly, in the hindbrain, where there is a precise correspondence between their anterior expression borders and the boundaries between the rhombomeres (Fig. 13.8).

Accumulating evidence supports the view that, by encoding positional value, *Hox* genes control the identity and phenotypic specializations of subregions of the epichordal neural tube in which they are expressed. Loss-of-function mutations of anteriorly expressed *Hox* genes result in malformations that represent a transformation of rhombomere identity. In the *Hoxb1* mutant mouse, for example, r4 (where the gene is normally expressed at a high level) loses its r4-specific character and takes on that of r2, a more anterior domain where the gene is not normally expressed (Studer, Lumsden, Ariza-McNaughton, Bradley, & Krumlauf, 1996). Similarly, overexpression of *Hoxb1* in r2 causes it to adopt phenotypic characters of r4 (Bell, Wingate, & Lumsden, 1999).

Anterior to r2, the brain does not express *Hox* genes but displays spatially restricted expression of other transcriptional control genes whose homeoboxes are divergent from the *Hox* type. These genes also are highly conserved between flies and vertebrates. Two homologues of the *Drosophila* segmentation gene, *engrailed (en)*, are expressed in a broad region either side of the midbrain–hindbrain boundary (MHB), which later forms the optic tectum and the cerebellum (Figs. 13.9 and 13.10). Expression of the *En* genes is graded, being strongest at the MHB and declining both anteriorly and posteriorly. Morphological derivatives of the entire domain of *En* expression are deleted in *En1* knockout mice, showing that *En* function is crucially involved in the morphogenetic specification of the region (Wurst, Auerbach, & Joyner, 1994).

The gap genes *orthodenticle* and *empty spiracles*, which function as homeotic selectors in the specification of particular head segments in *Drosophila*, have vertebrate homologues that are expressed in overlapping domains that encompass the entire rostral extremity of the AP axis with the exception of the ventral forebrain. The two *empty spiracles* homologues, *Emx1* and *Emx2*, are forebrain specific, whereas the two *orthodenticle* homologues, *Otx1* and *Otx2*, have wider expression, encompassing both forebrain and midbrain. The *Otx2* knockout mouse has an extreme phenotype that shows the importance of the gene but betrays little about its function—the entire head rostral to r3 is deleted. *Otx2* is also expressed in the PME that lies beneath the anterior ectoderm, where it is required for the induction of anterior neural structures during gastrulation (Simeone, Puelles, & Acampora, 2002). However, the gastrulation phenotype can be rescued by expressing *Otx1* in the visceral endoderm, while the ectoderm remains functionally null for *Otx2*. This reveals the brain-specific

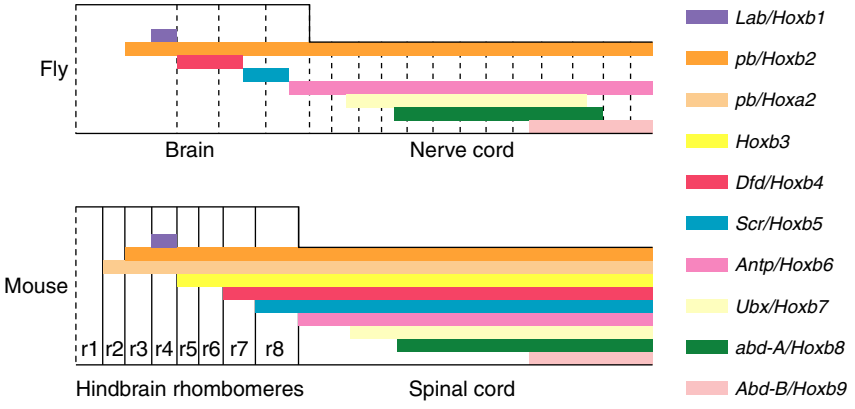

FIGURE 13.8 *Hox* gene expression domains in the CNS of fly and mouse. Nested domains of *Hox* genes along the AP axis of the *Drosophila* CNS closely parallel those of their homologues in mouse. Compare, for example, the fly gene *labial (lab)* with its mouse homologue *Hoxb1*. *Hox* genes specify a positional value along the AP axis, which is interpreted differently in fly and mouse in terms of downstream gene activation, resulting in neural structure; shared between the two organisms is the means of encoding the position of a cell along the AP axis. *From Hirth, Hartmann, and Reichert (1998).*

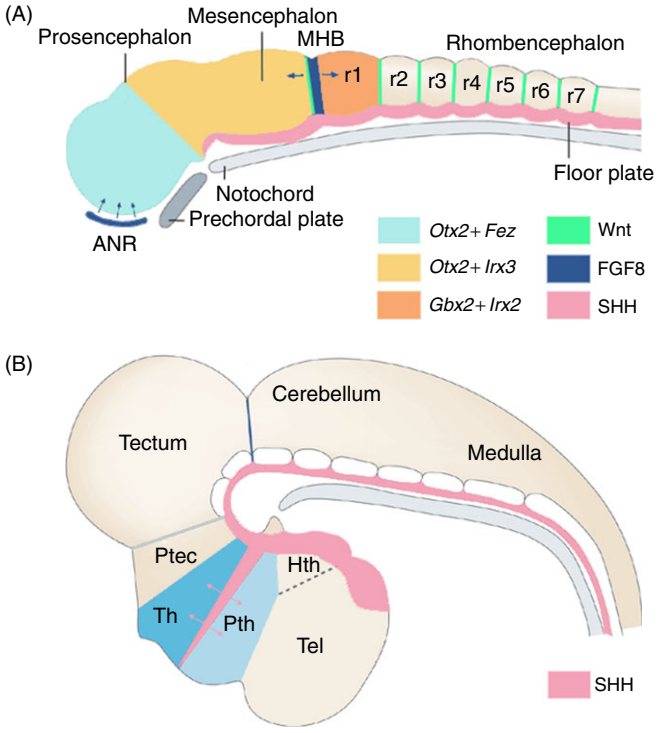

FIGURE 13.9 Boundaries in the avian embryo brain. (A) At an early stage signaling boundaries form at an interface between domains of Otx2 and Gbx2 expression, the midbrain–hindbrain boundary (MHB), and between adjacent rhombomeres (r1–r7). The zona limitans intrathalamica, organizer of the diencephalon, will later form at the interface shown here between Fez and Irx3 transcription factor domains. Dark blue arrows represent FGF8 signaling to both the presumptive optic tectum (mesencephalon) and presumptive cerebellum (r1). The anterior neural ridge (ANR) also secretes FGF, patterning the anterior forebrain. (B) At a later stage, a narrow wedge-shaped boundary region (ZLI) forms in the mid-diencephalon, and expresses Sonic hedgehog (pink), which induces the expression of regional determinants in flanking territories—the thalamus (Th) and prethalamus (Pth). Hth, hypothalamus; Ptec, pretectum; Tel, telencephalon.

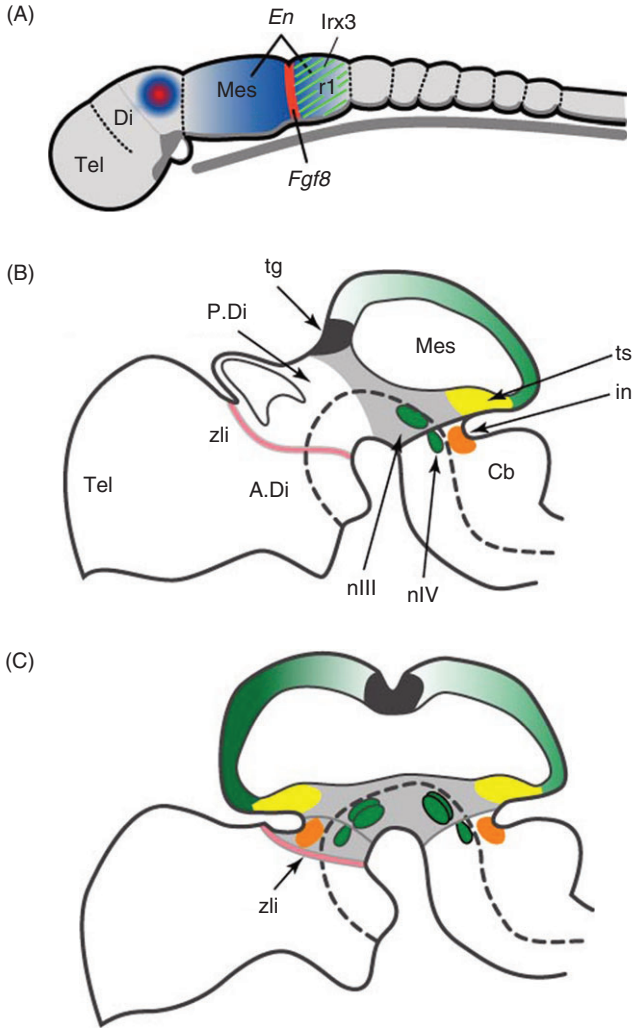

FIGURE 13.10 Role of FGF8 in mid/hindbrain patterning. (A) Implanting a bead that releases FGF8 protein (red) in the posterior diencephalon of an early chick embryo results in the induction of *En* (blue) and the transformation of normal posterior diencephalic territory (B) into midbrain (C). In the treated embryo (C), the posterior diencephalon forms a set of midbrain structures laid out in reverse AP polarity to the normal midbrain. This is thought to be due to the induced anterior-to-posterior gradient of EN protein that is the mirror image of the endogenous EN gradient. Also shown in (A) is the expression domain of the prepattern gene *Irx2* (green hatched), which establishes cerebellar competence in rhombomere 1. A.Di, anterior diencephalon; in, isthmic nuclei; Mes, midbrain; nIII, oculomotor nucleus; nIV, trochlear nucleus; P.Di, posterior diencephalon; r1, rhombomere 1; Tel, telencephalon; tg, tectal griseum; ts, torus semicircularis; zli, zona limitans intrathalamica. *Data from Crossley, Martinez, and Martin (1996) and Matsumoto et al. (2004).*

function of the gene, which is to maintain anterior neural identity; in the absence of neuroectodermal *Otx2*, the anterior brain becomes converted into hindbrain, with an enlarged cerebellum rather than forebrain forming at the anterior end of the CNS.

An important later function of *Otx2* is to set the position of the midbrain–hindbrain boundary (MHB), whose local organizer functions are discussed later. The sharp posterior border of *Otx2* expression coincides with the anterior expression border of another homeobox gene, *Gbx2*, in the anterior hindbrain, the interface between the domains being stabilized by mutual repression between the two genes (Fig. 13.9A). Experimentally extending the expression domain of *Otx2* into hindbrain territory causes the *Gbx2* border and MHB differentiation to retreat posteriorly, whereas extending the *Gbx2* domain into midbrain territory results in a corresponding anterior shift of the *Otx2* border (Rhinn & Brand, 2001).

Summary

Gene expression patterns have illuminated the time course and mechanisms underlying neural patterning. Functional studies show that homeobox genes direct AP pattern formation, establishing head-to-tail regionalization. In the hindbrain, *Hox* genes encode subregional (rhombomere) identity. At the midbrain–hindbrain boundary, *Otx*

and *Gbx* genes set up and position the MHB organizer, and *En* genes induced at the MHB confer AP polarity on the optic tectum.

Organizers of AP Pattern

Homeobox genes and other classes of transcriptional mediator regulate position-specific development. How is the expression of these genes, or their upstream regulators, directed to specific domains of the AP axis? In many cases, it appears that signals from local organizers are involved, directly or indirectly, in activating specific regional control elements of these genes at appropriate levels of the axis. However, in the case of *Hox* gene regulation, a more distributed source of retinoic acid (RA) signaling has this role of positional signal.

RA exerts its effects via multiple types of RA receptors, which are ligand-dependent transcription factors that bind to specific response elements in the promoters of target genes, including those of the *Hox* genes. In the early embryo, RA is produced by the somites that lie alongside the caudal hindbrain and spinal cord, through the activity of Raldh2. Expressed anterior to the hindbrain is another enzyme, Cyp26, which degrades RA. These enzymes appear to act, respectively, as source and sink for a gradient of RA activity that traverses the AP length of the hindbrain (White, Nie, Lander, & Schilling, 2007). Thus, targeted mutation of *Raldh2* in mice and treatment of chick embryos with an antagonist that specifically blocks all RA receptors both cause anteriorization of the hindbrain.

Immediately anterior to the expression domain of *Hox* genes is a large territory, r1 and midbrain, that forms the cerebellum and optic tectum. A unitary process of specification for these adjacent regions is reflected both at the molecular level and by aspects of their developmental potential: the *Drosophila engrailed* homologues, *En1* and *En2* and the *paired* homologues, *Pax2*, *Pax5*, and *Pax8*, are expressed in this domain. The development of midbrain and r1 is coordinated by signals from the MHB region itself: heterotopic grafts of MHB cells locally induce *En* expression in the host and change the fate of the host neuroepithelium such that it ultimately forms tectal structures (when grafted to the posterior diencephalon) or cerebellar structures (when grafted to the posterior hindbrain). These findings provide compelling evidence that a signal emanating from the MHB is involved in local AP patterning.

There are two prominent components of this organizing activity: Wnt1, expressed in a transverse ring just anterior to the MHB, acts as a mitogen and to maintain the expression of *En* but is unable to mimic the activity of MHB grafts. FGF8, expressed immediately posterior to the *Wnt1* domain, has both inducing and polarizing abilities (Figs. 13.9A and 13.10). When a bead coated with recombinant FGF8 is implanted in the posterior diencephalon of chick embryos, *Fgf8*, *Wnt1*, and *En2* expression is induced in the surrounding cells. The posterior diencephalon then becomes transformed into midbrain, whose AP polarity is reversed with respect to that of the normal host midbrain in accord with the gradient of induced *En* expression (Crossley et al., 1996). Loss of FGF8 function in the zebrafish mutant *Ace* results in loss of the MHB, cerebellum, and part of the tectum. Thus, *Fgf8* expression at the MHB is both necessary and sufficient to establish the polarized pattern of adjoining regions. The asymmetric responses of the mid- and hindbrain anlagen to the FGF8 signal is at least partially due to the prior expression of a competence factor: *Irx2* (a homologue of *Drosophila* prepattern gene *Iroquois*) is expressed early in presumptive r1 and directs the tissue to respond to FGF8 by making cerebellum. Ectopic expression of Irx2 in the midbrain transforms presumptive optic tectum into cerebellum on reception of the FGF8 signal, whereas expressing a constitutive repressor form of Irx2 in r1 transforms presumptive cerebellum into optic tectum. Interestingly, the role of FGF8 in this mechanism is to convert Irx2 protein from a repressor into an activator, which it does by phosphorylation via the MAP kinase pathway (Matsumoto et al., 2004). Diffusion of FGF8 away from the MHB (Scholpp & Brand, 2004) can be seen to act as an on-switch, setting the timing and extent of development of regions whose final identity has already been set up in latent form by prepattern gene expression.

Two further local organizers operate in more rostral regions of the neural tube where a number of early expressed developmental control genes are expressed in a patchwork quilt of small domains, subdividing the diencephalon and telencephalon (the main posterior and anterior subdivisions of the forebrain) into a number of transverse and longitudinal domains (Fig. 13.9). Signaling at the anterior end of the axis involves FGF secretion from a region known as the anterior neural ridge (ANR), which is responsible for inducing and/or maintaining telencephalic (e.g., *Foxg1)* gene expression and for maintaining telencephalic identity (Rubenstein & Beachy, 1998). The ANR is probably derived from the ANB cells that earlier in development secrete antagonists to Wnts (Houart et al., 1998), whose posteriorizing activity must be reduced in order to establish anterior neural identity, as discussed earlier.

A second local organizer of forebrain pattern, the zona limitans intrathalamica (ZLI), lies at the middle of the prospective diencephalon, roughly midway between the ANR and MHB, and is thought to be induced at the interface between Fez and Irx3 expression domains (Fig. 13.9A, B). The ZLI secretes the signal molecule Sonic Hedgehog (Shh), which is responsible for inducing the expression of regional determinant genes both anteriorly (e.g., *Dlx2* in

the prethalmus) and posteriorly (e.g., *Sox14*, *Gbx2* in the thalamus). Like the action of FGF8 at the MHB, the different inductive responses to Shh signaling from the ZLI are due, at least in part, to prepatterned differences in competence of the flanking regions: the *Iroquois* gene *Irx3* is expressed only posterior to the ZLI and directs thalamic differentiation on receipt of the Shh signal (Kiecker & Lumsden, 2005, 2012). The activity of Shh from the ZLI has an apparent dose-dependent activity on the thalamic primordium—cells close to the source, at a presumed high concentration of morphogen, express *Sox14* and develop into GABAergic neurons, whereas those further away express Gbx2 and later form glutamatergic neurons (Jeong et al., 2011; Scholpp et al., 2009; Vue et al., 2009).

Some Key Characteristics of Local Organizers

One of the hallmarks of hindbrain segmentation is the prevention of cell mixing between adjacent rhombomeres. This cell-lineage restriction phenomenon also exists at other boundaries that coincide with organizers (Kiecker & Lumsden, 2005): cell lineage restriction at the MHB has been demonstrated by sophisticated time-lapse imaging in zebrafish embryos and genetic fate mapping in the mouse (Langenberg & Brand, 2005; Zervas, Millet, Ahn, & Joyner, 2004), whereas the ZLI is flanked on both sides by lineage restriction boundaries (Zeltser, Larsen, & Lumsden, 2001). Lineage restriction has not been tested at the ANB, but it seems unlikely that cells intermingle freely across the neural-epidermal border.

Cell lineage restriction minimizes the contact between flanking cell populations, the interface between them, thus tending to form a sharply defined and often straight line across the region. The configuration and positional stability conferred by cell lineage restriction may be seen generally as a requirement for local organizers, ensuring that they can produce stereotypic and predictable molecular gradients in adjacent tissues (Irvine & Rauskolb, 2001).

A further peculiarity of the signal-producing cells in local organizer boundaries is that they proliferate more slowly and differentiate into neurons much later than those of flanking regions (Guthrie, Butcher, & Lumsden, 1991; Lumsden & Keynes, 1989). Transcription factors of the Hes family that mediate Notch signaling are required to inhibit neurogenesis at the MHB of zebrafish and frog embryos (Geling, Plessy, Rastegar, Strähle, & Bally-Cuif, 2004; Ninkovic et al., 2005; Takada, Hattori, Kitayama, Ueno, & Taira, 2005). All neural progenitors express *Hes* genes, but they usually become downregulated when cells undergo neurogenesis. An analysis in mouse embryos has revealed that in boundary regions *Hes* genes remain expressed and that it is this strong persistent expression that sets boundaries apart and allows organizer regions to persist (Baek, Hatakeyama, Sakamoto, Ohtsuke, & Kageyama, 2006).

Summary

Local signaling mechanisms direct the spatial expression of homeobox genes, which appear to be crucial for the delineation and subsequent development of specific anteroposterior subregions of the CNS. Retinoic acid, diffusing from the cervical somites, is in part responsible for establishing the nested expression domains of the *Hox* homeobox genes in the hindbrain. FGF8, produced by cells at the midbrain/hindbrain boundary (MHB), is involved in the elaboration of midbrain and cerebellar structures. Shh, produced by cells at the zona limitans intrathalamica (ZLI), is responsible for elaborating prethalamic and thalamic organization. For both the MHB and the ZLI, tissues lying anterior and posterior to the signaling center respond differently to the secreted morphogen because they have different competences, endowed at least in part by the prior expression of *Irx* prepattern genes. Local organizers are characterized by slow proliferation and late or absent neurogenesis.

AP Pattern of Spinal Nerves

Spinal nerves form a ladder-like array on either side of the spinal cord, an obvious manifestation of segmentation, but here, in contrast to the intrinsic patterning mechanism that operates in the hindbrain, spinal segmentation is imposed extrinsically by the somatic mesoderm that lies alongside. A serially reiterated asymmetry in the sclerotomal component of the somites allows axon to grow, and neural crest cells to migrate, only within the anterior half of each somite, where neural crest cells then condense to form dorsal root ganglia (DRG). The posterior half of each somite expresses glycoproteins that inhibit cell migration and cause growth cone repulsion or collapse. Thus, microsurgically substituting posterior halves for anterior halves results in the local absence of peripheral nerves, whereas the converse experiment results in enlarged DRG and motor nerves. Subdivision of the paraxial mesoderm into AP-polarized somites thus ensures a positional correspondence between the segmented dermomyotome on the one hand and its sensorimotor innervation on the other (Fig. 13.11).

Although it lacks intrinsic segmentation and has a superficial uniformity of organization, the developing spinal cord does manifest distinct AP variations in cellular subtype composition, particularly with respect to motor neurons arranged in discontinuous longitudinal columns. Posterior *Hox* genes have domains of expression in the spinal region that underlie this regional cellular diversity (Dasen & Jessell, 2009; Tsuchida et al., 1994).

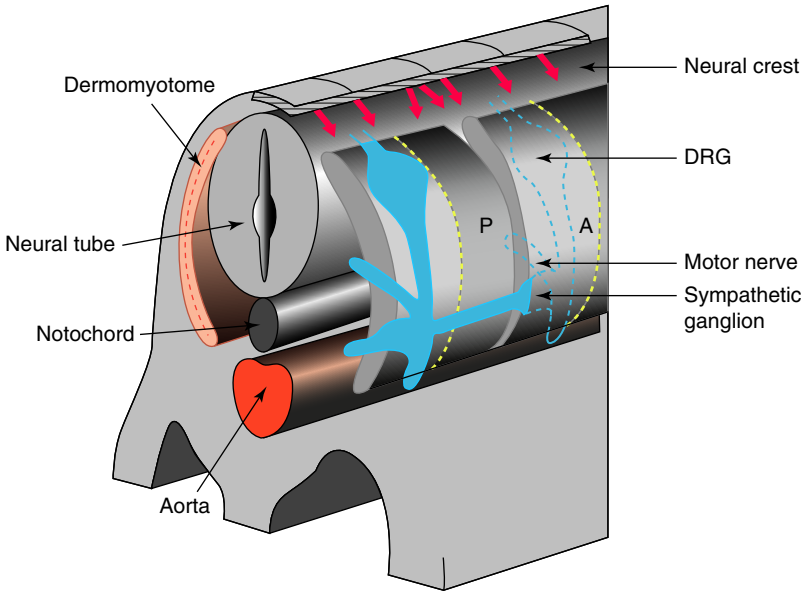

FIGURE 13.11 Segmented pathways for motor axon growth and neural crest migration in the trunk region. The AP positions at which motor axons collect to form a ventral root motor nerve and crest cells aggregate to form a dorsal root ganglion (DRG) are determined by the somites. By the stage at which these constituents of the peripheral nervous system appear, the medial (sclerotomal) region of somites has dispersed and surrounds the notochord and ventral neural tube. The sclerotome is divided into anterior (light gray) and posterior (dark gray) halves, which are distinct from each other according to cell density and molecular markers. All components of the peripheral nervous system are confined to the anterior half sclerotome of each somite, which is permissive for the migration of neural crest cells (arrows), some of which condense to form DRG, and the ingrowth of motor neuron growth cones.

Local Organizers of DV Pattern

The entire neural tube has a characteristic DV zonation where different cell types differentiate stereotypically at different DV positions. The ventral midline of the spinal cord, hindbrain, midbrain, and posterior diencephalon is formed by a palisade of specialized glia, the floor plate. Above the floor plate at spinal levels are five zones containing, in ventral to dorsal sequence, V3 interneurons, motor neurons, and three other types of interneuron, V2, V1, and V0 (Fig. 13.13A). Further subtypes of interneuron differentiate in the dorsal half, whereas the dorsal-most region, represented early on by neural folds that mark the transition between cells with neural and epidermal fates, forms the migratory neural crest cells that give rise to the glia and the majority of neurons in the peripheral nervous system. Later, after the neural crest has departed, the dorsal midline is populated by nonneurogenic roof plate cells.

The patterning of neuronal cell types has been studied intensively in the spinal neural tube, but the same molecules appear to be involved in regionalizing the DV axis of more anterior regions of the neuraxis. Unlike the AP axis, where local organizers signal position and fate to neighboring cells through single morphogen gradients, the DV axis has organizers at both dorsal and ventral poles, and their respective morphogen gradients appear to counteract one another.

Ventral Organizers

Crucially involved in patterning the ventral neural tube is the notochord, a narrow rod that forms from the AME and occupies the midline of the embryo directly beneath the neurectoderm. Grafting experiments in avian embryos have shown that both floor plate and motor neuron differentiation depend on notochord signals. Early removal of the notochord results in a normal-sized spinal cord in which both of these ventral cell types are absent, with dorsal cell types and dorsal-specific markers appearing in their place. Similarly, implanting a supernumerary notochord alongside and in contact with the lateral neural plate results in formation of an additional group of floor plate cells at the point of contact, with clusters of motor neurons on either side (Fig. 13.12A). These experiments show not only the power of the ventral midline signal to influence fate choice but also the multipotent competence of responding neural tube cells at different DV positions. At a slightly later developmental stage, the floor plate itself acquires the same inductive capabilities; it can also induce motor neurons and will induce itself homeogenetically. The floor plate thus becomes an organizing center for a ventral pattern that is built into the neural tube itself.

Although it first appeared that motor neuron and floor plate induction would require different signals, one diffusible and the other contact dependent, a single molecule can account for both processes (for a review, see Jessell, 2000). *Sonic hedgehog (Shh)* is expressed first in the notochord and then in the floor plate and can elicit ectopic floor plate and motor neuron differentiation when misexpressed in the dorsal neural tube. Similarly, an activated form of Smoothened, the signal-transducing component of the Shh receptor, acts in cell autonomous fashion to produce ventral cell types ectopically. Explant studies have shown that the choice of cell fate by progenitor cells is influenced by the concentration of the diffusible Shh protein to which they are exposed: threefold incremental

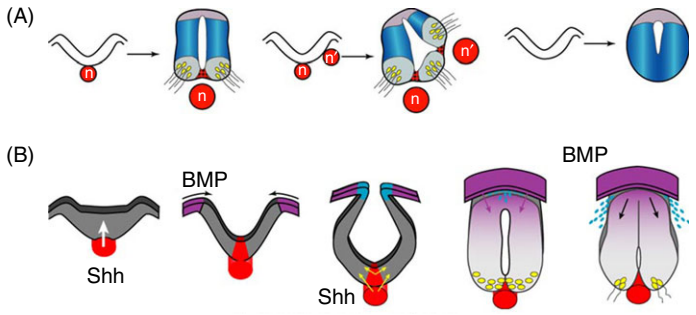

FIGURE 13.12 (A) Influence of ventral midline signals on spinal cord pattern. Cross sections through the developing chick spinal cord at the neural plate stage and resulting spinal cord, showing the effect of adding or removing notochord. (Left) Normal development: the floor plate (red) develops above the notochord (n) and motor neurons (yellow) differentiate in the adjacent ventrolateral region of the neural tube; *Pax6* (blue) is expressed in more dorsal regions. (Center) Grafting a donor notochord (n′) alongside the folding neural plate results in formation of an additional floor plate and a third column of motor neurons. *Pax6* expression retreats from the transformed region. (Right) Removing the notochord from beneath the neural plate results in the permanent absence of both floor plate and motor neurons in the region of the extirpation. *Pax6* expression extends through the ventral region of the cord. (B) Sequence of stages in the formation of DV pattern in the spinal cord and hindbrain. Notochord-derived Shh protein (red) induces differentiation of the floor plate, which also expresses *Shh*. BMPs (dark blue) are expressed in epidermal ectoderm adjoining the neural plate. As the neural plate closes, neural crest cells individuate (light blue) at the junction between neural and epidermal ectoderm. At the early neural tube stage, *Isl1*–expressing motor neuron precursors (yellow) appear close to the floor plate and neural crest cells leave the dorsal tube and midline ectoderm through breaks in the basal lamina. *BMP* expression transfers to the dorsal neural tube Finally, motor neurons differentiate in the ventral cord. White and yellow arrows denote Shh signaling; black and purple arrows denote Bmp signaling.

changes in Shh concentration can result in the generation of five distinct classes of ventral neural tube cell types *in vitro*, including, at the higher end of the range, motor neurons, V3 interneurons, and floor plate cells (Fig. 13.13B). Midventral neural plate cells that are contacted by the notochord are thus likely to be exposed to a high local concentration of Shh, exceeding the threshold for floor plate induction, whereas the lower levels of Shh that diffuse from floor plate are sufficient to induce motor neuron and ventral interneuron differentiation, but insufficient to induce the floor plate. Antibodies that block Shh activity abolish the induction of ventral cell types, showing that Shh is necessary as well as sufficient for establishing the ventral polarity of the neural tube. Importantly, the presumed declining ventral-to-dorsal gradient of Shh protein has been demonstrated in mouse embryos engineered to express a fluorescent-labelled form of Shh (Shh:GFP) from the *Shh* locus (Chamberlain, Jeong, Guo, Allen, & McMahon, 2008).

The ability of midline signals to influence development of the ventral neural tube is not restricted to the spinal cord. In addition to inducing motor neurons and floor plate in the hindbrain and midbrain, midline signals also are involved in the development of AP region-specific neuronal subpopulations. Serotonergic neurons of the hindbrain raphé nucleus form close to the hindbrain floor plate and dopaminergic neurons of the substantia nigra develop within the floor plate (Ono et al., 2007). Both cell types can be induced to form in competent neuroepithelium by the notochord, floor plate, or Shh protein. The issue of how ventral midline signaling can elicit different responses at different AP positions is considered later.

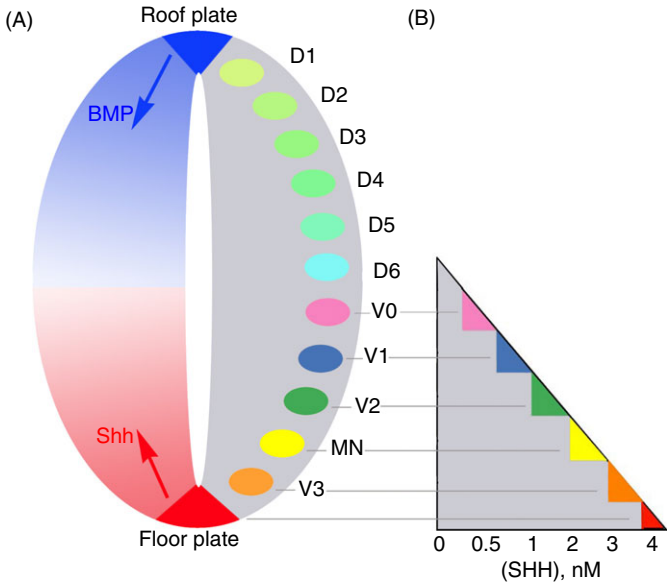

FIGURE 13.13 (A) Formation of different cell types at different DV positions in the spinal cord. Sonic hedgehog (SHH) is responsible for generating interneuron (V0–V3) and motor neuron (MN) diversity in the ventral half of the spinal cord, whereas BMPs are responsible for interneuron (D1–D6) diversity in the dorsal half. SHH protein (red), produced by the floor plate, and BMP protein (blue) by the roof plate act as counteracting graded signals, inducing different cell types at different DV positions *in vivo*. (B) Recombinant SHH protein has been shown to induce a similar range of responses and at different concentrations *in vitro*.

Dorsal Organizers

In genetically or surgically notochordless animals, dorsal markers are expressed in the ventral spinal cord, showing that cell pattern in the dorsal half of the spinal cord

does not require notochord signals. However, dorsal cell types such as neural crest and roof plate, do not develop by default, but are induced by an interaction that initially takes place between the neurectoderm and the flanking epidermal ectoderm when the two epithelia are still contiguous (Fig. 13.12B). This dorsalizing activity appears to be mediated by multiple types of Wnt and BMP proteins, which are expressed in the dorsal ectoderm and can mimic the ability of epidermal ectoderm to induce neural crest cells and roof plate differentiation. As for the ventral neural tube, where initial Shh activation is passed on to the floor plate by homeogenetic induction, so for the dorsal neural tube where BMPs are subsequently expressed in the roof plate and dorsal neural tube itself. BMP signaling is then responsible for inducing the six types of interneuron (dI1-6) that differentiate at progressively more ventral positions in the dorsal half of the cord (Fig. 13.13A; Helms & Johnson, 2003; Liu & Niswander, 2005).

The DV axis is thus patterned by two counteracting gradients, emanating from the ventral and dorsal poles. At either pole, the transfer of signal molecule expression from notochord or epidermal ectoderm to the neuroepithelium attends the physical separation of the neural tube from the initial source, presumably ensuring a more precise control of concentration within the tube.

Definition of DV Pattern by Differential Homeobox Gene Expression

At the time of neuronal differentiation, each of the five zones of neuronal cell types in the ventral neural tube is defined by the combinatorial expression of homeobox genes. These genes are either induced (*Nkx2.2*, *Nkx6.1*) or repressed (*Pax6*, *Pax7*, *Dbx1*, *Dbx2*) at defined concentrations of Shh protein (Fig. 13.14). The differential responses to a graded Shh signal are thought to set up a pattern of fuzzy zones in the ventral half of the cord, which is later refined and sharpened by cross-repressive interactions between the homeobox genes themselves (Briscoe & Ericson, 2001): the expression borders of complementary genes are seen to move following gain and loss of function of the opposing gene, as for *Otx2/Gbx2* at the MHB. Such shifts in the expression domains of these and other homeobox genes result in corresponding and predictable changes in neuronal identity, demonstrating the critical role of these homeobox genes as determinants of cell fate.

As for the AP axis, where positional determinants of identity are conserved with *Drosophila*, there are also striking similarities for the DV axis. For example, the homologue of *Nkx2.2*, *vnd*, is expressed close to the ventral midline of the fly embryo and is required for establishing the identity of its ventral-most neuroblasts (Cornell & von Ohlen, 2000).

Summary

Patterned cell differentiation along the DV axis of the neural tube involves the initial medial–lateral polarization of the neural plate and the later generation of distinct cell types at different DV positions under the spatial control and coordinate actions of an SHH-mediated ventralizing signal from the notochord (later from the floor plate) and BMP-mediated dorsalizing signals from the epidermal ectoderm (later from the roof plate). SHH is both necessary and sufficient for inducing a range of ventral cell types, including floor plate cells, motor neurons, and interneurons, at different concentrations; it therefore has the prime characteristic of a morphogen. Patterning along the entire DV axis involves the intersection of opposing signals emanating from the two poles: BMPs act to limit the ventralizing activity of SHH, whereas SHH acts to limit the dorsalizing activity of BMPs.

Intersection of AP and DV Patterning Mechanisms

The early inductive signals that establish DV cell fate appear to be similar along the entire epichordal neuraxis.

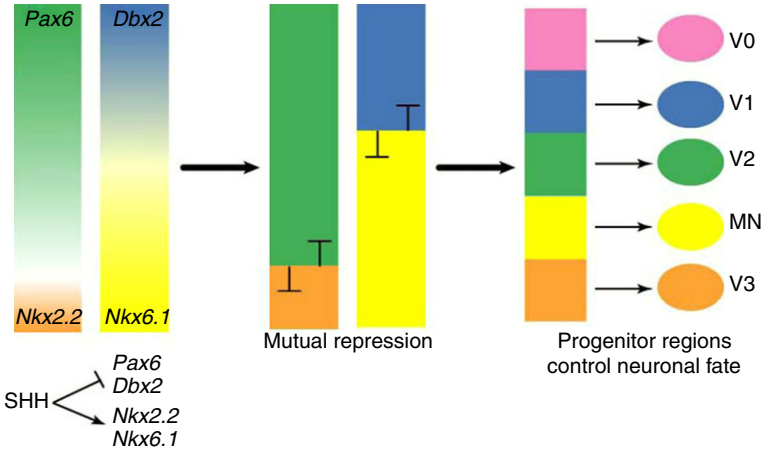

FIGURE 13.14 Model for ventral neural patterning. (Left) Graded SHH signaling from the ventral pole induces new expression of some homeobox genes (e.g., *Nkx2.2, Nkx6.1)* and represses the existing expression of others (e.g., *Pax6, Dbx2*). (Center) Cross-repressive interactions between pairs of transcription factors sharpen mutually exclusive expression domains. (Right) Profiles of homeobox gene expression define progenitor zones and control neuronal fate. *From Briscoe and Ericson (2001).*

However, at a same DV position, there are marked differences in the identity of neurons at different AP positions, such as between oculomotor neurons and dopaminergic neurons of the midbrain and branchiomotor neurons of the hindbrain. That these distinct cell types arise in response to apparently similar levels of Shh signaling suggests that the choice of fate depends on the competence of the responding tissue. Shh must act within the context of previously established AP positional cues and previously specified AP positional values (Simon, Hornbruch, & Lumsden, 1995).

DV Pattern in the Telencephalon

The DV axis of the telencephalon is conspicuously subdivided into a dorsal pallial region, which becomes the neocortex and archicortex (hippocampus) in mammals, and a ventral subpallial region that forms the basal ganglia. While the pallium remains a sheet-like roof over the lateral ventricles, proliferation in the subpallial region thickens the wall considerably, forming two swellings from which the basal ganglia arise: the lateral ganglionic eminence (LGE), which gives rise to the striatum, and the medial ganglionic eminence (MGE), which produces the globus pallidus. The pallial and subpallial moieties of the telencephalic vesicle are segregated by a longitudinal boundary, which marks the domain border of several dorsoventrally expressed developmental control genes and which may also act as a lineage restriction boundary, at least during early stages of development (Fig. 13.15; Campbell, 2003; Schuurmans & Guillemot 2002).

The telencephalon is devoid of peripherally extending motor neurons, has no floor plate, and is not underlain by notochord. The absence of these ventral and midline structures raises the question of how the bilateral organization of the forebrain and the differentiation of its ventral cell types are controlled. It appears, however, that even in this terminal expansion of the central nervous system a common mechanism is used for ventral patterning. SHH expression spreads rostrally in planar fashion from the diencephalic floor region into the ventral telencephalon, where it induces expression of the transcriptional mediator *Nkx2.1*, characteristic of the MGE (Fuccillo, Joyner, & Fishell, 2006). SHH from the MGE is subsequently required for generation of the more lateral region, the LGE, though some LGE markers, such as *Gsh* are still expressed in *Shh* null mutants (Khotz, Baker, Corte, & Fishell, 1998). The different responses of medial versus lateral regions appear to reflect a change in the competence of telencephalic cells with time, with the resulting DV pattern reflecting the delay in reception of the SHH signal rather than a difference in SHH concentration. BMP and WNT signals emanating from the roof plate and medial pallium regulate tissue growth and the expression of dorsal telencephalic markers such as *Lhx2*, *Emx1*, and *Emx2* (Campbell, 2003).

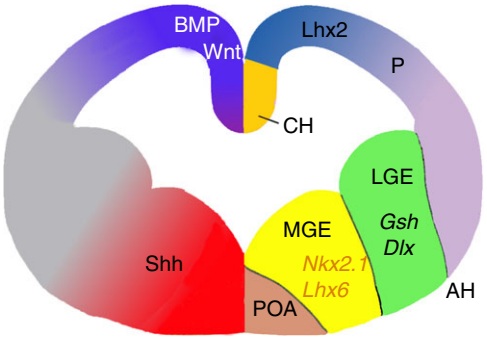

FIGURE 13.15 Cross section of the telencephalon of an early mouse embryo, with signaling on the left side with DV regions and gene expression on the right side. Ventromedial patterning of medial and lateral ganglionic eminences (MGE, LGE) is influenced by SHH signaling from the ventral midline. BMPs and WNTs, produced by dorsomedial regions (roof plate, and medial pallium) and later from the cortical hem (CH), are implicated in pallium (P) specification. AH, anti-hem; POA, preoptic area.

During early forebrain development, the telencephalic roof plate sinks into the prosencepahlic lumen, creating bilateral cortical hemispheres and giving rise both to the choroid plexus medially and to the cortical hem bilaterally. Immediately adjacent to the hem (Fig. 13.15), which expresses BMPs and Wnts, the pallium forms hippocampus and the cerebral cortex forms lateral to that. Genetic ablation of the telencephalic roof plate in mice results in a severe undergrowth of the cortical primordium, suggesting a nonautonomous effect of the hem on cortical specification and proliferation (Monuki, Porter, & Walsh, 2001).

Wnt signaling specifies dorsal identity at the earliest stages of telencephalic development (Gunhaga et al., 2003) and at later stages, Wnt secretion from the cortical hem is required specifically for hippocampus differentiation (Galceran, Miyashita-Lin, Devaney, Rubenstein, & Grosschedl, 2000). The boundary between the pallium and the subpallium (PSB) expresses Wnt inhibitors (secreted Frizzled-related proteins, SFRPs), raising the possibility that a gradient of Wnt activity is established across the pallium between the hem and the PSB (which has also been called the "anti-hem") (Assimacopoulos, Grove, & Ragsdale, 2003; Frowein, Campbell, Götz, 2002). The homeobox gene *Lhx2*, expressed in the pallium between the hem and anti-hem, in the large region destined to become neocortex, has been shown to act as a cell-autonomous determinant of cortical fate: when *Lhx2* is mutated in mice (Fig. 13.16), the *Wnt2b*-expressing hem and the *Dbx1/SFRP*-expressing anti-hem expand in place of neocortex (Mangale et al., 2008).

Patterning the Cortex

The adult mammalian neocortex comprises a very large number of anatomically and functionally discrete areas—more than 50 in humans. One difficulty in addressing the

question of how the elaborate areal pattern of the neocortex develops is that it is virtually uniform in structure and cytoarchitecture from one end to the other, at least in lower mammals such as the mouse and rat. Furthermore, few known developmental control genes were known to be expressed early enough to be candidate determinants for each, or indeed any of these prospective areas. Thus, it was long thought that the areal pattern must be imposed on the neocortex by extrinsic elements, principally via the thalamic afferents that penetrate the cortex in an area-specific manner. However, advances in gene discovery now reveal that the cortical neuroepithelium acquires regional pattern prior to afferent innervation and in a manner not unlike other regions of the neural tube, with transcriptional mediators being expressed in a graded fashion in response to local concentrations of morphogens diffusing from focal sources. The latter include the ANR, which secretes FGFs (see above, and Toyoda et al., 2010), and the Wnt-secreting cortical hem. It is likely that areal specification involves threshold levels of transcriptional control genes such as *Emx2* and *Pax6*, which are expressed in opposing gradients along the AP extent of the cortex (Fig. 13.17), and others such as *Lef1* (a mediator of Wnt signaling) that display graded expression from medial to lateral. In support of this, loss of *Emx2* function shrinks visual cortex (posterior) and expands sensory (mid) and motor (anterior) areas, whereas loss of *Pax6* function results in the opposite alteration. Furthermore, an ectopic source of FGF8 at the posterior end of the cortex results in a partial mirrored duplication of anterior cortical areas (Fukushi-Shimogori & Grove, 2001). Thus, in contradiction to longstanding ideas, cortical pattern is probably set up early in the parent neuroepithelium and the role of thalamic innervation is in secondary reinforcing, refining, or modifying of this initial pattern (O'Leary & Nakagawa, 2002; Ragsdale & Grove, 2001).

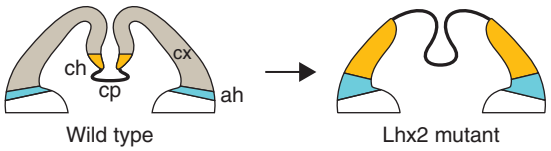

FIGURE 13.16 Schematic showing the effect of *Lhx2* mutation on pallial fate, in cross section through the dorsal telencephalon. When Lhx2 function is ablated, the neocortex (cx) fails to form and its pallial progenitor region instead forms expanded choroid plexus (cp), cortical hem (ch), and anti-hem (ah). *Data from Mangale et al. (2008).*

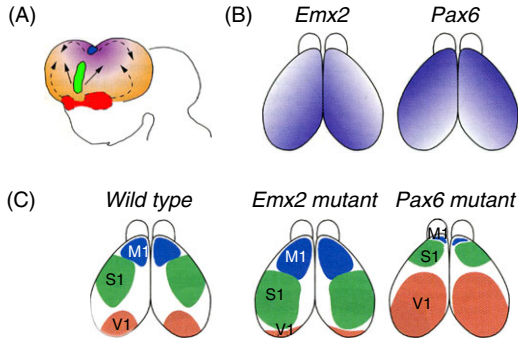

FIGURE 13.17 (A) Regulation of neocortical pattern by local signals: FGF8 (green) from the anterior neural ridge (ANR), Wnts and Bmps (blue) from the cortical hem; and SHH (red) from the medial ganglionic eminence. (B) These and other signals are thought to induce expression of the transcriptional factors *Emx2* and *Pax6* in opposed gradients that control regional identity. (C) Loss of function of either of these genes results in a specific shift of area identity from wild type (left), implying that visual cortex (V1) is specified by *Emx2* [high], *Pax6* [low] and that of motor cortex is specified by *Emx2* [low], *Pax6* [high]. *From O'Leary and Nakagawa (2002).*

CONCLUSIONS

Neural-inducing factors and modifiers produced during gastrulation have a basic role in establishing an initial crude AP regional identity in the neural plate that emerges from the dorsal surface of the embryo toward the end of this period. Abrogation of Wnt signaling, by depletion of ligand or blockade of signal transduction pathways, is important in conferring anterior neural identity. Wnts, Fgfs, and RA cooperate to posteriorize the neuraxis. The resulting coarse-grained AP pattern is subsequently refined by the action of local organizers. Acting on both the AP and DV axes, local organizers exert regional growth control and either induce or repress transcriptional mediators of regional fate. These mediators, in turn, may also interact among themselves, sharpening domains of action by cross-repression. The combined processes of segmentation and compartition provide an alternative or perhaps additional mechanism for sharpening gene expression borders and cellular domains. These events result in the precise delineation of regions and subregions. Although we tend to think of neuraxial patterning as a series of discrete steps leading to greater refinement, it is a continuous process that extends over a protracted period of development and involves the repetitive use of signaling systems (e.g., RA, FGFs, SHH, BMPs, Wnts). We have also presented this subject as if pattern is acquired separately on AP and DV axes, whereas it is clear that cell specification on the DV axis must intersect with and act on already existing AP positional values. It is also clear that patterning mechanisms must be integrated with those that control neurogenesis, a topic that is considered in Chapter 15.

CHAPTER

14

Cellular Determination

INTRODUCTION

There are a huge variety of cell types in the nervous system with completely different shapes, patterns of connectivity, neurochemistry, and physiological characteristics. The distribution of different types of neuron follows a highly invariant pattern in a given species. Neurons located at a given position within the nervous system are always the same type. In vertebrates, this is true on the level of populations of neurons (e.g., cells of layer III of the cortical area 17 are glutaminergic pyramidal cells projecting to cortical areas 18 and 19); in many invertebrates, it is true even on the level of individual, uniquely identifiable cells. Experimental studies carried out over the last few decades have provided substantial progress in understanding how the right types of neuron develop in the right place in the brain.

Neurons are specified gradually by a series of fate choices that begin with their distant progenitors who make the first decision between neural and ectodermal fates. Neural progenitors, those dividing cells that are determined to give rise to neurons and glia, arise from a specialized region of the ectoderm called the neurectoderm, known in vertebrates as the neural plate (Fig. 14.1). A highly conserved molecular network, discussed in Chapter 13, specifies the size and position of this region. The neural plate rolls or folds into the neural tube and detaches from the overlying epidermis. The neural tube consists of a continuous pseudostratified neuroepithelium that lines, on its apical surface, an inner lumen, called the ventricle (Fig. 14.1C, D). Neuroepithelial cells of the neural tube begin dividing symmetrically at the apical surface or ventricular zone, producing two more cells that divide (Fig. 14.1C′). After a period of time, during which this doubling process leads to an exponential expansion of cell numbers, these neural progenitors may begin to divide asymmetrically or spin off postmitotic daughters that differentiate and other daughters that divide again. Finally, at the end of neurogenesis, cell divisions lead only to differentiating daughters. The number of cells in any part of the nervous system is thus largely governed by the proliferative potential and division patterns of the neural progenitors.

Once a cell has exited the cell cycle, a newly born precursor must make a number of other decisions: whether to become a neuron or a glial cell, whether to be excitatory or inhibitory, what shape to take, what partners to connect with, and so forth. It is important to understand that much of what we know about this topic comes from work in invertebrate species such as *C. elegans* and especially the fruit fly, *Drosophila melanogaster*. Progenitors of the central nervous system of *Drosophila*, called neuroblasts (the equivalent of neuroepithelial cells in vertebrates), separate from the neurectoderm and move inside the embryo as individual cells (Fig. 14.1G). Mitotic divisions of *Drosophila* neuroblasts are asymmetric throughout development. Thus, each neuroblast divides unequally into one large and one small daughter cell. The large cell remains as a neuroblast and continues to divide asymmetrically for a number of rounds (Fig. 14.1G′). The small cell, called the ganglion mother cell (GMC), typically divides one more time and both of its daughter cells differentiate into mature neurons.

In this chapter, we begin to explore the molecular and cellular aspects of determination, such as the genes that specify neural versus nonneural fate, and how position and time of birth shape a neuron's fate as well as the mode of division of its parental cell. Running through all this is a network of transcription factors that influence almost every aspect of a neuron's specific identity. We will then discuss how these factors might work together and go through several well studied examples of neuronal determination in which we see them at work. These include neurons versus glia, the sensory cells of the peripheral nervous system, the retina, the spinal cord, and finally the cerebral cortex.

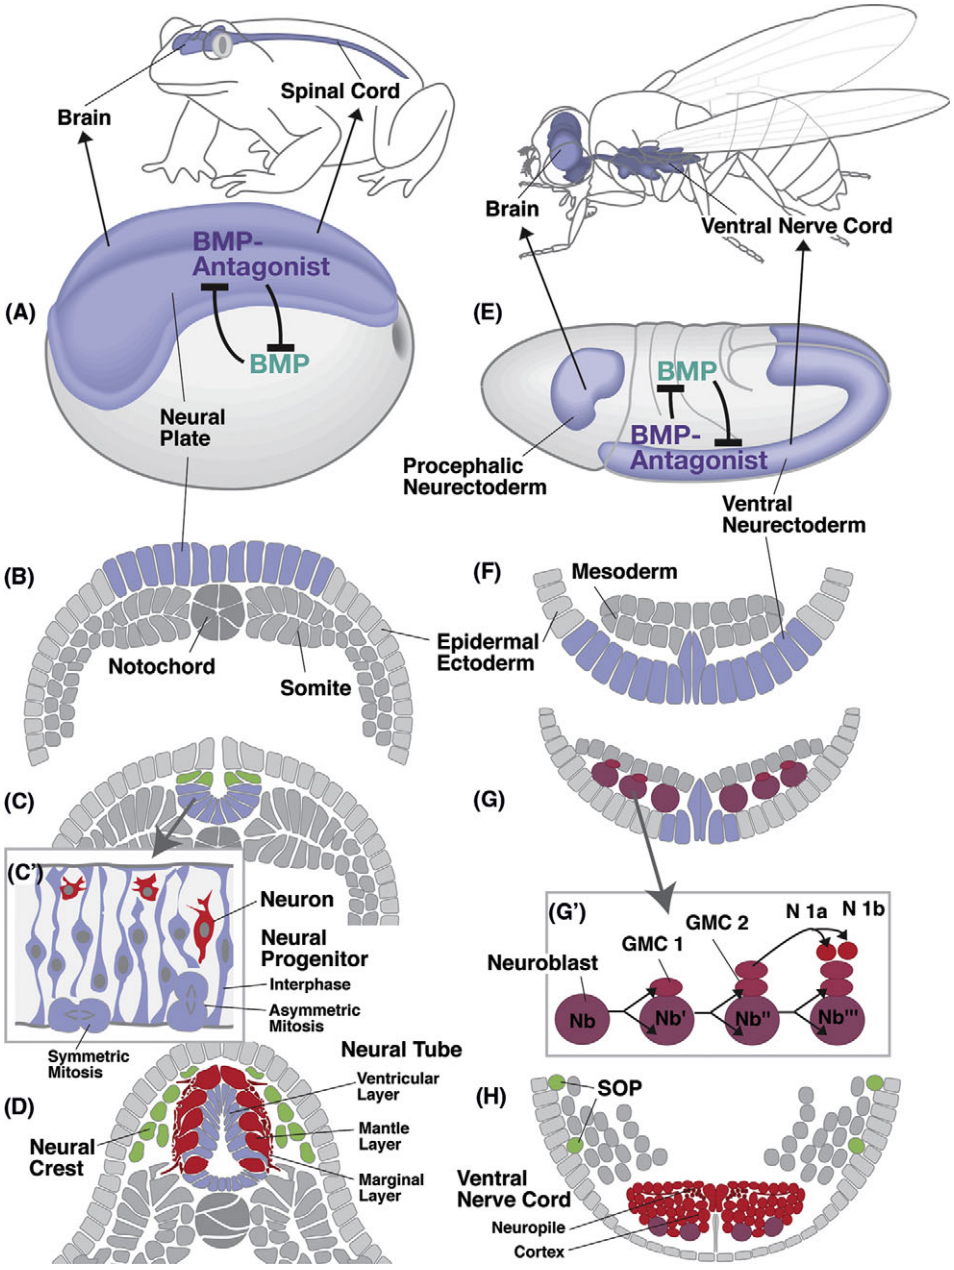

FIGURE 14.1 Synopsis of early neural development in vertebrates (example: the amphibian *Xenopus laevis*; A–D) and insects (example: the fruitfly *Drosophila melanogaster*; E–H). (A and E) Dorsolateral views of embryos at the onset of neurulation. The neurectoderm is shaded light blue. The expression of the signal Bone Morphogenetic Protein (BMP) and its antagonists is indicated. (B and F) Schematic cross sections of embryos depicted in (A and E). (C and G) Cross sections at a later stage when neurulation is well under way. In vertebrates, the neural plate folds in to become the neural tube. Cells at the junction between the neural tube and the epidermal ectoderm (green) form the neural crest, which gives rise to the peripheral and autonomic nervous systems. The neural tube is a proliferating neuroepithelium (C'); symmetric mitoses increase the number of epithelial neural progenitor cells, asymmetric mitoses result in daughter cells that delaminate from the epithelium and become neurons (red). In insects, individual neural progenitors (neuroblasts; purple) delaminate from the neurectoderm. They divide in a stem cell mode (G'), producing stacks of daughter cells called ganglion mother cells (GMC). Each ganglion mother cell divides into two neurons (e.g., N1a and N1b). (D and H) Cross sections of late embryos in which some neurons (red) have differentiated. In vertebrates, these neurons form the mantle layer that surrounds the neuroepithelium, now called ventricular layer. Neurites gather at the outside of the neural tube (marginal layer). In insects neuronal cell bodies form an outer layer (cortex); neurites gather in the center, forming the neuropile. Progenitors of the peripheral nervous system [sensory organ progenitors (SOPs); green] segregate from different locations in the epidermis.

NEUROGENESIS

Neurogenesis proceeds quite differently in different parts of the neural primordium. For example, neuroepithelial cells in the anterior part of the vertebrate neural tube (which includes the forebrain) undergo many more rounds of division than those of the posterior part (spinal cord). In addition, the maturing neurons have distinct phenotypes and establish different types of connections depending on where they are located. When pieces of neural tube are transplanted to new positions, features such as proliferative potential and cellular phenotype are often carried to the new position, implying that, in the neural primordium, intrinsic determinants profoundly influence the fate of neural progenitors. These determinants subdivide the neural primordium into a "geographic map" with many different domains, each one characterized by a unique identity. The mechanisms underlying the spatial regionalization, discussed in more detail in Chapter 13, are intricately involved in neural fate specification.

Along its anterior-posterior axis the neural tube is subdivided into transverse domains that give rise to morphologically defined partitions of the CNS, including the spinal cord, hindbrain, midbrain, and forebrain (Fig. 14.2B). Each of these major sections of the neural tube becomes further

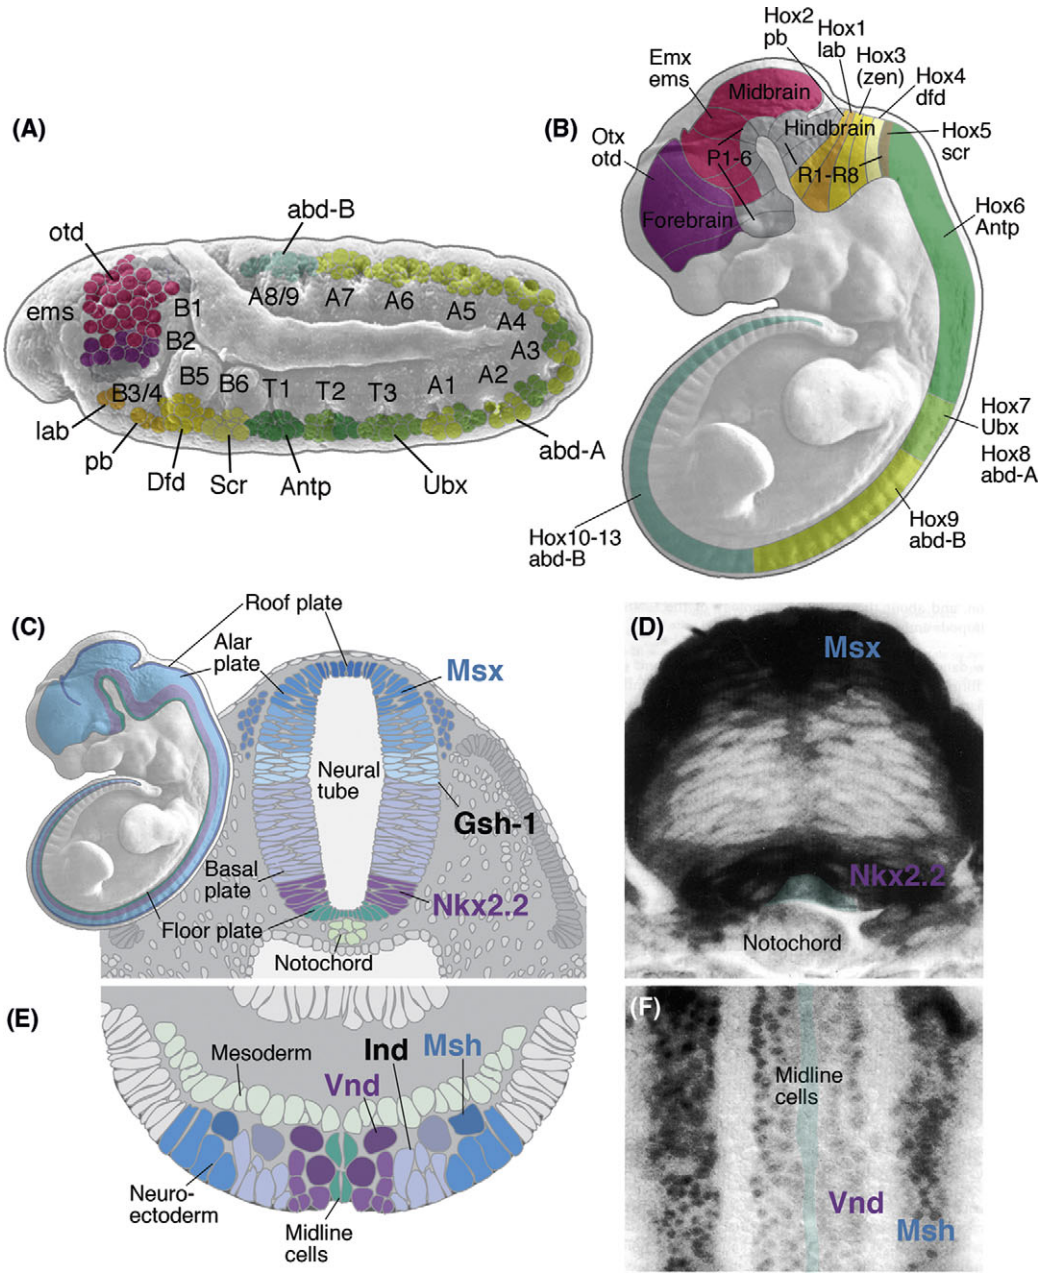

FIGURE 14.2 Specification of regional identity of the neural primordium. (A and B) Homeobox genes control regional identity along the antero-posterior axis. (A) *Drosophila*. The neurectoderm and neuroblast layer is subdivided into a series of neuromeres, each of which gives rise to a segmental ganglion. Transcription factors of the Hox family are expressed in blocks of neuromeres and provide neuroblasts with a segment-specific identity. In the segments of the abdomen (A1–A9), thorax (T1–T3), and posterior head (B3–B6) genes of the Hox complex are expressed (*lab, pb, Dfd, Scr, Antp, Ubx, AbdA, AbdB*); head gap genes (*otd, ems*) are found in the anterior head (B1–2). B: Mouse. Homologous Hox genes and Head gap genes are expressed in sets of vertebrate neuromeres in the same antero-posterior sequence (P1–P6: prosomeres of forebrain; R1–7: rhombomeres of hindbrain). Otx is expressed in the dorsal telencephalon (P1–3) that gives rise to cerebral cortex. Emx defines alar plate of prosomeres 4–6, that will form the dorsal thalamus and ventral thalamus, as well as the dorsal midbrain. Hox genes are expressed in hindbrain and spinal cord. Note that for the Hox genes, the level indicated represents the anterior boundary of a wider domain that extends posteriorly for an unspecified distance. (C–F) Regional identity along the dorso-ventral axis. (C and D) Vertebrate. The neural tube (shown in C for mouse) is subdivided into four domains, the floor plate, basal plate, alar plate, and roof plate. Floor plate and roof plate do not give rise to neurons. The basal plate produces motoneurons and interneurons. Interneurons formed by the alar plate are the target of sensory input to the spinal cord and brain. The Homeobox gene Nkx2.2 is expressed in the ventral part of the basal plate; Msx is expressed in the dorsal part of the alar plate. The expression of these two genes in a cross section of the zebrafish spinal cord are shown in (D). A third homeobox gene, Gsh-1, is expressed at a lateral level in between Msx and Nkx2.2. (E and F) Homologs of these genes are expressed in the same dorso-ventral succession in *Drosophila*. The schematic cross section of the fly neurectoderm (E) shows that the Nkx2.2 homolog Vnd forms a medial stripe adjacent to the midline cells; Ind (homolog of Gsh-1) and Msh (homolog of Msx) are expressed at an intermediate and lateral level, respectively. Panel F shows a ventral view of a whole mount *in situ* preparation demonstrating the expression of Vnd and Msh.

partitioned into neuromeres, each neuromere delineated by its own peripheral nerve. In the spinal cord of mammals, one distinguishes 7 cervical (neck) neuromeres whose neurons innervate the upper extremity, 12 thoracic neuromeres, 5 lumbar neuromeres belonging to the lower extremity, and a variable number of sacral neuromeres. Seven or eight neuromeres are present in the hindbrain, where they are called rhombomeres. Similar to spinal neuromeres, rhombomeres are characterized by the pattern of peripheral nerves they emit. The midbrain is thought to represent a single neuromere. The forebrain possesses no peripheral nerves; however, based upon other morphological landmarks, as well as the expression of molecular markers, it is subdivided into six prosomeres. The posterior three prosomeres (P4, P5, and P6) give rise to the diencephalon, while prosomeres 1, 2, and 3 form the telencephalon. The vertebrate neural tube is divided in the dorsoventral axis into four longitudinal domains, called the floor plate, basal plate, alar plate, and roof plate. The basal plate next to the floor plate includes all motor neurons. In the lateral wall of the neural tube, a furrow called sulcus limitans separates the basal plate ventrally from the alar plate dorsally. The alar plate later gives rise to the dorsal sensory column. Both the anterior-posterior and the dorsal-ventral axes of the neurectoderm are regulated by the expression of conserved homeodomain transcription factors (see Chapter 13). Thus, in both vertebrates and invertebrates, these spatially arrayed transcription factors of the anterior-posterior and the dorsal-ventral axes collaborate to divide the developing nervous system into grids of molecular coordinates that specify the positional identity of neural progenitors down to the level of small groups or, in some invertebrates, even single cells.

Neurogenesis is patterned in time as well as space. This is exemplified in *Drosophila* neuroblasts, which go through a program of proliferation where each neuroblast gives rise to a series of distinct GMCs. The first GMCs of a neuroblast lineage tend to lie deeper in the CNS and usually generate neurons with long axons, whereas the later arising GMCs stay closer to the edge of the CNS and produce neurons with short axons. In the stages when the first GMCs are generated, most neuroblasts express *Hunchback (Hb)*, and GMCs that arise at this time inherit this *Hb* expression. Later, the same neuroblasts turn off *Hb* and express *Krueppel (Kr)* instead, and GMCs generated at this stage inherit *Kr* expression. Experiments in which *Hb* or *Kr* is eliminated or expressed at the wrong time lead to predictable switches in the fates of early and later-born descendants of these neuroblasts (Isshiki, Pearson, Holbrook, & Doe, 2001). It is likely that a temporal succession of transcription factors like those in *Drosophila* also patterns neurogenesis in vertebrates (Elliott, Jolicoeur, Ramamurthy, & Cayouette, 2008).

In many CNS tissues there is a clear relationship between cell birth and cell fate. For example, during the development of the *Drosophila* nervous system, GMCs and immature neurons form a stack on top of the neuroblast from which they originated. Postmitotic neurons generally do not migrate, so the progeny of a neuroblast remain spatially close to one another, with the position of each neuron dependent on the position of the neuroblast and the time at which it was born. Thereby, a two-layered cortex-neuropil architecture typical of the mature ganglion is generated (Fig. 14.1H). The histogenesis of the six-layered, mammalian cerebral cortex is also easy to describe. It is "inside out" with the earliest cells to exit the cell cycle forming the deepest layers and the last cells to be born forming the most superficial layers. While intrinsic temporally controlled transcription factors play a key role in regulating histogenesis, it is also becoming clear that environmental factors can also influence histogenesis. For example, in the retina, the first cells to be born are retinal ganglion cells, which by negative feedback influence the next born cells to choose a different fate—by downregulating the transcription factors that are important for the determination of retinal ganglion cells. There is also a rich dialogue between factors that drive cell cycle exit and cell fate, such that some transcription factors (see below) have direct effects on the cell cycle, and some cell cycle exit factors influence cell fate (Ohnuma & Harris, 2003).

THE PRONEURAL AND NEUROGENIC GENES

In the developing nervous system of *Drosophila*, the functions of the genes known as the proneural and the neurogenic genes, which have proved to be so important for the initial differentiation of neurons in all animals, were first elucidated. The neurectoderm of the *Drosophila* embryo is a mixed population of cells. Only some of these cells become neuroblasts; others develop as dermoblasts. Cell–cell interactions that take place within the neurectoderm define the number and pattern of neuroblasts. Experimental and genetic studies suggest a two-step mechanism for this process (Campos-Ortega, 1995). First, discrete groups of neurectodermal cells are made competent to become neuroblasts. These groups of cells, called proneural clusters, represent "equivalence groups" in which all cells initiate a neural rather than an epidermal fate (Fig. 14.3A, B). In *Drosophila*, a group of proneural genes expressed in the proneural clusters is responsible for making these cells competent to become neural progenitors. In a second step, cells of the proneural cluster interact to sort out which of them will become neurons and which will fall back to become dermoblasts (Fig. 14.3A). As the first cell in each cluster begins to differentiate as a neuroblast, it sends out inhibitory signals to its neighbors, inhibiting them from also becoming neuroblasts. This can be demonstrated by ablating a developing neuroblast with a laser micro-beam,

as what happens next is that a neighboring cell of the equivalence group, which would otherwise have developed into dermoblast, switches its developmental program and replaces the lost neuroblast. It is the neurogenic genes that mediate this inhibitory cell–cell interaction.

Most proneural genes are transcription factors of the basic helix-loop-helix (bHLH) family. Loss of proneural gene function leads to a reduction in neuron production. Misexpression of proneural genes often has the opposite phenotype. For example, misexpression of proneural gene mRNA in vertebrates leads to an increased number of neural progenitor cells in the neural tube or transforms of epidermal cells into neurons (Fig. 14.3D, E). The neurogenic genes encode a cell communication mechanism that

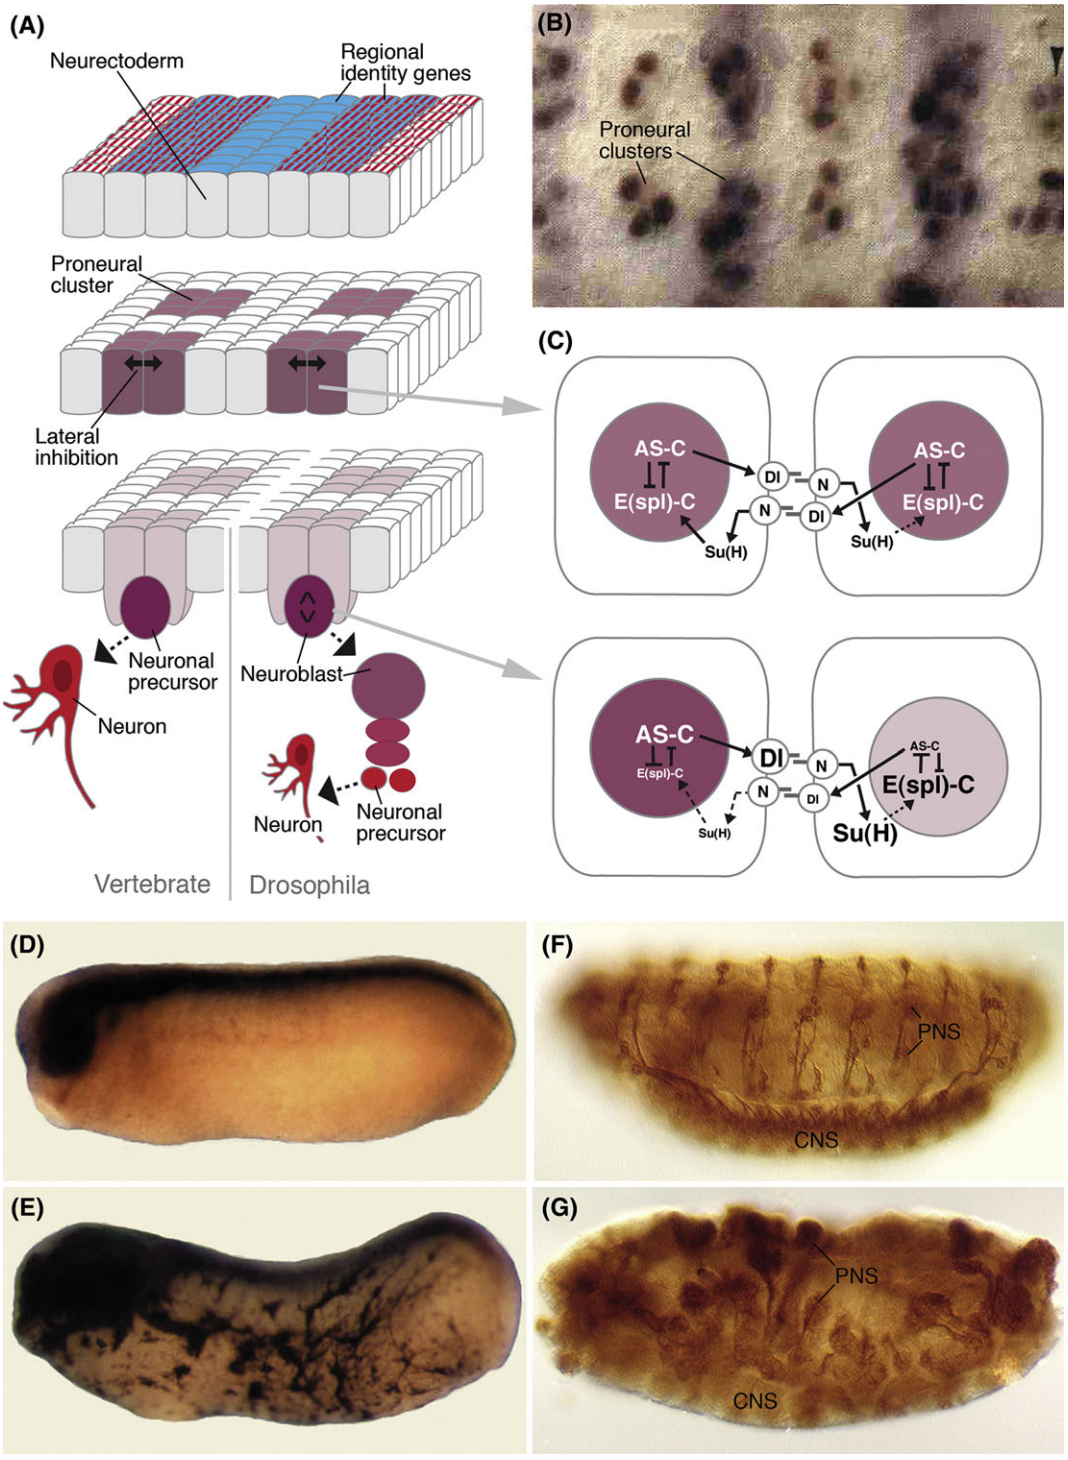

FIGURE 14.3 Function of proneural and neurogenic genes in neural development. (A) The sequence of events that leads to the segregation of individual neural progenitors (in insects) or neurons (in vertebrates). First, proneural genes are turned on in discrete cell populations, called proneural clusters (purple). In *Drosophila*, a number of genes (called "regional identity genes" in the diagram) have been identified. They are expressed in a distinct pattern of transverse and longitudinal stripes before proneural genes appear and are proven or likely factors to control the expression of proneural genes. Proneural genes in turn trigger different events in the proneural clusters. One outcome of their expression is a cell–cell interaction process, mediated by the neurogenic genes, that selects a single cell (or a smaller group of cells) from each proneural cluster. Only this cell continues along the neural pathway and segregates from the neurectoderm as a neuroblast (right side of panel; intense purple), which divides and produces a neural lineage (red); the other cells of the proneural cluster remain within the neurectoderm. In vertebrates (left side of panel), the entire neurectoderm (i.e., the neural plate/neural tube) is formed by neural progenitors. Here, the proneural/neurogenic gene cassette seems to select cells that become postmitotic and differentiate from other (neural progenitor) cells, which remain in the neuroepithelium and continue to proliferate. (B) Detail of proneural gene expression in the neurectoderm of the *Drosophila* embryo (*from Skeath & Carroll, 1992*). (C) Interaction between proneural and neurogenic genes in the *Drosophila* neurectoderm. The upper panel shows two cells of a proneural cluster in which proneural genes of the *achaete-scute* complex (AS-C) are expressed. Genes of the AS-C activate the expression of the signaling molecule Delta (Dl). Dl activates the receptor Notch (N) in neighboring cells; this leads to cleavage of the N molecule and the translocation of the cytoplasmic domain of N along with the transcription factor Suppressor of Hairless [Su(H)] to the nucleus, where they upregulate the expression of proteins of the Enhancer of split complex [E(spl)-C]. E(spl) initiates or maintains the development of an undifferentiated neurectodermal cell; at the same time, it directly inhibits the expression of AS-C genes, which promote differentiation of a cell as a neural progenitor or neuron. Imbalances introduced by an unknown mechanism into the levels of AS-C or E(spl)-C expression, respectively, are rapidly amplified (lower half of C) and lead to the segregation of a single neural progenitor (high levels of AS-C) from other cells that stay epithelial [high levels of E(spl)-C]. (D–G) The proneural gene turns epidermal cells into neurons. (D) A normal *Xenopus* embryo stained for the neural marker NCAM shows no staining in the epidermis. (E) A neuroD-injected embryo has NCAM-stained cells with neuronal morphology in the entire epidermis. (F) Wild-type *Drosophila* embryo labeled with the neuronal marker 22C10 contains discrete clusters of neurons forming the central nervous system (CNS) and peripheral nervous system (PNS). (G) Loss of the signaling molecule Dl causes a massive increase in neurons at the expense of epidermis.

acts to restrict the number of developing neurons. The neurogenic genes are also known as the Notch signaling pathway. The *Delta* and *Notch* genes encode membrane proteins that function as signal and receptor, respectively. Activation of Notch by Delta sets in motion a signal transduction cascade (Fig. 14.3C) that involves another neurogenic gene called *Suppressor of Hairless* in *Drosophila* or CBF-1 in mammals. Su(H)/CBF-1 forms a complex with the intracellular domain of Notch, which is released from the membrane when the pathway is activated. This complex moves into the nucleus and activates the *E(spl)-C* genes in *Drosophila* or the ESR and Hairy genes in mammals. These are bHLH transcription factors that antagonize and repress the proneural bHLH genes, completing an inhibitory feedback loop. In *Drosophila* loss of function of any of the neurogenic genes results in a higher number of neural progenitors, at the expense of dermoblasts (Fig. 14.3F, G). In mammals, loss of the Notch signaling pathway usually results in a higher number of a specific type of neuron at the expense of other types or at the expense of glial cells, depending on when and where this function is lost.

TRANSCRIPTIONAL HIERARCHIES AND NETWORKS

As we have seen above with respect to spatial and temporal determination as well as in the proneural and neurogenic pathways, many of the key players in neuronal determination are transcription factors. Transcription factors are protein products of genes that turn on or repress the transcription of other genes or themselves. We find again and again, whether in simple worms or mammals, that transcription factors have a central role in cell-fate determination. Often we find complex transcriptional hierarchies whereby one transcription factor induces the expression of another, which induces the expression of yet another. Such linear hierarchies often make fate decisions progressive and incremental. Such a drive forward in the cell fate progression is sometimes accomplished by a more complex network of transcription factors such that each one activates the next one and represses the previous one so that once a progenitor turns on a particular set of intrinsic factors, it can no longer revert to a more primitive state. Once a particular state is reached, transcription factors can work in interactive circuits that reinforce decisions by mutual cross-activation. But, as we shall also see, some networks of transcription factors work by cross-repression to sharpen boundaries between domains and to make sure that neighboring cells have distinct fates. We also note that a single progenitor will express a variety of transcription factors at any one time and that these can often act together as a combinatorial transcription factor code. Theoretically, a set of just 4 transcription factors on or off in a cell could specify one of 16 distinct fates. The developing nervous system expresses hundreds or even thousands of different transcription factors, so it isn't difficult to imagine how transcriptional codes could finely specify the fate of billions of distinct neuronal types.

ASYMMETRIC CELL DIVISION AND CELL FATE

Neural progenitors, as we mentioned above, can divide symmetrically to increase geometrically in number; or they divide asymmetrically, whereby one daughter cell

retains progenitor fate and keeps dividing, whereas the other one differentiates as a neuron. To produce these two distinct fates, intrinsic determinants expressed in the neural progenitors are often differentially distributed during asymmetric divisions. The mechanism controlling asymmetric divisions has been elucidated in great detail for the *Drosophila* neuroblasts, which, as we know, generate one large daughter neuroblast that will divide again and a small GMC that divides just once more to produce postmitotic neurons.

The machinery involved in asymmetric cell division (Betschinger & Knoblich, 2004) involves a number of proteins at the apical and basal cortex of the neuroblast (Fig. 14.4A). At the apical side of the neuroblast is a highly conserved complex of localized proteins called the "Par-complex." Members of this complex include the so-called Par proteins (Par3, Par-6) and atypical protein kinase C (aPKC). As the neuroblast delaminates from the neurectoderm, the Par complex maintains its polarized localization, defining the apical pole of the cell (Fig. 14.4A).

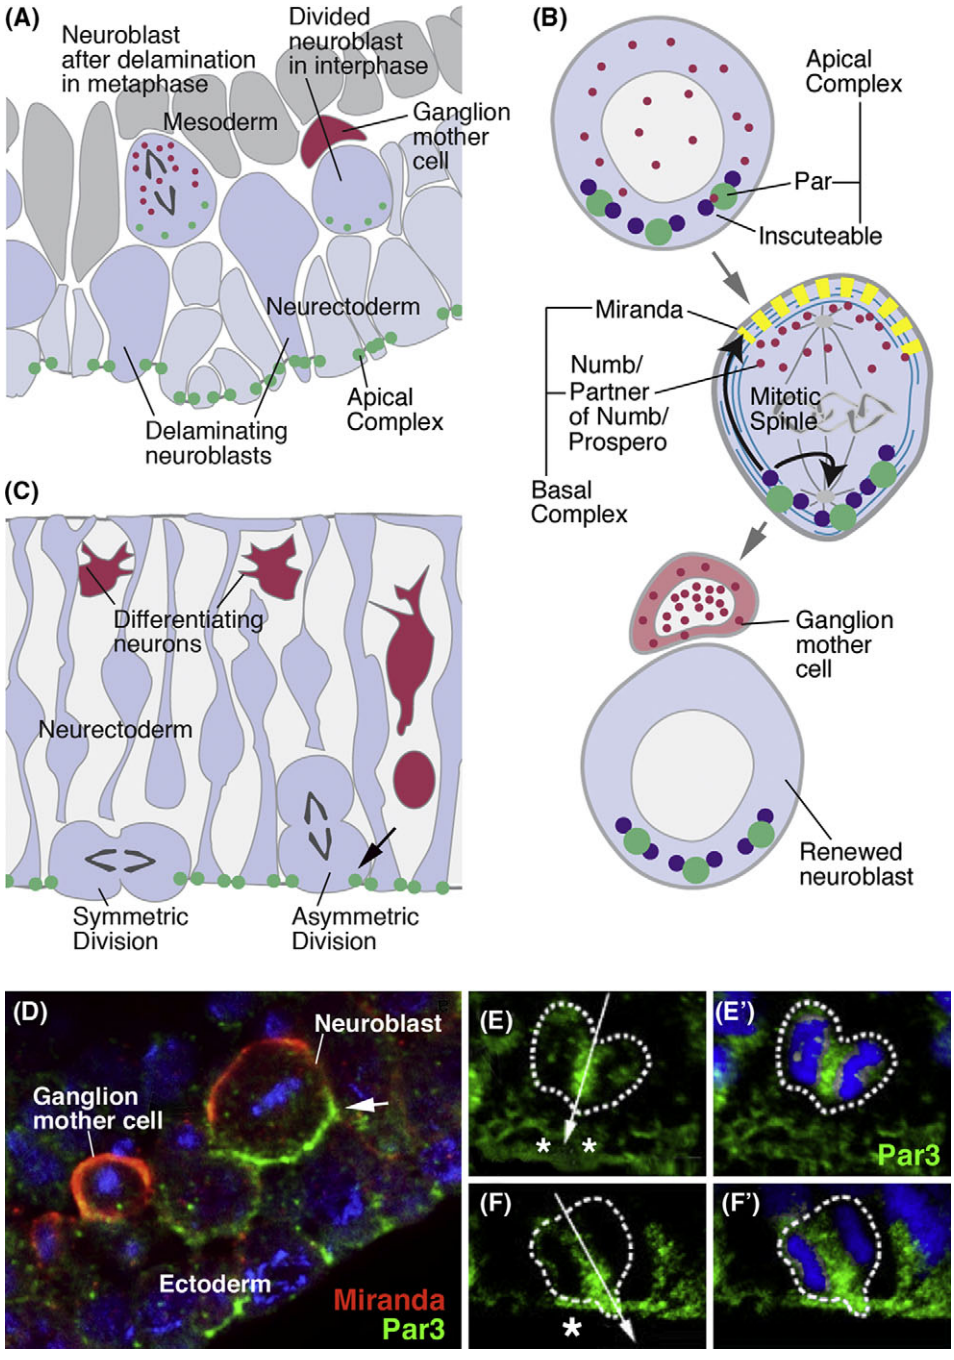

FIGURE 14.4 Control of asymmetric cell division in neural progenitors. (A) Schematic section of *Drosophila* neurectoderm at the stage of neuroblast delamination. Proteins of the apical complex (e.g., Par3, Inscuteable) are expressed apically in the neurectoderm and are carried interiorly by delaminating neuroblasts. (B) Schematic of neuroblast before (top), during (middle), and after (bottom) mitosis. The apical complex controls asymmetric distribution of intrinsic fate determinants, such as Numb and Prospero (red), by orienting the mitotic spindle vertically and by localizing the Miranda protein (yellow) basally. Miranda "traps" Numb at the basal pole of the dividing neuroblast (middle panel) and thereby channels it into the ganglion mother cell (bottom panel). (C) Schematic cross section of the mouse neuroepithelium. The mouse Par complex is also expressed apically in neural progenitors (green). In asymmetric divisions, Par 3 is maintained only in the epithelial daughter cell and not the delaminating neural precursor (arrow). (D) Confocal section of *Drosophila* neurectoderm (*from Wodarz & Huttner, 2003*). Expression of apical complex (represented by Par3, green) in ectoderm (arrowhead) and delaminated neuroblast (arrow). Miranda (red) is expressed basally; following neuroblast mitosis, it is restricted to ganglion mother cell. (E–F') Confocal sections of dividing neural progenitors in mouse neural tube (neurectoderm), showing expression of Par3 (*from Bultje et al., 2009*). (E, E') Symmetric division. Apical expression of Par3 (small asterisks) is inherited by both daughter cells. (F, F') Asymmetric division. Par3 ends up only in the one daughter cell to the left; the other daughter cell, lacking Par3, delaminates and adopts a neural fate.

During neuroblast divisions, the Par-complex recruits another group of proteins, Inscuteable (Insc) and Partner of Inscuteable (aka Pins), to the apical pole (Fig. 14.4B). The importance of the apically localized Par/Insc complex for asymmetric cell division is twofold: (1) Pins locally activates a G-protein-coupled pathway that attracts one of the centrioles toward this complex. The result of this is that the axis of the mitotic spindle is apicobasal (Fig. 14.4B). An apicobasally directed spindle, resulting in an apical daughter cell and a basal daughter cell, constitutes a general feature of asymmetric divisions in the developing nervous system; by contrast, symmetric divisions are generally characterized by horizontal spindles. (2) Proteins of the Par-complex interact with the cytoskeleton in such a way that a group of other proteins, which are also highly conserved among different animal groups, are transported toward the basal pole of the cell. These basal proteins include Miranda (Mir), Numb, and Prospero (Fig. 14.4B, D). As a result of the apicobasal mitotic spindle, only the basal daughter (i.e., the GMC) cell will receive these proteins. Prospero is a homeodomain transcription factor whose function is to switch on genes required for neuronal differentiation and switch off genes that are crucial for continued proliferation (Choksi et al., 2006). Numb acts as a negative regulator of the Notch pathway (discussed above), which keeps Notch pathway activity low in the GMC. Low Notch activity causes the de-repression of proneural genes, as well as the arrest of proliferation (after one more mitoses) of the GMC. By contrast, in the basal daughter cell, Notch pathway activity is kept high by proteins of the apical complex (Par-3, Insc), which promotes continued division of this cell.

In the vertebrate CNS, neuroepithelial cells first tend to divide symmetrically, giving rise to two dividing progenitor cells, but as neurogenesis proceeds, some neuroepithelial cells begin to divide asymmetrically—in this case giving rise to one neuroepithelial progenitor and one differentiated neuron. The mechanism responsible for vertebrate asymmetric divisions, including many of the genes involved, is similar to what has been described above for *Drosophila*.

In vertebrates, the orientation of the spindle axis is also thought to play a decisive role in switching between symmetric and asymmetric divisions. Divisions along the horizontal plane produce two cells that stay in contact with the ventricular (apical) surface, whereas more apicobasal divisions produce a basal daughter that migrates away from the ventricular surface, while the other daughter remains in contact, consistent with it retaining a neuroepithelial fate (Fig. 14.4C) (Chenn & McConnell, 1995). Recent findings show that mitotic spindles that are only slightly tilted away from the horizontal axis are sufficient to generate daughters with different fates. Neuroepithelial cells are highly columnar and have only a small apical membrane domain contacting the ventricular surface. As in *Drosophila*, the Par-complex proteins are restricted to the apical domain. What appears to matter in determining the fate of a daughter cell is whether or not it inherits the apical domain (Wodarz & Huttner, 2003). Only perfectly apicobasal cleavage planes will cut through the apical domain, such that both daughters will receive half of it. In this case, the mitosis is symmetric, producing two progenitors that remain epithelial and continue to divide. If the plane is tilted, even if only slightly, one daughter cell will inherit all of the apical domain and remain proliferative; the other one will delaminate and differentiate (Fig. 14.4.E, F).

Among the vertebrate homologues of the *Drosophila* genes involved in asymmetric cell divisions are several members of the apical complex. Par-3 acts as an activator of Notch pathway activity in the neuroepithelium, maintaining progenitor proliferation. mInsc is the mammalian homologue of Insc, and ASG3 is the mammalian homolog of Pins. Interfering with the expression or function of these homologues leads to the loss of apicobasal spindle orientation in the mammalian nervous system, resulting in too many cells dividing in the horizontal plane. In the mouse retina this causes the production of large clones arising from neuroepithelial cells, which can be explained if these cells divide symmetrically to produce two progenitors rather than one. Several members of the basal complex, such as Numb and Prospero, may also play a key role in the distinct fates of daughter cells, for example, knockout of the mammalian homolog of Numb is essential for cortical neuroepithelial cells to remain in a progenitor state (Petersen, Zou, Hwang, Jan, & Zhong, 2002).

The orientation of division may thus have an important role in determining cell fate by the uneven segregation of determinants between the daughter cells, but it can also cause the two daughter cells to inhabit slightly different chemical niches—for example, one daughter might remain closer to a source of a secreted growth factor or an extracellular differentiation factor.

NEURONS AND GLIA

The nervous system is composed of two main classes of cells: neurons and glia. Glial cells of the vertebrate CNS include three major types, microglia, astrocytes, and oligodendrocytes. Microglia are derived from the bone marrow and will not be further considered here. Astrocytes are multipolar cells whose processes interact with neuronal synapses, as well as the capillary network; astrocytes form the blood-brain barrier. Oligodendrocytes produce large, lamellar processes that make up the myelin sheath around axons.

Lineage tracing experiments show that neurons and glial cells are often produced from a common progenitor, which we can call a "neuroglioblast" in *Drosophila*. Neuroglioblasts form part of the neuroblast population that arises

in the embryo (Fig. 14.5A, B). Two generic determinants of glial fate have been identified. These include, *glial cells missing (gcm)* and *reversed polarity (repo)*, both of them expressed at an early stage in neuroglioblast development (Jones, 2005). Their crucial involvement in glial fate is attested to by the fact that ectopic expression of these genes converts neurons into glial cells and that loss-of-function mutants lack glial cells. Interestingly, neither *repo* nor *gcm* appear to play a role in glial development in vertebrates.

In the central nervous system of vertebrates, as in *Drosophila*, multipotent neural progenitors give rise to glia, as well as neurons (Fig. 14.5C). It is usually the case that neurons arise first and glia later. The first rounds of division of the neural progenitors are symmetric and lead to an increase of the progenitor pool (Fig. 14.5D1). Subsequently, asymmetric divisions give rise to neurons (Fig. 14.5D2). Neurons move away from the ventricular surface and form a mantle layer of increasing thickness.

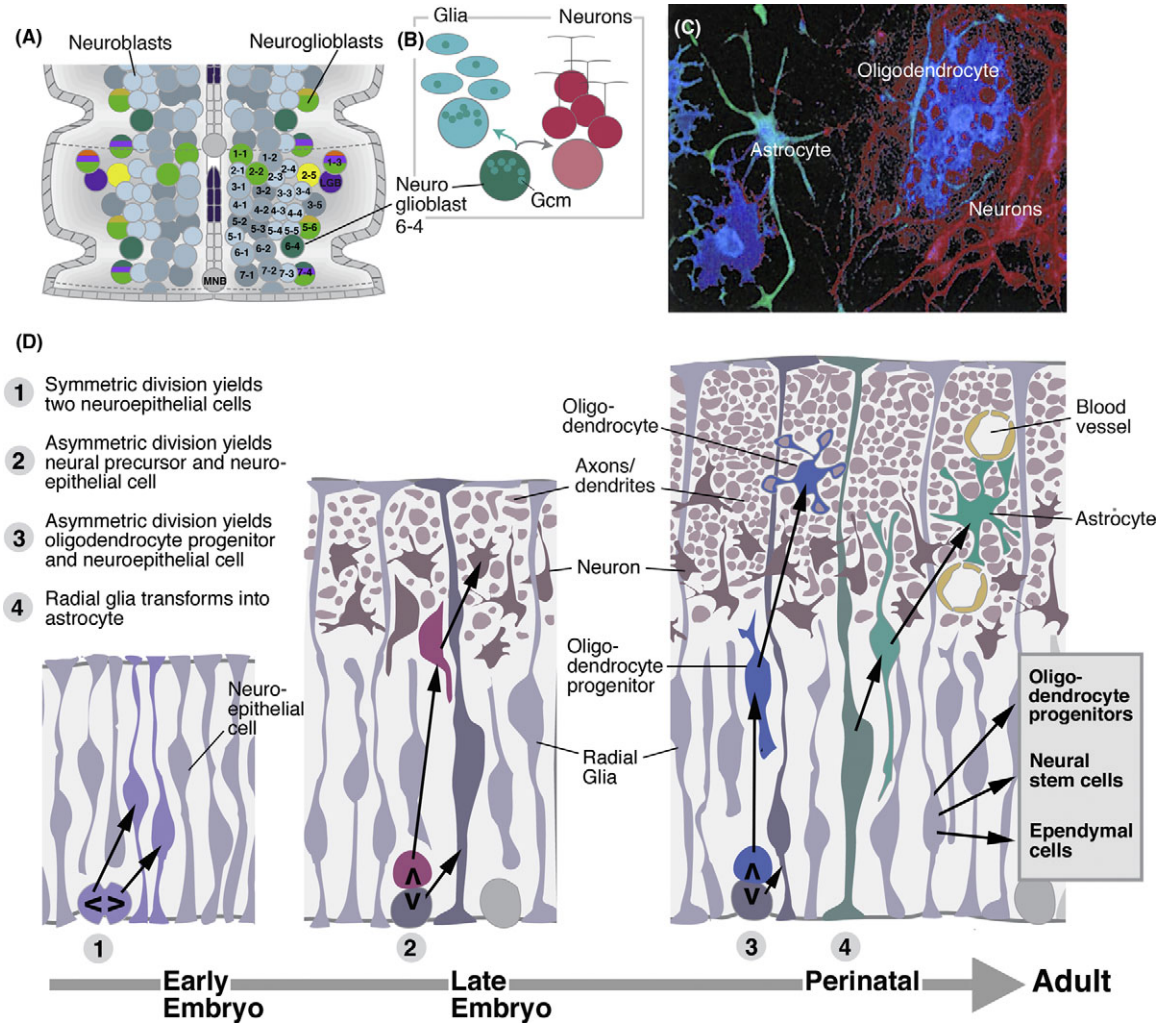

FIGURE 14.5 Specification of glial lineages. (A) Neuroblast map of the ventral nerve cord with glioblasts and neuroglioblasts indicated. Neuroblasts/neuroglioblasts of one hemineuromere are identified alphanumerically. (B) Neuroglioblast Nb6-4 expresses the glial regulatory protein Gmc (green). When this cell divides into two daughter cells, 6-4 G and 6-4 N, the Inscuteable complex and Miranda segregate Gmc into 6-4 G, which thereby becomes specified as glioblast. 6-4 N generates neurons. (C) Photograph of cell lineage obtained by injecting an individual neuroepithelial cell from mouse cortical progenitor cultured in a dish. Neural and glial-specific antibodies reveal the presence of both neurons (purple) and glia (astrocytes: green; oligodendrocytes: blue) in the lineage (*from Qian et al., 2000*). (D) Schematic cross section of neural tube of early embryo (left), late embryo (middle), and around birth (right; see time line at bottom). At early stage, symmetric divisions of neuroepithelial cells (1) result in an increased number of neural progenitors. At later stages, neuroepithelial cells (now synonymous with radial glial cells) start to divide asymmetrically, producing neurons (red), and maintaining their own number. Perinatally, production of neurons ceases, and neuroepithelial cells/radial glia switch to the production of oligodendrocyte progenitors (blue). Many radial glial cells delaminate and become astrocytes (green). Radial glia also give rise to the ependymal cells lining the ventricles of the adult CNS, to more oligodendrocyte progenitors, and to neural stem cells that remain active throughout adult life (*after Kriegstein & Alvarez-Buylla, 2009*).

As a result, toward the end of neurogenesis, the neuroepithelial cells that are left become elongated cells, called radial glia (Fig. 14.5D2). These cells still have their original apicobasal polarity; with their apical poles they form the lining of the ventricle; the long, basal process (that serves migrating neurons as guidance cue; see Chapter 15) is in touch with the basal surface, where blood vessels and meninges (the connective tissue layers surrounding the CNS) appear. Radial glia keep dividing, now mostly producing oligodendroctye progenitors (OLPs; Fig. 14.5D3). OLPs migrate throughout the central nervous system and differentiate into oligodendrocytes; many OLPs remain mitotically active throughout adult life. At the same time, most of the radial glia withdraw their apical attachments to the ventricular layer and differentiate into multipolar, mature astrocytes (Fig. 14.5D4). Astrocytes continue to divide throughout life; they react to neural injury by strong proliferation, forming glial scars (gliosis). A few radial glia, at specific locations, form a reservoir of adult neural stem cells (see Box 14.1).

BOX 14.1

NEURAL STEM CELLS

The proliferating progenitor cells or neuroblasts that give rise to more differentiated progeny but themselves remain in the cell cycle are called neural stem cells (NSCs) (Gage, 2000). Some frogs and fish continue to grow bigger throughout their lifetimes, and their brains grow with their bodies, adding new cells from localized stem cell populations. However, in most animals, including humans, the majority of proliferating neural cells use themselves up during development so the sources of new neurons in an adult animal are extremely limited. This is why damage to the central nervous system is medically much more serious than damage to the other organs, such as the skin or liver, where stem cells that persist into adulthood can replace injured tissue. Nevertheless, it has been found that even in adult mammals, NSCs persist in certain "niches" near ventricular layers. Interestingly, one pocket of rich stem cell activity is in the hippocampus, where certain aspects of learning take place. It is thought that a turnover of pyramidal cells in the hippocampus may be important for replacing old memory traces with new ones.

There is excitement about the potential of using NSCs in a replacement strategy for brain damage due to injury, stroke, or degenerative diseases such as Parkinson's disease, or retinal degeneration. One could imagine using NSCs to treat patients suffering from Parkinson's disease or Retinitis Pigmentosa. The cells could be expanded in culture under conditions where they begin to differentiate along particular pathways such as dopaminergic neurons or photoreceptors, and these new neurons could be transplanted into the brain or retina to replace ones lost due to damage or disease.

Important questions about neural stem cells in the adult brain abound. Why do these cells remain undifferentiated and capable of division when their neighbors have exited the cell cycle and differentiated? What signals do these cells need in order to stimulate their proliferation and differentiation? How can their differentiation toward particular types of neurons or glia be controlled experimentally? While there is much speculation on the role of various signaling and growth factors in regulating these processes, more work needs to be done to identify the molecules that prevent stem cells from differentiating and the signals that release their potential.

Interestingly, the environment of the organism plays a key role in regulating NSCs (Kempermann, 2011). Exercise is clearly important for the generation of new neurons in the adult rat hippocampus, and an enriched environment is important for the survival of new generated hippocampal cells. Rats put in simple cages without exercise wheels generate fewer new neurons, and these neurons have a higher chance of dying than in rats that are given exercise regimes and who are held in complex cages with a variety of toys. Stress works in the other direction and seems to inhibit stem cell proliferation and survival in the hippocampus. The identification of the regulatory factors that regulate these NSC activities might prove invaluable in treating neural or glial degenerative conditions without the need for transplants.

Another source of stem cells in mammals is the inner cell mass of the early conceptus. These are the cells that give rise to all the tissues of the embryo proper (Vallier & Pedersen, 2005). When these embryonic stem cells (ESCs) are grown in culture under certain conditions, they can produce neural precursors. It seems that the lessons learned about the mechanisms of neural induction are paying off in this context, because neural inducing signals increase the probability that ESCs will follow a neural pathway. ESCs may have an advantage over neural stem cells from adults because they come from a stage in development when their potential fates are less restricted by the inheritance of intrinsic determinants. More recently, using a cocktail of transcription factors that are normally expressed in ESCs, it has become possible to turn almost any cell in the body back to a pluripotent stem cell (Takahashi & Yamanaka, 2006).

BOX 14.1 (*cont'd*)

Stem cells produced in this way are called induced Pluripotent Stem Cells (iPSCs) and can be taken from the skin or blood of patients. Human iPSCs, besides having a potential role in therapy for neuronal injury and disease, are also very useful for the cellular modeling of disease processes, such as certain forms of autism (Marchetto et al., 2010).

Various laboratories are trying to turn ESCs or iPSCs into various types of neurons. Since a great deal is known about the inductive signals that are critical to the generation of motor neurons in the vertebrate spinal cord, it may be asked whether this knowledge can be used to direct stem cells to a motor neuron fate. Jessell and colleagues (Wichterle et al., 2002) combined inducers that first turn mouse ESCs into neural progenitors with factors such as retinoic acid that drives posterior regional identity such as spinal cord and Shh that drives ventral fates in the spinal cord to push these ESCs to differentiate into neural then spinal and finally into motor neurons that express the same combinatorial codes of transcription factors as motor neurons *in vivo*. These ESC-derived motor neurons can be labeled by Green Fluorescent Protein (GFP) under the control of the HB9 promoter (expressed only in motor neurons) and when these fluorescents cells are transplanted into the embryonic spinal cord of a chick embryo, they extend axons, and form synapses with target muscles (Fig. B14.1). Moreover such ES-derived motor neurons develop appropriate transmitter enzymes and receptors, and electrical properties, such that they can make perfectly functional synapses with muscle fibers. Thus, by using signaling pathways discovered by studying normal cell determination in the developing nervous system, biologists may be able to direct stem cells to form specific types of neurons.

Clearly, the more we know about neuronal determination, the more likely we will be able to direct stem cells down appropriate developmental pathways that will be useful in treating the damaged nervous system.

(B) Fluorescence image showing GFP-labeled motor neurons in thoracic and lumbar spinal cord. (C and D) Location of ES-cell derived GFP-labeled motor neurons clustered in the ventral spinal cord and sending axons out the ventral root. (*From Wichterle et al., 2002.*)

Oligodendrocytes arise during several waves. During the first wave, high levels of the ventrally expressed Shh morphogen activate transcription factor determinants of oligodendrocyte fate, called Olig 1 and Olig 2, in the ventral spinal cord (Kessaris, Pringle, & Richardson, 2001; Zhou, Choi, & Anderson, 2001). At later developmental times, oligodendrocyte and astrocyte formation occurs at more dorsal levels of the neural tube. Early expressed transcriptional regulators akin to Olig have not yet been identified for astrocytes. However, we do know that BMPs and some cytokines (e.g., ciliary neurotrophic factor, CNTF) promote astrocyte fate. BMPs and Shh act in an antagonistic manner in the decision between astrocyte and oligodendrocyte formation: BMP activates astrocyte formation and inhibits oligodendrocytes, while Shh does the reverse.

The Notch signaling pathway also plays an important role in glial development. First, high Notch activity in the neuroepithelium acts as a permissive factor for gliogenesis. Thus, activation of the Notch pathway suppresses the transcription of proneural bHLH transcription factors. Lowering Notch levels will result in premature conversion of neuroepithelium into neurons, thereby depleting the pool of cells that would normally give rise to glia at a later stage. Zebrafish embryos with reduced Notch activity in the spinal cord show increased numbers of neurons, at the expense of glia. In addition, at a later stage, Notch may also play a direct role in promoting the expression of glial specific genes. Introducing a constitutively active form of Notch into cultured neural progenitors triggers astrocyte differentiation.

SENSORY NEURONS OF THE PERIPHERAL NERVOUS SYSTEM

With the exception of the eye, all sensory organs of the vertebrate are derived from sensory placodes and neural crest. A placode is a morphologically visible thickening of an epithelium that often subsequently invaginates into the interior and transforms into a distinct tissue or organ (Schlosser, 2006). Sensory placodes appear during the late stages of neurulation in the dorsal ectoderm that flanks the invaginating neural tube (Fig. 14.6A–C). The most anterior placode is the olfactory placode that gives rise to the olfactory sensory neurons of the nose. Further posterior is the otic placode that forms the inner ear. Slightly more laterally is the placode of the trigeminal system that produces the sensory neurons innervating the receptors of the skin and muscles of the face and the head. Developing later and at a more lateral level in contact with the pharyngeal clefts (the gill slits in fish and amphibians) are the epibranchial placodes. They give rise to sensory neurons that innervate the taste receptors of the mouth, and receptors in the inner organs, such as the heart, large blood vessels, and digestive tract.

Sensory neurons of the trunk are derived from the neural crest (Fig. 14.6B–D). The neural crest is a transient population of cells that arises along the lateral edges of the neural plate (Chapter 13). Crest cells become localized to the dorsal part of the neural tube as it folds up, and then leave the neural tube and migrate along several well-defined pathways. Cells destined as sensory neurons aggregate in segmentally reiterated masses that form the dorsal root ganglia. Long peripheral dendrites extend from the dorsal root ganglia toward the skin, muscles, and skeleton. Here, dendritic endings of sensory neurons interact with specialized, mesodermally derived support cells, forming small "corpuscules" that are tuned to a specific type of stimulus, including touch, vibration, stretch, temperature, and pain.

Classical embryological experiments in which parts of donor embryos were transplanted to different sites in host embryos indicated that as they invaginate, placodes come in contact with the neural tube, the archenteron, the mesoderm, and the epidermal ectoderm. These structures all have inductive capacities and influence the fate of the placodal cells. In some instances, specific signaling molecules have been identified. The picture that emerges is that neural crest and sensory placodes are specified in a stepwise manner from the border territory in between neural plate and epidermal ectoderm. (1) At an early stage, prior to neurulation, BMP signals expressed in the epidermal ectoderm and FGF from mesoderm underlying the ectoderm trigger the expression of "border genes," including the homeobox transcription factors Msx1 and Dlx3/5 (Fig. 14.6A). (2) As neurulation sets in, the border territory splits into neural crest, medially, and preplacodal ectoderm, laterally (Fig. 14.6B). BMP expression reaches peak levels in, and is required for, neural crest ectoderm; at the same time, BMPs inhibit placode formation. Coinciding with high BMP activity are Wnt signals. Both signaling pathways promote the expression of a new set of transcription factors required for neural crest development, including Sox10 and FoxD3. (3) Antagonists of BMP and Wnt are secreted from the mesoderm underlying the lateral part of the former border territory. In response, cells in this region turn on the transcription factors Six1/4 and Eya1/2, which specify the lateral border territory as preplacodal ectoderm (Fig. 14.6B). (4) The preplacodal ectoderm splits into the different sensory placodes as a result of signals from adjacent neural tube, mesoderm, and ectoderm. For example, FGF3 and Wnt8c from the hindbrain and FGF19 from the axial mesoderm work together to induce the otic placode (Fig. 14.6C, D). Each placode acquires its own characteristic set of transcription factors. Different members of the Six and Eya family, initially expressed in an overlapping pattern in the entire preplacodal ectoderm, become restricted to individual placodes. Another class of transcription factors, the Pax proteins, is added as well. Notably, *pax2* expression is strongly correlated with the otic placode; *pax6* appears in the olfactory and lens placode, and *pax3* and *pax8* in the trigeminal placode (Fig. 14.6C). Absence or downregulation of these genes results in loss of the corresponding sensory organ.

Homologues of most of the molecules involved in specification of sensory placodes also operate in the *Drosophila* sensory system. Indeed, molecular evidence shows that the proteins encoded by the *pax*, *eya*, and *six* genes form complexes that as a whole unit bind to DNA and regulate transcription. Genes that in this manner encode cooperating proteins are called gene networks. The fact that their function is dependent on all members of the complex explains why entire gene networks are often conserved throughout evolution. The *pax/six/eya* network, activated by BMP and/or Wnt signals, is one of the best-studied examples of such a conserved gene network.

Specification of the sensory placode is just the first step in a long chain of events leading up to the mature sensory organ. Let us take a look at this process for the otic placode that gives rise to all cells of the inner ear. Following invagination from the dorsal ectoderm, the otic placode forms a hollow vesicle, the otic vesicle or otocyst (Fig. 14.6E, F). The lumen of the otocyst ultimately becomes the endolymph filled cavity of the inner ear. Initially, the wall of the otocyst is formed by a homogenous epithelial layer. Subsequently, the otocyst folds in a complex manner to give rise to the cochlea for sensing sound, the utricle for sensing gravity, and the semicircular canals for sensing rotational head movements in the three dimensions (Fig. 14.6G). Again, signals acting upon the otic placode from the outside induce these different structures. For example, Shh from the floorplate of the neighboring neural tube acts on the ventral otocyst and specifies this territory as cochlea; ectopic

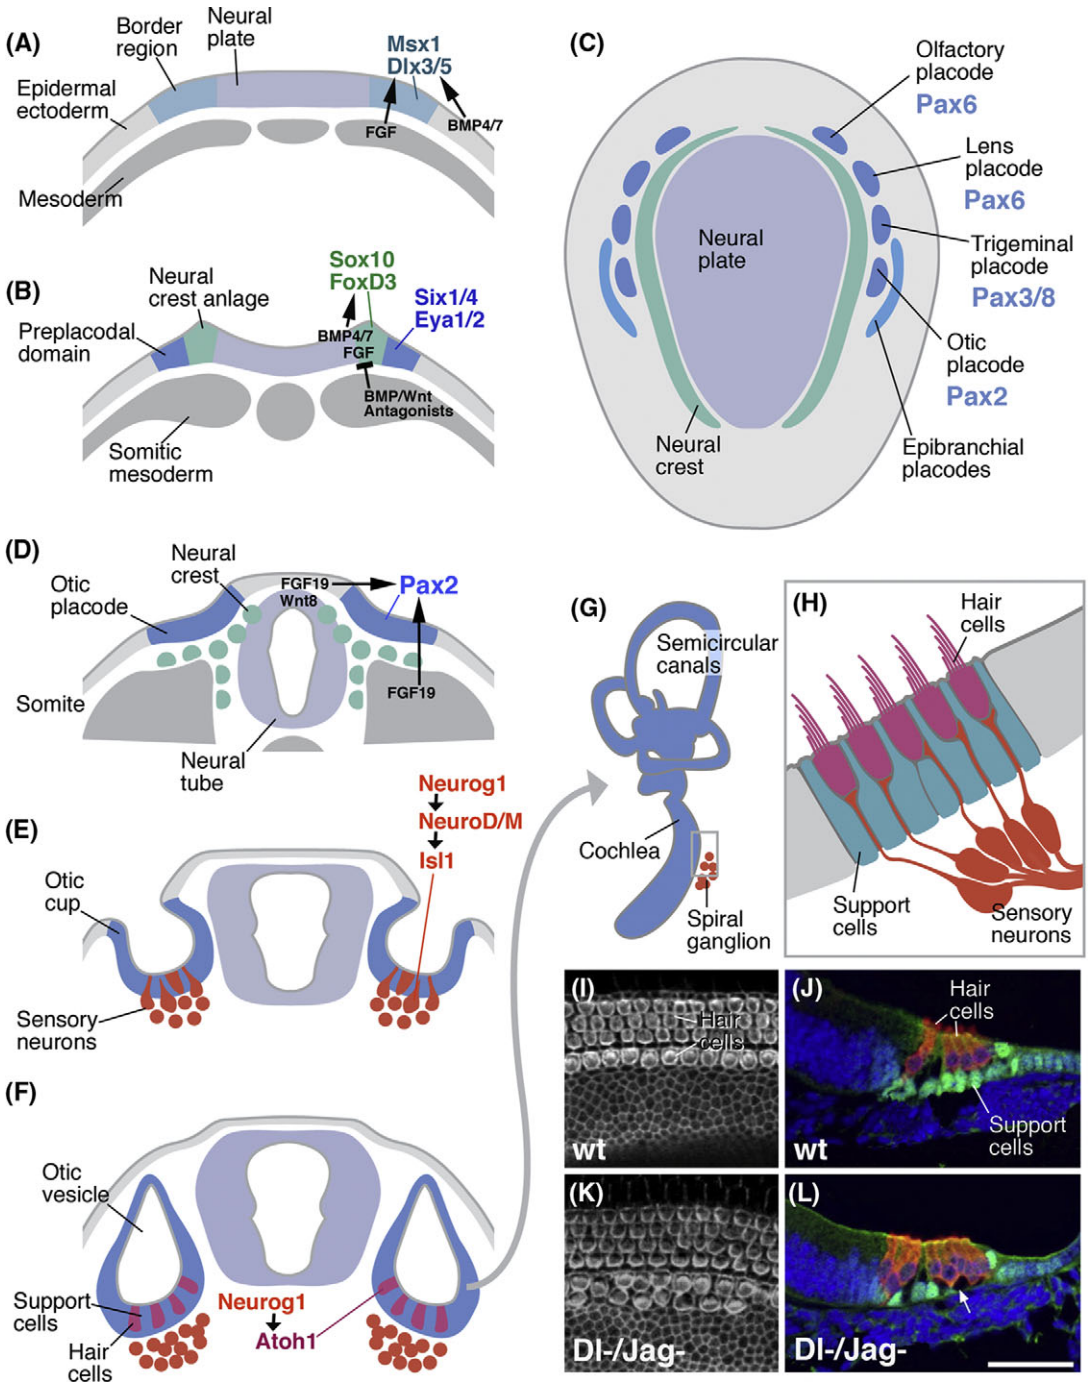

FIGURE 14.6 Sensory organ development in vertebrates. (C) Schematic dorsal view of neurula stage embryo, showing neural plate (light blue) flanked by sensory placodes (dark blue; anteriorly) and neural crest (green). Placodes express specific transcription factors of the Pax family. (A, B, D–F) Schematic cross sections of vertebrate embryo at successive stages, showing specification of the neural crest and sensory placodes (A, B) and development of the otic placode (D–F). (A) BMP signals from the lateral (epidermal) ectoderm and FGF signals from the mesoderm specify border region in between neural plate and epidermal ectoderm. (B) Peak levels of BMP and Wnt at the lateral boundary of the neural plate specify neural crest. Further laterally, these signaling pathways are inhibited, allowing for the appearance of the preplacodal ectoderm, from which all sensory placodes are derived. (D) Otic placode is induced from dorsal ectoderm by inductive signals (e.g., FDG19, Wnt8c) from neural tube and somites. (E) Otic placode invaginates. Precursors of sensory neurons (red) delaminate from placodal epithelium. (F) Cells of the placodal epithelium differentiate. Precursors of hair cells (sensory receptors; magenta) and support cells (green) appear. (G) Otic placode grows and forms cochlea and semicircular canals. (H) Magnified view of cross section of part of cochlea. Dendrites of sensory neurons (spiral ganglion) form synaptic contacts with sensory hair cells. These specialized, ciliated cells are surrounded by support cells. (I and J) Surface view (I) and section (J) of mouse cochlea, showing normal number and pattern of hair cells and support cells. (K and L) In Dl/Jag double mutants, hair cells are increased in number, and support cells are decreased. (*From Kiernan, Cordes, Kopan, Gossler, & Gridley, 2005.*)

expression of Shh in the entire otocyst causes lack of semicircular canals, and expansion of the cochlea.

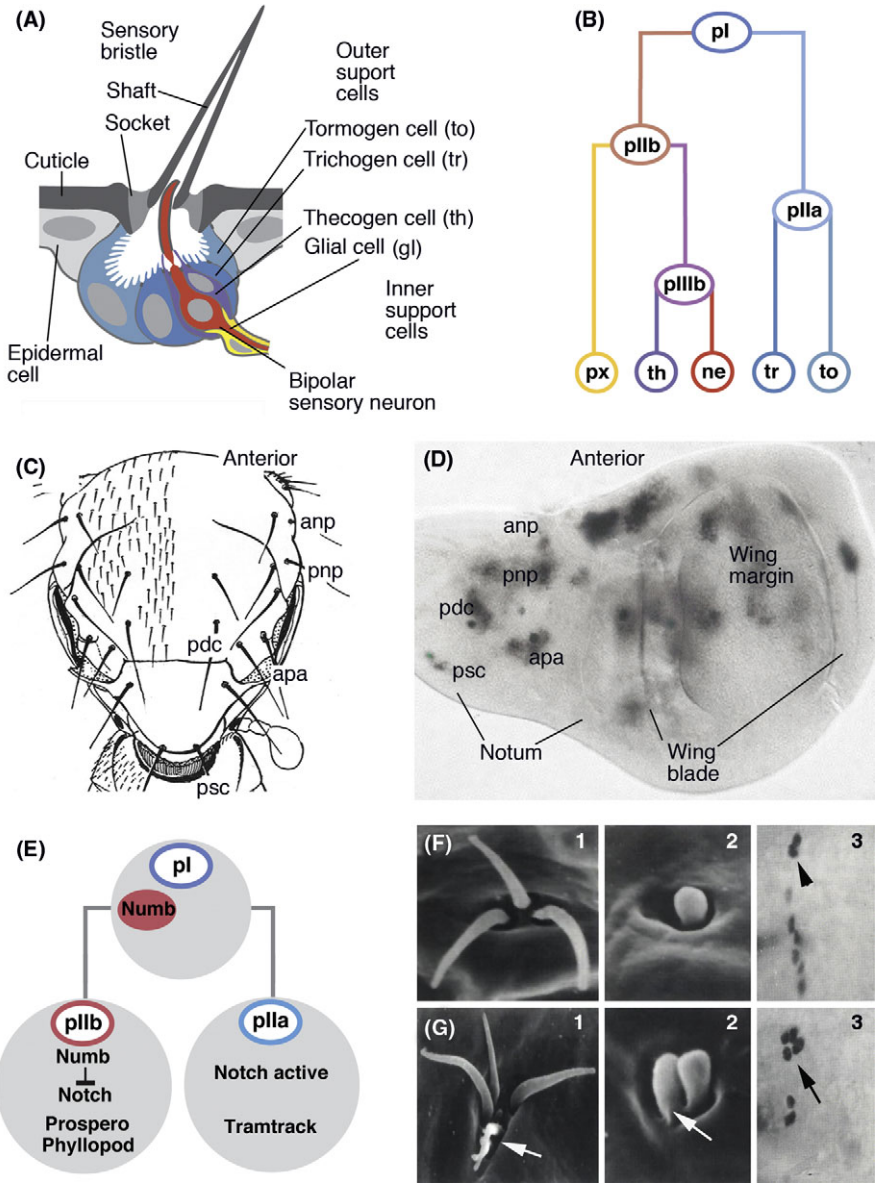
As the inner ear takes shape, the cells that form the otocyst wall diversify. In the same way that we learned about for the neural tube, different cell types delaminate from the epithelium and form additional layers basally adjacent to the epithelium (Fig. 14.6D). The anterior part of the otocyst forms a neurogenic region that sequentially, in two phases, produces the sensory neurons and hair cells of the inner hair. During the first phase of neurogenesis, expression of the proneural genes Neurogenin 1 and NeuroD promotes the formation of sensory neurons which innervate the cochlea and semicircular canals (Fig. 14.6E, H). During the second phase, cells of the neurogenic part of the otocyst switch on another proneural gene, Ath1 (homolog of the *Drosophila* atonal gene; see below), which prompts cells to adopt the fate of sensory hair cells (Fig. 14.6F, H). Cells of the neurogenic region that become neither sensory neurons nor hair cells will form support cells that anchor the hair cells in the epithelium lining the inner ear.

During the first phase of neurogenesis, Notch pathway activity restricts the number of cells that become sensory neurons. Notch activity is also required during the second phase of neurogenesis to distinguish between hair cells and support cells. Thus, precursors of hair cells appear at regular intervals, separated by support cell precursors (Fig. 14.6I–L). A Notch dependent lateral inhibition mechanism operates to determine the spacing of hair cells. Thus, at an early stage, the Notch receptor and the Delta ligand are expressed in all cells of the otic epithelium. Subsequently, Delta becomes restricted to the developing hair cells, which thereby inhibit their neighbors from choosing the same fate; these neighbors become the support cells. Genetic studies, using mouse and zebrafish, show that loss of Delta in the developing inner ear results in an increased number of hair cells (Takebayashi et al., 2007) (Fig. 14.6K, L).

In *Drosophila* and many other invertebrates, sensory organs are comprised of small clusters of sensory neurons and support cells, which together are called sensilla (Fig. 14.7). Sensilla are scattered over the entire body surface of the larval and adult fly. The cells that compose each sensillum are clonal descendants of a single Sensory Organ Progenitor cell (SOP) (Lai & Orgogozo, 2004). The fate of sensory neurons and their support cells is determined by factors expressed in the SOP and delivered through a series of asymmetric divisions to the individual cells. In most cases, all cells of a sensillum are born in three consecutive divisions. The SOP, also called the primary precusor cell or pI, divides into two pII daughters called pIIa and pIIb (Fig. 14.7B). PIIa divides one more time and gives rise to the outer support cells, which form processes in the shape of hairs or bristles. PIIb gives rise to the sensory neuron and inner support cells in two consecutive divisions (Fig. 14.7B). The first step in sensillum development, the determination of SOPs, is controlled in a manner similar to that regulating neuroblast determination. Thus, the expression of proneural genes defines proneural clusters in the ectoderm that are competent to form SOPs (Fig. 14.7C, D). At the same time, proneural genes activate the Notch pathway, mediated by the neurogenic genes, which single out one SOP and prompt all other cells of the proneural cluster to abort neural development. The identities of individual SOPs are specified by different proneural genes. For example, *Poxn* and *Amos* are expressed and required in precursors of chemosensory receptors. *Atonal* (*ato*) is expressed and required in the proneural clusters that give rise to stretch receptors (chordotonal organs). Loss of *ato* function results in the absence of these cell types; likewise ectopic expression of *ato* in other SOPs induces the production of chordotonal organs.

Once determined, SOPs divide asymmetrically, using the same mechanism discussed above for neural progenitors of the CNS. A crucial factor in generating the asymmetry of SOP divisions is the basal complex member, Numb (Fig. 14.7E). After the the first SOP mitosis, the cell receiving Numb becomes pIIb. Numb disrupts the Notch signaling pathway in pIIb, allowing for the expression of genes that are required for sensory neurons, including Prospero and phyllopod. If Numb is deleted, Notch can act in both pII cells, which changes the fate of pIIb to that of pIIa,

FIGURE 14.7 Sensory organ development in *Drosophila*. (A) Structure of mature sensilla. Schematic section of external mechanoreceptor (microchaete). Bipolar sensory neuron (red) is surrounded by two inner support cells, the thecogen cell (purple) and glial cell (yellow). Two outer support cells, the tormogen cell (light blue) and trichogen cell (dark blue), form the socket and shaft of the bristle-shaped cuticular component of the sensillum. (B) Tree diagram of canonical cell lineage of mechanoreceptive sensillum (microchaete). Progenitor of sensillum (SOP or pI; top) divides into two daughter cells, pIIa and pIIb. Division of pIIa gives rise to outer support cells (trichogen and tormogen cell). PIIb divides into progenitor pIIIb that then produces sensory neuron and thecogen cell; the other daughter of pIIb develops as glial cell (as shown here for the microchaete) or expresses a number of other different fates (not shown). (C and D) Sensillum patterning. (C) Schematic dorsal view of *Drosophila* thorax (notum) indicating invariant pattern of mechanoreceptive bristles. Some of the large bristles (macrochaetes) are identified individually. Anp, anterior notopleural; apa, anterior postalar; pdc, posterior dorsocentral; pnp, posterior notopleural; psc, posterior scutellar. (D) Expression of the proneural gene *scute* (grey) in wing imaginal disc. In the proximal region of the disc which gives rise to the notum, *scute* is expressed in proneural clusters which can be assigned to individual macrochaetes. (E–J) Distribution of fate determinants and Notch signaling in the sensillum lineage. (E) During the pI mitosis, Numb, an inhibitor of Notch signaling, is distributed to pIIb. This activates determinants of neurons like Prospero and Phyllopod. Loss of Numb in pI causes transformation of pIIb into pIIa, with a concomitant doubling of outer support cells and absence of neuron/inner support cells. (F, G) Examples of this transformation are the mechanoreceptive Keilin's organ that, in wild type (F1), has three sets of shaft/socket, and, in numb mutant (G1), has four to five sets of these outer support cells. Likewise, duplication of shaft/socket occurs in a basiconical sensillum (F2: wild-type; G2: numb mutant). F3 shows molecular marker Cut expressed in two outer support cells of a mechanoreceptive sensory organ of the embryo (arrowhead). In the numb mutant (G3), these cells are doubled in number (arrow).



and causes a duplication of outer support cells (the descendants of pIIa) and loss of neuron/inner support cells (the descendants of pIIb; Fig. 14.7G). It is clear that recurring themes, such as spatially restricted homeobox containing transcription factors, proneural bHLH genes, asymmetric cell divisions, and Notch signaling play a role in sensory neuron determination in vertebrates and invertebrates just as they do in the central nervous system of these animals.

THE RETINA

The retina is a sensory organ with different origins. The *Drosophila* retina arises from an imaginal disc, whereas the vertebrate retina arises from an outpocketing of the anterior neural plate. Studies of how specific neurons arise and diversify in the retinas of these distinct animals reveal surprising similarities despite their very different embryological origins, betraying a shared molecular evolution of visual organs that predates the separation of vertebrates and invertebrates (Lamb, Collin, & Pugh, 2007).

The insect compound eye is built of a large number of identical facets, called ommatidia. *Drosophila* possesses approximately 800 ommatidia in each eye. Each ommatidium contains eight identifiably unique photoreceptor neurons and several accessory cells. Six of the photoreceptors (R1–R6) form an outer trapezoidal array, whereas two (R7 and R8) are located in the center (Fig. 14.8A). Among the accessory cells are cone cells, which form the lens of each ommatidium, and pigment cells, which surround the photoreceptors and optically shield the ommatidia from one another.

FIGURE 14.8 Determination of ommatidial cell fate in the *Drosophila* compound eye. (A) Schematic longitudinal section of ommatidium depicting cell types in different colors. (B) Surface view of part of the eye imaginal disc at a stage when photoreceptor clusters become assembled in a sequential fashion. Gray profiles indicate the apical surface of undifferentiated cells; colored profiles demarcate different types of photoreceptors and cone cells. At the left margin, all cells are undifferentiated. This is followed by a phase in which eye disc cells become more closely packed and constricted at their apical pole, thereby forming the morphogenetic furrow. As they leave the furrow, cells form more or less regularly spaced rosettes (light red). Within each rosette, a single cell becomes singled out as the photoreceptor R8 (dark red). At the time when it becomes distinguishable morphologically, four other photoreceptors (R2, R5: lilac; R3, R4: blue) have joined R8. Together, these five cells form the so-called preclusters. Three more photoreceptors (R1, R6: blue; R7: orange) join the preclusters, leading up to complete photoreceptor clusters. This step is followed by the appearance of four cone cells (green) that surround the photoreceptors in a circular fashion. On the right side of the panel, photoreceptors can be seen to segregate from the surface. Their apical membranes (all shown in purple) become increasingly smaller (arrow) and finally disappear altogether. (C) Initiation of compound eye development. During midlarval stages (Top), the signal Hedgehog (Hh; red) is expressed at the posterior tip of the eye disc. Hh activates the expression of another signaling protein, Dpp (blue), which turns on several "early eye genes," which commit the undifferentiated, proliferating cells that comprise the eye disc to an eye fate. During late larval stages, Hh and other factors initiate differentiation of the first ommatidial cells, the R8 photoreceptors, by turning on the proneural gene atonal (*ato*). This sets in motion other signaling pathways (EGFR signaling; Notch/Delta signaling) required for the proper spacing of ommatidia and the determination of other ommatidial cell fates. (D) Determination and spacing of R8 are controlled by the proneural gene *atonal (ato)*, as well as the inhibitory signals Delta (Dl) and Scabrous (Sca). Initially switched on in the entire morphogenetic furrow, *ato* expression then becomes restricted to a mosaic of regularly spaced cells, which subsequently differentiate as R8. Continued secretion of Hh, which signals across the MF toward the more anterior cells of the eye disc, drives the morphogenetic furrow across the eye disc. (E) Determination of photoreceptors R1–R7 and cone cells. Secretion of the TGF β homologue Spitz (Spi) from R8 stimulates cells surrounding R8 via the *Drosophila* EGF receptor homologue (DER), the Ras signaling pathway (symbolized by black arrows). In conjunction with other signaling events, including Notch/Delta, photoreceptors are induced to express specific transcription factors, which are required for their respective fates. The *lozenge* (*lz*) gene is expressed in R1, R6, R7, and cone cells; *seven-up* (*svp*) is expressed in R1, 6, 3, and 4; *rough* (*ro*) in R2, 3, 4, and 5; *BarI* in R1, and 6; *prospero* (*pros*) in R7, and *Pax-2* in cone cells.

Cells of the ommatidia are formed from clonally unrelated, uncommitted precursor cells that are generated from the proliferation of cells in the eye imaginal disc (Mollereau & Domingos, 2005). The ommatidial cells do not appear all at once, but follow a reproducible temporal sequence (Fig. 14.8B). During late larval life, a wave of differentiation passes over the eye disc in a posterior-to-anterior direction. In front of the wave, cells are still dividing

and uncommitted, whereas behind the wave front, which is visible as a depression in the disc called the "morphogenetic furrow" (MF), cells are mostly postmitotic and are beginning to differentiate. As they leave the MF, cells of the eye disc become arranged in a pattern of "rosettes" that foreshadow the regular ommatidial pattern. Soon afterward, one cell is singled out in each rosette to become R8. Being the first cells to differentiate, R8 cells can be considered as "crystallization centers" around which the other ommatidial cells aggregate in a stereotyped pattern.

R8 cells express the proneural gene *atonal (ato)*. Atonal is turned on by the signaling protein Hedgehog (Hh, a homologue of vertebrate Sonic hedgehog, Shh). Atonal thus first turns on in a continuous band of cells, similar to a preneural cluster, within the morphogenetic furrow, which then initiate lateral inhibition through Delta Notch signaling (Fig. 14.8C, D). By this mechanism, *ato* expression becomes restricted to a set of spaced cells, which subsequently differentiate as R8 photoreceptors. Atonal expression causes Hh to be produced and released. Thus, these R8 precursors continue emitting Hh, which signals across the morphogenetic furrow toward the more anterior cells of the eye disc to induce the next set of R8 cells (Ma, Zhou, Beachy, & Moses, 1993). This Hh-mediated feedback mechanism drives the wave of differentiation—that is, the morphogenetic furrow, across the eye disc, leaving in its wake a beautifully spaced mosaic of R8s, each crystallizing an ommatidium. Deleting *ato* results in the total failure of retinal development, which indicates that R8 plays a pivotal inductive role, triggering the determination of other cells that join the ommatidial clusters. The first cells to join the R8 cell shortly after its determination are R2, R3, R4, and R5 (Fig. 14.8A). Together with R8 they make up an ommatidial "precluster." The next cells to join the cluster are R1 and R6, followed by R7 and four cone cells; the last cells to join the cluster are the different types of pigment cells.

Shortly following its own determination, R8 puts out signals that activate two different signaling pathways: Notch and Ras. The Notch pathway, as we know, is activated by Delta. The Ras pathway represents a highly conserved biochemical cascade of cytoplasmic kinases (Ras, Raf, MPK), which in this case are activated by the epidermal growth factor receptor (EGFR). R8 emits a signal, Spitz (Spi), that activates this receptor and another signal, Argos (Aos), that acts as an inhibitor. Activation of these signaling cascades spreads concentrically from R8 to the precluster cells (R2, R3, R4, and R5) and then the remainder of the ommatidial cells (Fig. 14.8D). The precise, temporally regulated activation of EGFR and Notch signaling pathways assigns distinct phenotypes to the cells that join the ommatidial clusters.

The way in which differential signaling pathway activation controls ommatidial cell fates has been studied most closely for two cell types, R7 and the cone cells, which appear at a relatively late stage when all other photoreceptors are already in place. The *Pax-2* gene specifies cone cells (Fig. 14.8E). To express *Pax-2*, the cone-cell-to-be depends on three inputs (Flores et al., 2000): (1) the previous expression of the transcription factor lozenge (*lz*); (2) activation of the Notch pathway; and (3) activation of the EGFR signaling pathway. If any one of these prerequisites is not met, the cells will fail to express *Pax-2* and will not differentiate as cone cells. Conversely, if a set of cells that normally does not receive all three inputs is exposed to them experimentally, these cells will express *Pax-2* and become cone cells. R7 cells normally express *lz*, but do not activate the Notch pathway, and experimental misexpression of activated Notch in the R7 precursor will turn this cell into a cone cell.

The determination of the R7 cell deserves special mention in view of the pivotal role it has played in opening up the molecular-genetic study of signaling pathways (Zipursky & Rubin, 1994). The important advantage a genetic model system like *Drosophila* has to offer is that developmentally relevant molecules, such as signaling proteins, receptors, and signal transducers, can be identified by mutant screens. One of the first of such screens in the field of cell determination took advantage of the fact that only one of the photoreceptor cells of each ommatidium, R7, is sensitive to ultraviolet (UV) light. Thus, mutagenizing flies and screening for offspring that are blind to UV light yielded a fly line that lacked the R7 cell in every ommatidium and was therefore aptly called *sevenless* (Harris, Stark, & Walker, 1976) (*sev*) (Fig. 14.9). The close study of this gene showed that it encodes a receptor with

FIGURE 14.9 Photoreceptors in the eye of normal and *sevenless* mutants. (A) If a light is shone from the back of a fly's head and focused in the facets of the eye, individual photoreceptors can be seen because of their ability to pipe light. The wild-type animal has the normal pattern of seven photoreceptors visible in each facet. The small one in the center is photoreceptor R7. (B) The same technique used in a *sevenless* mutant shows only the six large photoreceptors R1–6 in each facet. R7 is missing. Insets show electron micrographs through single facets.

tyrosine kinase activity and that this receptor is expressed (among other cells of the eye disc) in the cell that will become R7. Lack of the receptor causes the cell that would normally become R7 to develop as a cone cell instead. In several follow-up screens, many signal transducing molecules and transcription factors activated by the Sev receptor were identified. Among them were the *Drosophila* homologues of Ras, Raf, and MAPK. One of the most rewarding findings was the identification of the signal that binds to Sev. Given the widespread expression of Sev, it was clear that a signal emanating from a point source must exist, in order to ensure that Sev would become active only in one cell in each ommatidium. The logical candidate to emit such a signal would be R8, the only cell in broad contact with the presumptive R7. A genetic screen for R7-less flies yielded identification of a membrane bound signaling molecule, called Bride of sevenless (Boss), which is expressed specifically in R8 cells and serves as the ligand for Sev (Reinke & Zipursky, 1988). These experiments provided an impressive demonstration of the awesome power of genetic screens combined with precise knowledge of the developing system in identifying new genes and proteins controlling development.

The vertebrate retina, like the *Drosophila* retina, develops from a population of pluripotent neuroepithelial progenitors, which produce a diversity of neurons and glia (Fig. 14.10A). As in *Drosophila*, vertebrate neurogenesis and determination in the retina follows a temporal order (Livesey & Cepko, 2001). Thus, at any given time during retinogenesis, only a few fates are available to differentiating cells. Such temporal fate restrictions are likely to be caused by transiently expressed transcription factors that switch on over particular periods of neurogenesis, such as Ikaros, a vertebrate homologue of Hb, which plays a similar role in *Drosophila* histogenesis. Cells born early in the vertebrate retina generally adopt fates as retinal ganglion cells (Fig. 14.11A–C), followed sequentially by horizontals and amacrines, bipolars, photoreceptors, and Müller glia. This is also similar to *Drosophila* in which first R8s and then sequentially other cell types differentiate. This progressive shift in cell type genesis in vertebrates is supported by dissociation experiments in which cells are put into culture at low density at various stages of development. If progenitors are isolated at the time when retinal ganglion cells (RGCs) are normally born, they tend to turn into ganglion cells in culture. Later progenitors in the same culture medium become mainly photoreceptors (Watanabe & Raff, 1990).

There is an intrinsic element to the succession of cellular fates in the vertebrate retina (Cayouette, Poggi, & Harris, 2006), which is revealed when rat retinal progenitors are isolated and allowed to divide on their own in culture. These isolated progenitors give rise to clones of cells of the same general birth order, size, and composition as clones *in vivo*. If one follows these clones as they develop, there is another surprising similarity to *Drosophila* retinal determination, which is that cells seem to choose their cell type in a stochastic manner—that is, lineage does not predict fate.

So how do vertebrate retinal cells become determined so that there are the right number of all the different cell types? As in *Drosophila*, vertebrate homologue of *ato*, *ath5*, is turned on early, when the first retinal cells are being born. Delta-Notch signaling then ensures that not too many cells become RGCs. If *ath5* expressing progenitors are followed by time-lapse analysis in the zebra fish retina (Poggi, Vitorino, Masai, & Harris, 2005), they appear to divide to generate one RGC that expresses ath5 at high levels and one other cell in which ath5 levels are reduced (Fig. 14.10B). Several other transcription factors are expressed at about this time in various populations of cells as they begin to differentiate. One such factor, Ptf1a, is turned on in the subset of newly postmitotic cells that will become inhibitory neurons in the retina (i.e., the amacrine and horizontal cells).

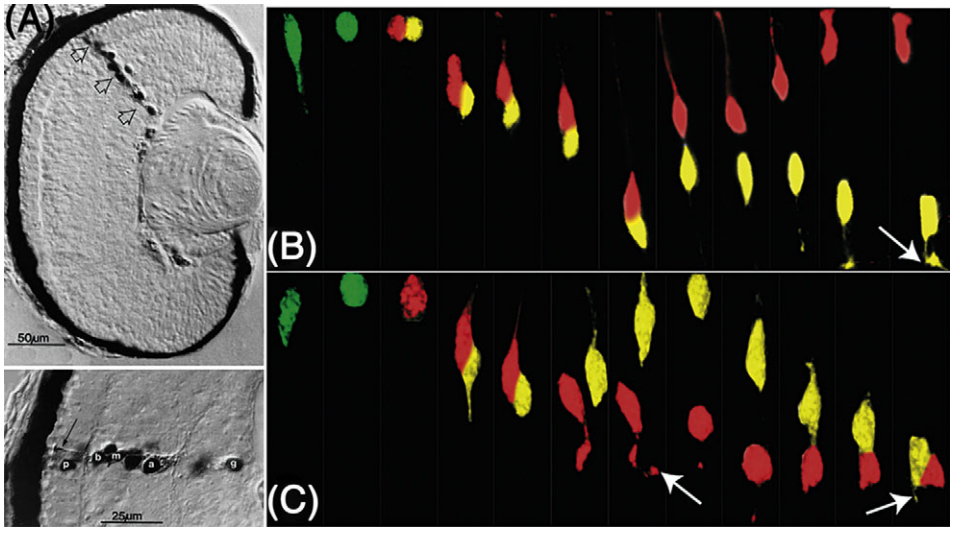

FIGURE 14.10 Clones of cells in the *Xenopus* and zebra fish retina. (A top) Daughters of a single retina progenitor in *Xenopus* injected with horseradish peroxidase are seen to form a column that spans the retinal layers and contributes many distinct cell types, (A bottom) p, photoreceptor; b, bipolar cell; m, Muller cell; a, amacrine cell; and g, ganglion cell. (B) Time-lapse images of an RGC progenitor in zebra fish dividing at the apical surface of the retina to produce two cells one of which (yellow) becomes an RGC. (C) A similar RGC progenitor in a mutant retina where there are no host RGCs because it is mutant for the *ath5* gene. This cell divided to produce two daughters, both of which become RGCs (arrows point to emerging axons).

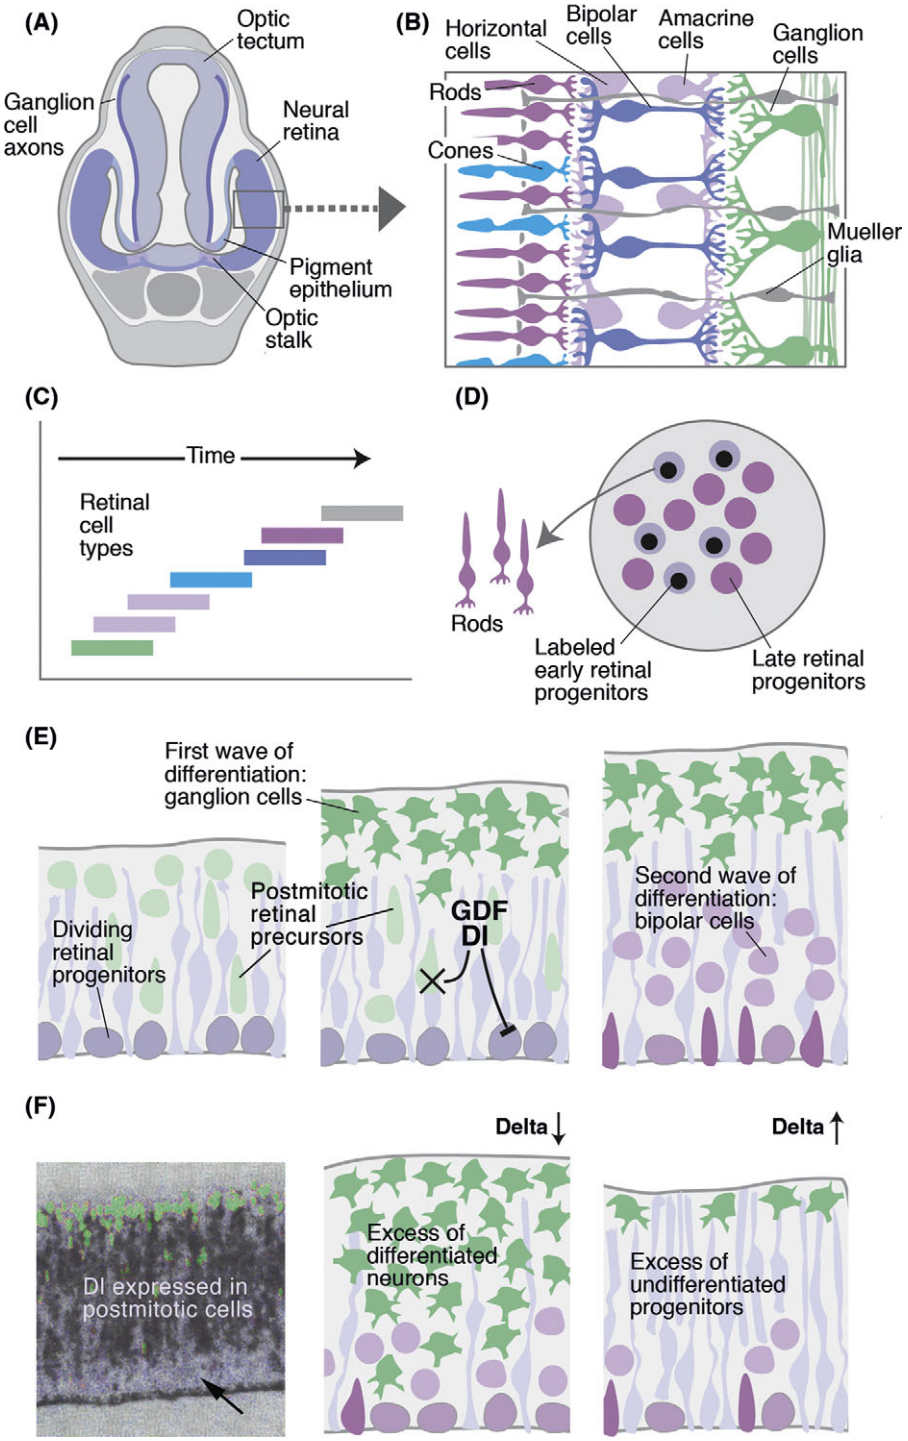

FIGURE 14.11 Vertebrate retina development. (A) The neural retina bulges out of the ventral neural tube at the level of the diencephalon. It is joined to the brain by the optic stalk along which the axons of retinal ganglion cells will course on their way to the tectum. (B) The seven major cell types in the retina coded by color. Their laminar arrangement by cell type is evident. (C) Birth dating studies in the retina show that different cell types are born in different but overlapping periods of development. (D) When early generated retinal precursor cells (labeled by a pulse of BrdU) are mixed with older cells in culture, they show an increased probability of turning into late cells, such as rods. (E) Development of the retina. Schematic section of retinal neuroepithelium at three different stages (early: left; late: right). Dividing retinal progenitors (purple) produce different cell types depending on the developmental stage. Differentiation inhibitors (Dl) released from postmitotic neural precursors inhibit retinal progenitors from producing more ganglion cells. Postmitotic cells also secrete differentiation factors such as GDF which limit the time window during which postmitotic cells can become retinal ganglion cells. (F) Expression and function of Dl in the developing retina. Left panel: expression of Dl in postmitotic neural precursor; dividing progenitors of the ventricular layer (arrow) or differentiated neurons of the basal mantle layer (green) do not express Dl. Middle: Loss of Dl results in increased number of early-born retinal cells (retinal ganglion cells), at the expense of undifferentiated retinal progenitors. Right: Overexpression of Dl causes the opposite phenotype.

Ath5 is necessary for the determination of RGCs, while Ptf1a is essential for the generation of inhibitory neurons. Ptf1a also controls inhibitory neuron differentiation in the spinal cord (see the following section). In the absence of Ath5 cells that would have become RGCs and in the absence of Ptf1a, cells that would have become amacrine or horizontal cells choose excitatory fates instead. All horizontal cells, it turns out, express both Ath5 and Ptf1a. This begins to look like a combinatorial code. Indeed, other studies have shown that particular combinations of retinal transcription factors, sometimes two or three together, drive cells to become specific cell types, while single factors are much less effective (Ohsawa & Kageyama, 2008).

How these different intrinsic determinants are turned on in these combinations is unknown, but it is clear that fate determination in the retina is not just an intrinsic affair.

When retinal cells are removed at the stage when RGCs are being born, mixed into aggregates, and cultured *in vitro*, they differentiate into RGCs as one would expect. However, if the same cells are mixed with an excess of retinal cells several days older (i.e., when photoreceptors are generated), they generally become photoreceptors (Fig. 14.11D). This work shows that individual cells have the capacity to differentiate into different cell types, and the fate they choose depends on the environment in which they are born. This makes good sense, for as retinal development proceeds, the environment changes simply as a result of various retinal cell types being generated, much as in the *Drosophila* retina. Indeed, there is strong evidence for negative feedback in influencing the fate of RGCs. Young embryonic chick progenitors are inhibited in their ability to produce RGCs when cultured adjacent to older retinas in which there are lots of RGCs, and depletion of the RGCs from these older retinal cell populations abolishes this inhibition (Waid & McLoon, 1998). When normal retinal progenitor cells that express a fluorescent protein under the control of the *ath5* promoter are transplanted to normal embryos, the cells that turn on ath5 usually generate only a single RGC daughter (see above), but these same cells when transplanted into mutant retinas that lack RGCs, they often generate two RGC daughters, providing evidence that such lineages are sensitive to feedback signals (Fig. 14.10C) (Poggi et al., 2005). It seems that Ath5 itself is negatively regulated by such feedback signals. Similarly normal progenitors transplanted into Ptf1a mutant retinas are more likely to turn on Ptf1a to try to compensate for the missing cell types, suggesting again that negative feedback normally keeps the level of Ptf1a expression appropriate to generate the correct proportion of inhibitory neurons in the retina (Jusuf et al., 2011).

What could these feedback signals be? First, as mentioned above, the Notch signaling pathway contributes to retinal diversity in the vertebrate retina (Fig. 14.11E, F). When Notch signaling is compromised in early retinal progenitors, too many cells differentiate as early cell types, whereas later interference with Notch signaling leads to an increase in later-born cell types. The Notch signaling pathway, by allowing only a certain number of cells to express particular proneural genes and thus differentiate at any one time, is important in creating cellular diversity in the vertebrate retina (Dorsky, Chang, Rapaport, & Harris, 1997). RGCs also express Shh, and the Shh knockout mouse contains increased number of RGCs. These results suggest that Shh provides a feedback inhibition signal in the developing mouse retina, echoing what happens in the *Drosophila* retina where R8 cells express Hh, which regulates the expression of *ato*. The growth differentiation factor 11 (GDF11) is another factor secreted by RGCs, and it acts by limiting the temporal window during which progenitors are competent to express *ath5* and thus produce RGCs.

THE SPINAL CORD

The vertebrate spinal cord plays a central role in conveying motor commands to the periphery via somatic and autonomic motor neurons. It also harbors neurons that receive and transmit cutaneous, proprioceptive, and visceral sensory information from specialized receptors in the body and limbs. This information is used to activate protective reflexes such as the nociceptive withdrawal reflex, and to shape motor activity needed for locomotion. The component neurons of these spinal sensorimotor circuits are generated by the patterning events that specify neuronal identity in the embryonic spinal cord. Antero-posterior positioning contributes to neural patterning in the cord as evidenced by differences in the number and types of specialized cells that are found at different axial levels. This is most apparent for branchiomotor, phrenic, preganglionic, and lateral motor column motor neuron cell types that are patterned by the Hox genes (Dasen, Liu, & Jessell, 2003; Dasen, De Camilli, Wang, Tucker, & Jessell, 2008). The Hox genes are also likely to regulate the diversity and abundance of specialized interneuron cell types that are similarly distributed in different numbers along the neuroaxis.

The dorso-ventral position in which a neuronal progenitor is located within the neural tube is one of the major determinants of neuronal cell fate in the spinal cord. Signaling centers at the ventral and dorsal midline establish opposing gradients of Shh and BMP signaling, respectively. As a result of this signaling the ventricular zone is subdivided into many discrete progenitor domains that in turn produce motor neurons and all the classes of spinal interneuron. The ventral-most region of the spinal cord, the "floor plate" is induced by a Shh signal emitted from the underlying notochord (Chapter 13). Once induced, the floor plate serves as a secondary source of Shh, which percolates dorsally through the cord to provide graded Shh signaling to ventral neural tube progenitors (Fig. 14.12A). Differential Shh signaling partitions the ventral basal plate into five discrete progenitor domains that in turn generate six neuronal cell types (Jessell, 2000).

How do cells at different dorso-ventral levels interpret their exposure to different levels of Shh in order to acquire different fates? Threshold levels of Shh activate homeobox transcription factors such as Nkx2.2 and Nkx6.1 (Class II) ventrally, while at the same time turning off other factors such as Pax6, Dbx2, and Pax3/7 (Class I) dorsally (Goulding, Lumsden, & Gruss, 1993; Jessell, 2000). Thus, neural tube progenitors in different dorso-ventral regions express specific homeodomain proteins, which either are turned on or off at particular Shh thresholds (Fig. 14.12B). The boundaries between these domains are sharpened through reciprocal repression of the two classes of transcription factor. The ventral border of the class I Pax-6 gene initially overlaps the dorsal border of the class II

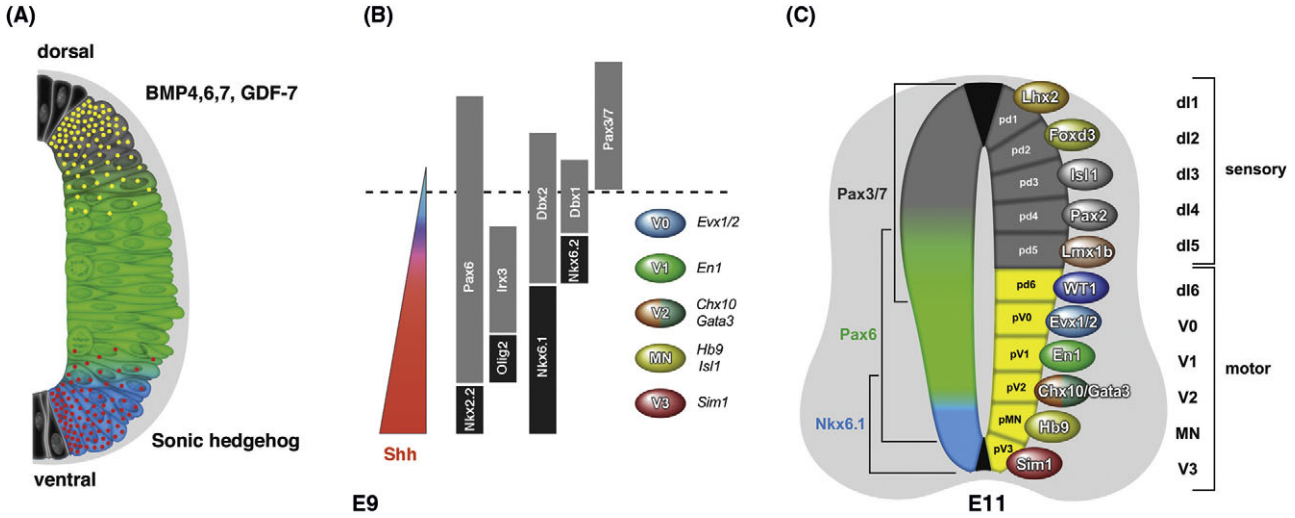

FIGURE 14.12 Specification of neurons in the vertebrate spinal cord. (A) Schematic cross section of the mouse neural tube. Shh protein (red) is released ventrally from the notochord and floor plate (black cells). It forms a gradient with high concentrations ventrally and low concentrations dorsally. BMPs and other TGF-B-related molecules are released from the dorsal epidermis and dorsal neural tube to form an opposing gradient. These opposing gradients lead to the expression of Nkx6.1 (blue) ventrally, Pax6 (green) medially, and Pax3/Pax7 (dorsally). These expression patterns are refined further (see C) and they contribute to the subdivision of the ventricular zone (inner band of cells) into eleven distinct progenitor domains (pd1–pd6 and pV0 –pV3). (B) A Shh gradient (red) in the ventral half of the neural tube establishes the expression domains of the class I and class II homeodomain genes (see text for details). This in turn leads to the development of five ventral progenitor domains that give rise to V0, V1, V2, MN, and V3 neurons. Cross-repressive interactions between class I (gray) and class II (black) homeodomain genes establish the boundaries between these progenitor domains. (C) Representative cross section through the mouse spinal cord at E11.5 showing the primary classes of neuron that are generated in the embryonic spinal cord. Neurons that arise ventrally (dI6 –V3) are thought to become components of the spinal motor circuitry, while more dorsal cell types (dI1–dI5) contribute to the reception and transduction of sensory information from the body.

Nkx2.2 gene, but then reciprocal repression sets in, so that only one of these factors is expressed in any particular progenitor cell. By this process, specific domains uniquely express particular combinations of Class I and Class II homeodomain transcription factors.

Each domain that is generated by cross-repression produces a single generic class of neuron. V3 interneurons that arise close to the floor plate are generated from progenitors that express Nkx2.2, but not Pax6 or Olig2. Motor neuron progenitors express *Nkx6.1* but not *Irx3* and *Nkx2.2*. *Nkx6.1* turns on Olig2, a bHLH transcription factor that is required for motor neuron differentiation, and Olig2 in turn activates the expression of motor neuron specific transcription factors, such as HB9, Lim3, and Isl1/2, that are each involved in motor neuron differentiation (Fig. 14.12B, C).

A variety of interneuron cell types are generated from the other progenitor domains, with each domain producing a single primary generic class of interneuron (Fig. 14.12C). The V2 progenitor domain is unique in that it generates two interneuron classes: V2a and V2b INs. Notch signaling controls the specification of these two cell neuronal types, which results in the production of equivalent numbers of V2a and V2b neurons (Peng et al., 2007). Dll4 is selectively expressed in a subset of V2 progenitors and these cells activate the Notch pathway in sibling V2 neurons, which in turn induces the expression of Scl and the V2a differentiation program (Del Barrio et al., 2007). The V1 interneuron class that arises just dorsal to the V2 progenitor domain exemplifies many of the features of these early interneuron classes. While these cells share a number of similar attributes, rostral directed ipsilateral axons and inhibitory neurotransmitter phenotype, they are comprised of multiple specialized cell types, possibly five or more. This specialization of neuronal phenotype appears to be regulated by a strict temporal program that overlays the DV spatial program (Stam et al., 2012).

In the dorsal embryonic cord, the alar plate can be coarsely subdivided into two major progenitor regions: a more dorsal region of the neural tube comprising three progenitor domains that generate Class A dI1–dI3 neurons and a second intermediate region that generates Lbx1-expressing Class B neurons (Fig. 14.13). Class A neurons (dI1–dI3) are generated in a BMP and Wnt-dependent manner, whereas Class B (dI4–dI6) interneuron differentiation is independent of BMP/Wnt signaling. The downstream targets of the dorsal BMP/Wnt pathway include the bHLH transcription factors Olig3, Atoh1, Neurog1/2, and Ascl1, which function as cell type specific determinants in Class A progenitors. Olig3 is expressed in all Class A progenitors, where it is required for dI1–dI3

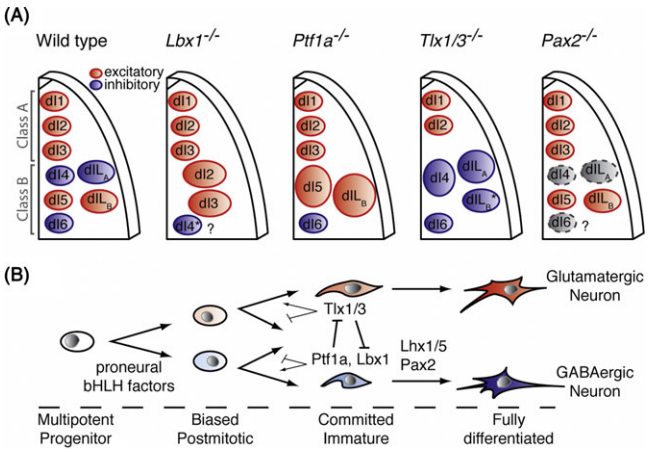

FIGURE 14.13 Genetic control of neuronal cell types and neurotransmitter phenotype in the dorsal spinal cord. (A) Six early (dI) and two late (dIL) populations are generated in the embryonic spinal cord. dI1–3, dI5, and dIL_B neurons are excitatory glutamatergic neurons (red), and dI4, dI6, and dIL_A differentiate into inhibitory cell types (blue). From left to right: In *Lbx1* mutant mice, Class B neurons fail to form, and cells are converted to Class A fates. Excess dI2–dI3 glutamatergic cells are generated. In *Ptf1a* mutant mice, dI4 and dIL_A interneurons transfate to glutamatergic dI5 and dIL_B neurons. This results in the complete loss of inhibitory neurons in the dorsal spinal cord and an excess of excitatory neurons. In *Tlx1/3* mutants, dI3, dI5, and dIL_B excitatory interneuron formation is impaired, and there is a concomitant upregulation of GABAergic markers. Mutant dIL_B cells (*) maintain Lmx1b expression, but they switch to an inhibitory phenotype. In *Pax2* mutants, inhibitory neuron markers are lost, but dI4/dIL_A neurons do not adopt the identity of excitatory dorsal neurons. (B) Model for the specification of excitatory or inhibitory transmitter phenotype in the dorsal spinal cord. Crucial genetic interactions occur in early postmitotic neurons between HD and bHLH transcription factors. Gain or loss of these factors produces a fate switch, with additional factors such as Pax2 operating in postmitotic neurons to consolidate the neurotransmitter program.

neuron specification. It does so by repressing the expression of Lbx1 (Muller et al., 2005), an essential postmitotic regulator of Class B neuronal identity. Within the Class A region, the proneural bHLH transcription factors Atoh1, Neurog1/2, and Ascl1 function at two levels. They act as proneural determinants for dI1, dI2, and dI3 neurons, respectively, and they regulate boundary formation between the dI1, dI2, and dI3 progenitor domains via a cross repression mechanism (Gowan et al., 2001), thereby subdividing the Class A region into three distinct progenitor domains.

A number of homeodomain transcription factors, including Pax3/Pax7, Msx1/3, and Gsx1/Gsx2, also have essential roles in patterning the alar plate. Pax3 and Pax7 are broadly expressed in alar plate progenitors where they appear to act as general determinants of dorsal identity (Fig. 14.12C). Gsx1 and Gsx2 are expressed in dI3–dI5 progenitors, where they control the specification of dI3, dI5, and dIL_B neurons (Mizuguchi et al., 2006) by upregulating the expression of Ascl1, which is an essential proneural determinant for all three cell types. Gsx2, which is required for the differentiation of dI3 interneurons, promotes Ascl1 expression in dI3 progenitors by blocking the expression of Neurog1/2. This suggests that homeodomain patterning factors like Gsx2 promote specific differentiation programs by functioning as permissive factors for proneural determinants such as Ascl1.

Class B Lbx1-expressing neurons come in two flavors: GABAergic inhibitory interneurons and excitatory glutamateregic interneurons. These two populations are marked by the mutually exclusive expression of Pax2, Lhx1/5, Gbx1 (inhibitory dI4 and dIL_A neurons), or Lmx1b, Tlx1/3 (dI5 and dIL_B excitatory neurons). This dichotomy suggests neurotransmitter choice and neuronal identity are closely linked. Indeed, the aquisition of a glutamatergic phenotype depends on the activity of the Tlx1 and Tlx3 selector HD transcription factors that determine dI5 and dIL_B identity (Cheng et al., 2004). Tlx1/3 in turn represses the Pax2-dependant inhibitory differentiation program. Conversely, the bHLH factor Ptf1a drives Class B neurons to differentiate as GABAergic INs by repressing Tlx1/3 expression (Glasgow, Henke, MacDonald, Wright, & Johnson, 2005; Mizuguchi et al., 2006). While the Tlx1/3 and Ptf1a transcription factors appear to be the primary determinants of Class B neurotransmitter phenotype, Pax2 and Lhx1/5 function downstream of Ptf1a to consolidate the GABAergic neurotransmitter program. Inactivation of the *Pax2* gene results in the loss of inhibitory neurotransmitter markers from dorsal dIL_A neurons. In this instance, Tlx1/3 and glutamatergic markers are not upregulated, which indicates that these cells do not convert to excitatory sensory neurons.

MOTOR NEURONS

Motor neurons in the spinal cord are organized in columns at different anterior-posterior levels. At limb levels, three major columns are evident: the medial motor column that innervates the axial muscles of the back, the hypaxial motor column that projects to the ventral body wall muscles, and the lateral motor column that innervates the appendicular musculature muscle (Dasen et al., 2003, 2008; Jessell, 2000). In the cervical region and lumbar spinal cord, the Lateral Motor Column (LMC) innervates forelimb and hindlimb muscles, respectively. In the midthoracic region, the Preganglionic Motor Column (PGC) innervates the sympathetic chain (Fig. 14.14A–C). A gradient of FGF and retinoic acid signaling selectively establishes differential Hox gene expression along the AP axis at different levels, boundaries between which are sharpened by reciprocal inhibition. This anterior-posterior logic of motor neuron identity is thus similar to that governing the positioning of the neurons in the dorsal ventral axis of

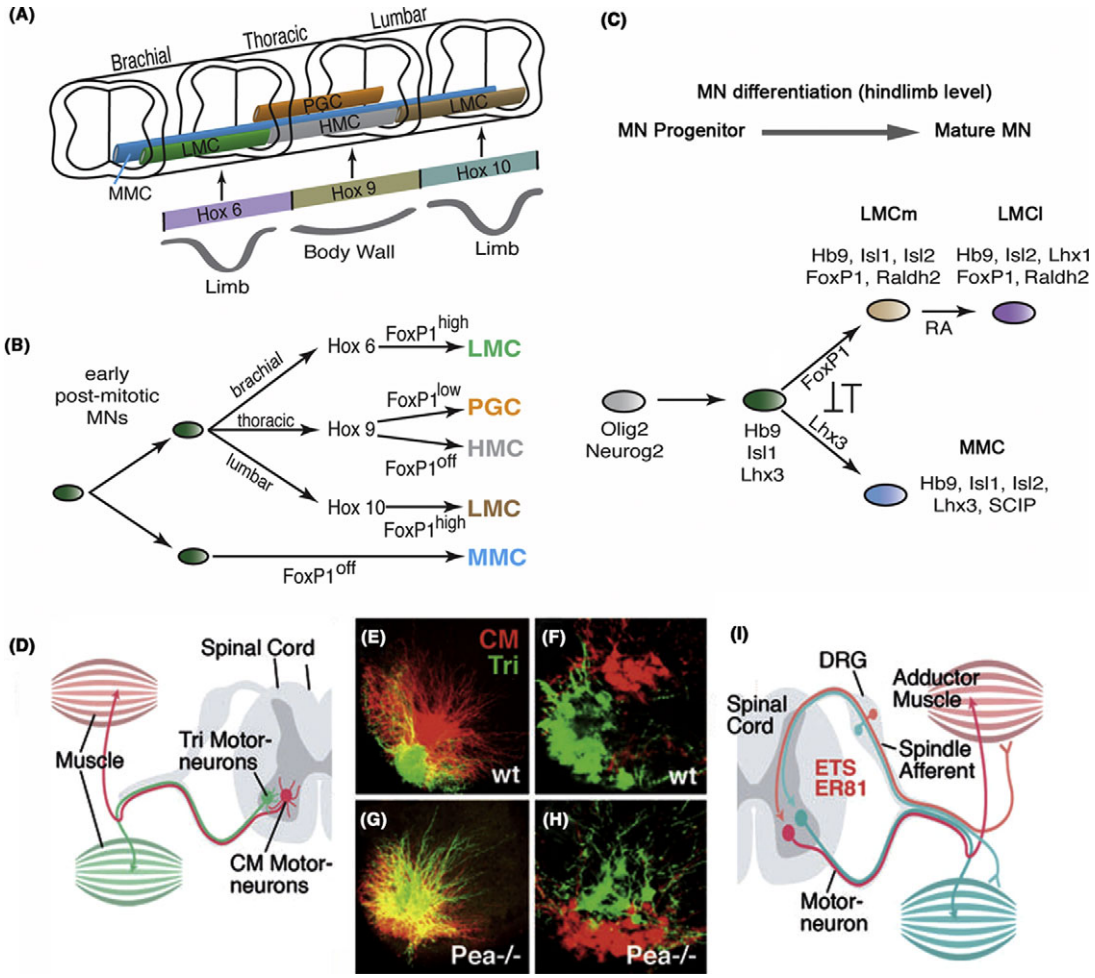

FIGURE 14.14 Establishment of motor neuron identity along the antero-posterior axis of the spinal cord. (A) Polarized expression of FGF and retinoic acid (RA) is responsible for the regionally specific expression of Hox genes along the antero-posterior axis of the neural tube. In addition, inhibitory interactions among the Hox genes themselves sharpen the boundaries within which a given Hox gene is expressed. Hox genes are differentially expressed along the AP axis of the spinal cord and function in conjunction with the forkhead domain gene FoxP1 to establish motor neuron columnar identity. Motor columns are patterned in a manner that corresponds to the arrangement of their targets at brachial, thoracic, and lumbar levels. The MMC innervates muscles of the body wall and therefore extends along the length of the spinal cord. The LMC innervates limb muscles and is present at brachial and lumbar levels. The HMC and PGC innervate muscles of the body wall and autonomic neurons of the sympathetic ganglia, respectively, at thoracic levels. (B) MNs acquire columnar identity based on differential expression of Hox6/9/10 and FoxP1 off/low/high along the AP axis. In *FoxP1* mutants, MNs assume MMC or HMC fates along the entire AP axis and other motor columns do not form. (C) Proposed model of the genetic specification of MN progenitors in lumbar cord. The actions of FoxP1, Lhx3, and retinoic acid (RA) establish the combinatorial expression profiles associated with each of the motor columns in lumbar spinal cord. (D) The motor column is subdivided into pools of motor neurons innervating specific muscles. These pools, including the Tri motor neuron pool and the CM motor neuron pool, occupy discrete locations in the ventral horn of the spinal cord and show distinct dendritic branching patterns. These properties, which depend on the expression of specific transcription factors such as the LIM gene PEA3, can be visualized by backfilling the motor neurons with fluorescent labels injected in the corresponding muscles. (E and F) Two different markers visualize the dendritic arborization (E) and cell body position (F) of the Tri motor neurons (green) and CM motor neurons (red). (G and H) Knockout of the PEA3 gene results in ventral shift of CM motor neuron location, and dorsal expansion of Tri motor neuron dendrites. (I) Reflex circuits between sensory afferents (from muscle spindles) and motor neurons innervating the corresponding muscle are formed because both spindle afferents and motor neurons targeted by them express a common transcription factor, such as ETS ER81 shown here. Among the downstream targets of ETS ER81 are homophilic adhesion molecules that allow the ingrowing sensory axon to "recognize" the proper motor neuron target. Abbreviations: MMC, median motor column; LMC, lateral motor column; HMC, hypaxial motor column; PGC, preganglionic autonomic motor column; RA, retinoic acid. *A–C adapted from Dasen et al. (2008); Rousso et al. (2008). E–H adapted from Vrieseling and Arber (2006).*

the spinal cord. FoxP1, which acts as a co-factor for the Hox transcription factors is required for the specification of LMC type motor neurons, and the PGC or Column of Terni as it is otherwise known (Dasen et al., 2008; Rousso, Gaber, Wellik, Morrisey, & Novitch, 2008).

The lateral motor columns are subdivided into pools of motor neurons that innervate different muscles. One major subdivision within the LMC is between motor neurons that innervate dorsal limb muscles and motor neurons that innervate ventral limb muscles. Transcription

factors of the LIM homeodomain (LIM-HD) family are involved in specification, as motor neurons expressing different combinations of LIM-HD factors such as Isl1, Isl2, Lhx1, and Lhx3 are expressed in different motor neuron classes that innervate different muscle groups (Fig. 14.14C). This is particularly well illustrated in the primary motor neurons (Rop, Mip, and Cap) of zebra fish, which can easily be distinguished by their relative rostral to caudal position in each spinal segment, as well as their axon trajectories to distinct muscle regions. These three neurons express different combinations of LIM transcription factors. The identity of these neurons, as judged by their projection to different muscle regions, is influenced by the position in which they develop. These projection patterns can be changed by transplantation in which the position of these neurons is changed prior to axon extension. Transplantations that lead to such switches in projection correlate with induced changes in LIM-HD code suggesting a causal link (Appel et al., 1995).

Motor neurons that innervate specific muscles are grouped into motor pools, which are distinguished by the expression of distinct members of the ETS family of transcription factors. For example, the ETS gene *ER81* is expressed in the motor neurons that innervate the limb adductor muscle in chicks, whereas the iliotrochanter motor neurons express the *PEA3* ETS gene (Fig. 14.14D–I). The initial expression of these ETS genes depends on peripherally derived signals such as GDNF and coincides with the arrival of motor neuron terminals in the vicinity of their specific targets. In PEA3 knockout mice, the motor neurons that are normally PEA3 positive fail to develop normally so muscles that are normally targets of these neurons are hypoinnervated and become severely atrophic. Not only do these motor neuron pools fail to branch normally within their target muscles, but the cell bodies and dendrites of these motor neurons also are mispositioned within the spinal cord, which is critical for the control of their reflexive and descending innervation (Fig. 14.14E–H). Recent work suggests that these ETS genes may regulate the expression of cell adhesion and axon guidance factors that help motor neurons recognize their target. Interestingly, the sensory afferents that innervate the stretch receptors in a particular muscle express the same ETS gene as the motor neurons that innervate that muscle, suggesting this may help the sensory neuron axons find the dendrites of these motor neurons to complete the connection that is the basis of the monosynaptic stretch reflex.

The motor neuron system in the ventral nerve cord of the *Drosophila* larva, which is responsible for crawling, displays a relatively simple repetitive organization (Landgraf & Thor, 2006). In each half segment, there are approximately 36 motor neurons arising from about 15 neuroblasts (Fig. 14.15A, B). Some project through the intersegmental nerve (ISN) to innervate the more interior muscles that span the length of each segment and cause the animal to shorten. Others project through the segmental nerve (SN) to innervate the more exterior set of muscles that are more radial in orientation and cause the animal to lengthen. This is somewhat comparable to the division in vertebrate limbs, where the sets of (usually antagonistic) muscles derived from the ventral and dorsal muscle masses are innervated by pools of motor neurons whose axons project along divergent paths. ISN and SN motor neurons are further subdivided into subclasses of motor neurons that innervate distinct muscle territories.

No master/selector gene has been identified that specifies generic motor neuron fate in *Drosophila*, although combinatorial codes of transcription factors specify different motor neuronal subtypes (Landgraf & Thor, 2006). The first subdivision in *Drosophila* is between ventrally projecting motor neurons, vMNs, and dorsally projecting motor neurons, dMNs. Interestingly, vMN identity is controlled by the combinatorial action of the *Nkx6* and *HB9* homeobox genes (Broihier & Skeath, 2002; Cheesman, Layden, Von Ohlen, Doe & Eisen, 2004), a similar combination to that used to specify generic motor neuron fate in vertebrates. The vMNs in *Drosophila*, like the motor neurons in vertebrates, are then specified into subclasses that project along specific nerves to innervate specific muscles, by the further expression of combinatorial codes of LIM-HD factors (Fig. 14.15C). dMNs depend upon other sets of transcription factors: even-skipped (eve) and grain (grn) (Garces & Thor, 2006; Landgraf, Roy, Prokop, VijayRaghavan, & Bate, 1999). In contrast to the LIM-HD factors, Nkx6 and HB9, the vertebrate orthologues of even-skipped (Evx1/2) and grain (Gata2/3) are not involved in vertebrate motor neuron specification. Thus, *Drosophila* vMNs appear to be evolutionary more similar to vertebrate motor neurons.

What aspects of motor neuron phenotype do combinatorial codes of transcription factors control? This issue has remained elusive, but more recent studies have pointed to two important motoneuron properties: axon pathfinding molecules and electrophysiological aspect of identity. Specifically, Dfr has been found to be involved in the regulation of a specific immunoglobulin-containing cell-adhesion molecule called Beat-1c, and the *beat-ic* gene is likely a direct target of this transcription factor (Certel & Thor, 2004). Similarly, *eve* controls Unc-5, a receptor for the pathfinding guidance molecule netrin, in dorsally projecting motor neurons. Eve also controls the expression of genes involved in generating voltage- and ligand-gated currents in dorsally projecting motor neurons (Pym, Southall, Mee, Brand, & Baines, 2006).

THE CEREBRAL CORTEX

The cerebral cortex of mammals is the neural structure that is important for conscious thought, perception, and associative learning, as well as providing executive control over voluntary movement. The overall architecture of the

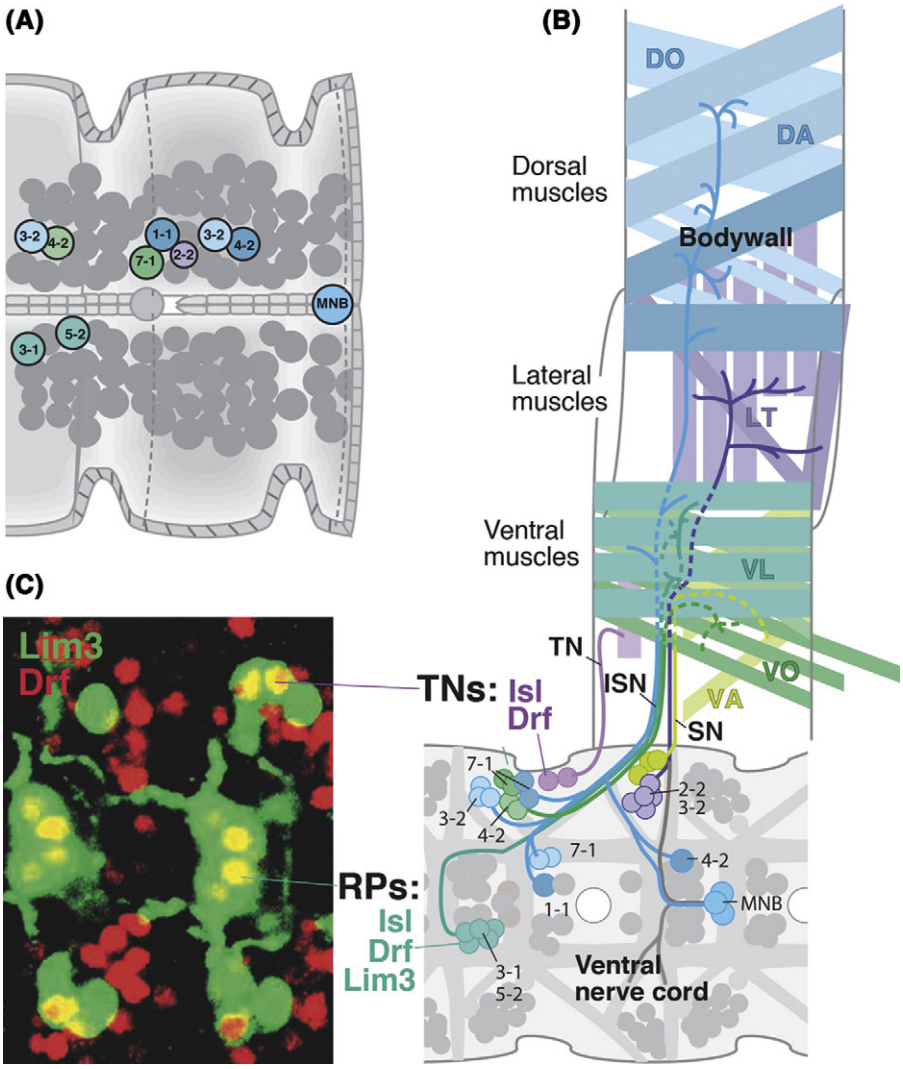

FIGURE 14.15 Specification of motor neurons in the *Drosophila* ventral cord. (A) Neuroblast map of two embryonic segments, showing in color the subset of neuroblasts that give rise to motor neurons. (B) Schematic flattened view of one body segment, showing in different colors the pattern of bodywall muscles and motor neurons innervating these muscles. The specific motor neuron(s) innervating each of the 30 muscle fibers comprising the musculature has been mapped. Motor neurons are color coded such that their color matches the one of the neuroblast from which it descends (see A) and the muscle it innervates. As in vertebrates, distinct groups of motor neurons are specified by expressing transcription factors of the LIM and POU family. Shown here and, photographically, in panel C are the RP neurons, expressing the combination Isl, Drf, and Lim3, and the transverse nerve (TN) motor neurons that express only Isl and Drf. Mutations in any of these genes result in motor neuronal abnormalities. *B from Certel and Thor (2004).*

cortex is relatively simple both in terms of its areal structure and the general composition of cells that make up the cortex. The neocortex, which forms most of the cerebral cortex in humans, is a six-layered structure, with each layer having its own particular array of neuronal cell types. Differences in the thicknesses and cellular densities of particular layers have enabled histologists to distinguish as many as 100 cytoarchitectonically distinct cortical areas in humans. There are two primary classes of neurons in the cortex. The majority of these cells, approximately 80%, are glutamatergic pyramidal neurons that originate from neuroepithelial cells in the ventricular zone of the telencephalic vesicles. Asymmetric divisions of these cells generate one daughter that remains neuroepithelial and apical, and another daughter that migrates basally. In most instances, the migrating daughter becomes a postmitotic cortical neuron, but as development proceeds, an increasing number of migrating daughter cells travel only a short distance to the subventricular zone, where they divide symmetrically to generate two neurons. The second major class of neurons in the cortex, GABAergic inhibitory interneurons, arise from the ventral telencephalon or ganglionic eminence (Anderson, Eisenstat, Shi & Rubenstein, 1997).

Cortical precursors, once generated, migrate away from the ventricular and subventricular zones, through an intermediate zone that will later be filled with axons, until they arrive at the cortical plate where they stop migrating and begin to differentiate into an enormous variety of specialized cortical cell types. This basal migration is coupled with an inside-out pattern of histogenesis in which the firstborn cells take up the deep layers of the cortical plate and the later-born cells migrate past the earlier generated neurons to occupy more superficial layers (Fig. 14.16A) (Angevine & Sidman, 1961). Cortical cells are specified with respect to their laminar fates before they migrate, for if postmitotic cells from the ventricular zone of a young embryo (destined for deep layers) are transplanted into the ventricular zone of an older one that is generating superficial cells, then the transplanted cells will

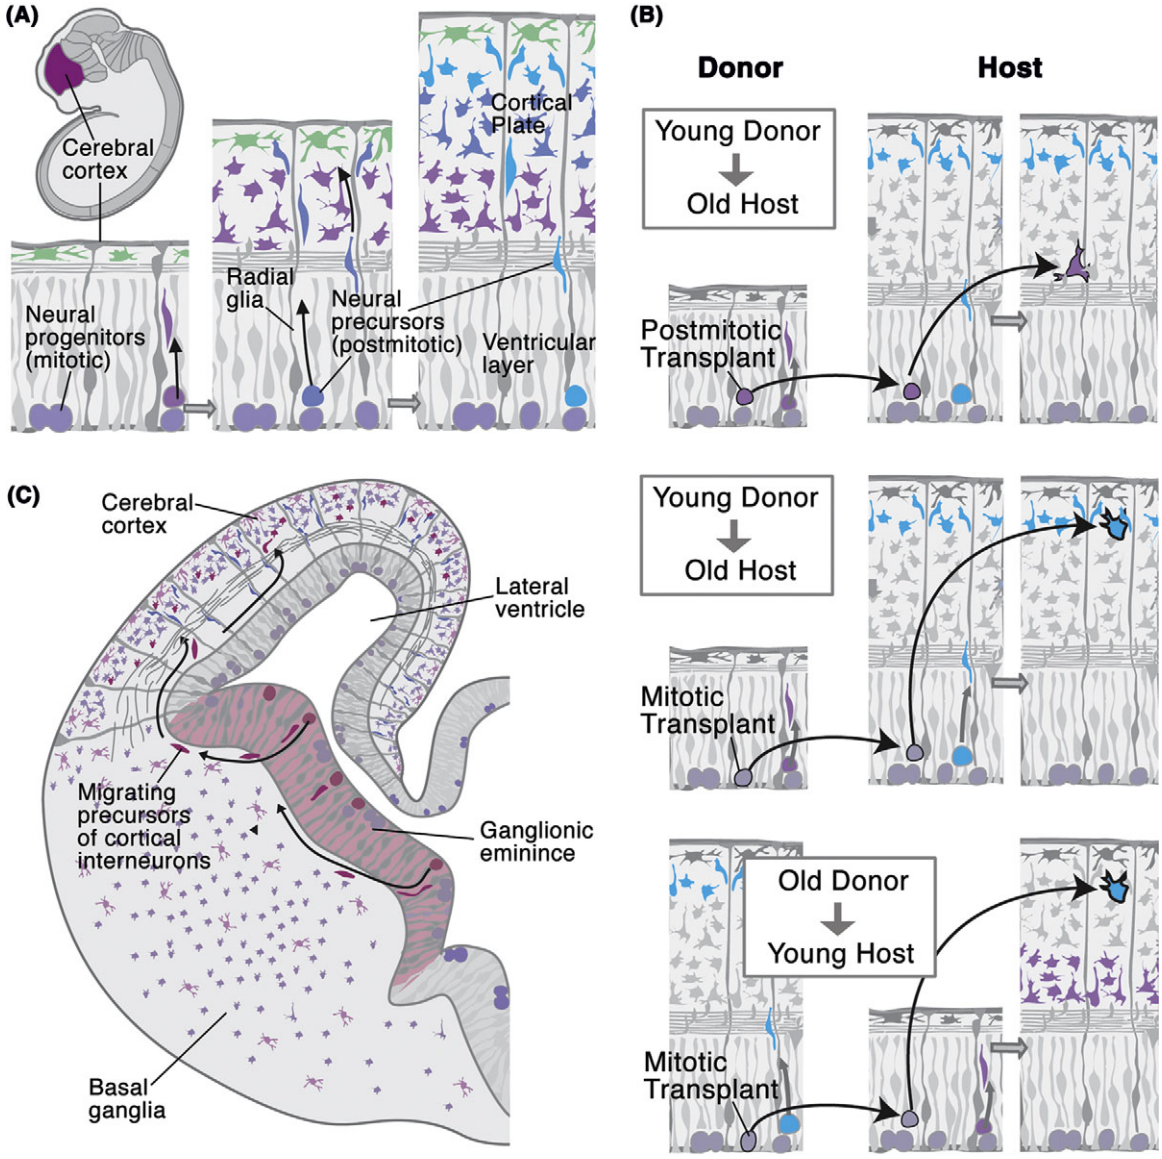

FIGURE 14.16 Laminar fate determination in the cerebral cortex. (A) Morphogenesis of the mammalian cerebral cortex. Neural precursors are born in the ventricular layer and migrate away from the ventricular surface, following tracks provided by radial glial cells. The firstborn cells are the Cajal-Retzius neurons (left in figure). Later-born neurons accumulate in a dense matrix of cells, the cortical plate (middle of figure). In this plate, neurons are ordered by birth date in such a way that older neurons (magenta) remain in deep layers, and younger neurons (blue) migrate through the deep layers to attain a superficial position (right in figure). (B) Top: If postmitotic ventricular cells from young donors (which normally would become deep cells) are transplanted into an old host, they do not adapt to their new environment and develop as deep layer neurons (arrow). However, if ventricular cells that have not yet exited the cell cycle are transplanted from young donors into an old host (middle panel), they adapt to their new environment and develop as superficial neurons (arrow). If, on the other hand, premitotic progenitors from old donors are transplanted into young brains, they can take later fates and become upper layer neurons. (C) Migration route of GABAergic interneurons from the ganglionic eminences in the ventral telencephalon into the cortical plate in a mammalian embryo.

still migrate to deep layers and have deep-layer fates (Fig. 14.16B, top panel). However, if progenitors from a young ventricular zone are in their last mitotic cycle when they are transplanted to the older environment, they can change their laminar identity, suggesting that cortical cell fate is still undetermined until the cells exit the cell cycle (Fig. 14.16B, middle panel). Interestingly, the reverse experiment of transplanting premitotic progenitors of old donors to younger ventricular zones does not result in these cells assuming earlier, deeper-layer fates (Fig. 14.16B, bottom panel), suggesting that progression of determination is a one-way street (McConnell, 1995).

The specification of excitatory neuron cell types appears to be largely under the control of intrinsic determinants, many of which are transcription factors. Pax6, Emx1,

FoxG1, and Lhx2 function at early times to regulate arealization and to broadly specify cortical progenitors. Cell type specification is closely linked to the laminar position, and while a number of genes have been identified that mark neurons in different laminae, in most instances the programs that specify neuronal cell identity are still poorly defined. Nonetheless, some key components of the developmental switch that controls the differentiation of subcortically versus intracortically projecting pyramidal neurons have been identified (Leone, Srinivasan, Chen, Alcamo, & McConnell, 2008). Neurons in laminar V project subcortically to the superior colliculus, hindbrain, and spinal cord, and they are derived from cells that express the Fezf2 transcription factor. Fezf2 in turns activates expression of the Ctip2 zinc-finger factor, while repressing expression of Satb2, a chromatin remodeling transcription factor. In the absence of Fezf2, glutamatergic pyramidal neurons, neurons in lamina V do not express Ctip2 and instead of sending their axons subcortically, they instead extend axons across the corpus callosum to other cortical areas. Interestingly, Satb2, is markedly upregulated in Fezf2 mutants. Satb2 is required for neurons in the cortex to cross the corpus callosum. Overexpression of Satb2 represses Ctip2 expression and results in fewer lamina V cells sending axons subcortically to the hindbrain and spinal cord. Conversely, overexpression of Fezf2 generates an excess of subcortically projecting neurons.

As noted previously, GABAergic neurons arise from the medial and caudal ganglionic eminences (MGE and CGE). They then migrate tangentially to the cortex, where they intercalate into the developing cortical plate and form connections with glutamatergic pyramidal neurons. Multiple inhibitory interneuron cell types are derived from these two domains (Anderson et al., 1997; Batista-Brito and Fishell, 2009). The MGE produces somatostatin-positive (SST^+) interneurons and fast spiking interneurons that express the calcium-binding protein parvalbumin (PV) and the potassium channel Kv3.1, which enable neurons to generate trains of high-frequency action potentials. While fast spiking PV neurons arise from ventral regions of the MGE, there is also a temporal gradient of PV versus SST interneuron differentiation, revealing spatial and temporal cues that regulate the development of these two cell types. Bipolar neuron cell types (calretinin and VIP cells) that are generated from the CGE develop later than their MGE-derived counterparts. Nkx2.1 is a key early determinant of GABAergic interneuron identity, by promoting MGE fates over LGE and CGE fates. This function may reflect an early role for Nkx2.1 in patterning the subpallium. Loss of Nkx2.1 results in a marked depletion of MGE derived neuronal cell types including PV^+ and SST^+ interneurons. Dlx1/2 and Mash1, which is regulated by Dlx1/2, are required for the specification of GABAergic cell types in the forebrain. These genes are global determinants of GABA neuron differentiation, as they are also required for the development of GABAergic neurons in the striatum, including medium spiny neurons.

Extrinsic signaling contributes to the laminar specification of cortical progenitors as indicated by experiments showing that BDNF is able to induce late-born progenitors to acquire early-born laminar fates. Extrinsic signals also appear to control the migration and distribution of inhibitory interneurons in the cortex. The loss of subcortically projecting pyramidal neurons in mice that lack Fezf2 is associated with changes in the laminar distribution of PV^+ and SST^+ interneurons, with reduced numbers of both cell types in lamina V (Lodato et al., 2011). Neuronal activity also regulates the development of subsets of inhibitory interneurons, including migration and their axonal and dendritic morphology. It therefore appears that neuronal differentiation in the cortex is regulated by time of birth, intrinsic transcriptional determinants (some of which may be activated in a time dependent manner—e.g., Fezf2 is expressed in deep-layer pyramidal neurons and is downregulated when upper-layer neurons that are born later are generated), and by extrinsic signals and activity as these cells migrate and intercalate into the cortical circuitry. Neuronal activity also plays a prominent role in regulating neuronal connectivity in the cortex. This is perhaps best exemplified by the activity-dependent refinement of the ocular dominance columns in the visual cortex (see Chapter 19).

CONCLUSIONS

The generation of neurons involves a variety of extrinsic signals and intrinsic transcription factors that confer individual identities on postmitotic neurons. Whether vertebrate or invertebrate, this process of determination involves a similar set of molecular and cellular mechanisms, such as regional and temporal identity genes, proneural genes, signaling molecules and receptors, the Notch pathway, and asymmetric cell division. All these conspire, over the course of neuronal generation, to create progenitors with distinct combinations of transcription factors that uniquely specify the fates of the differentiating neurons by regulating the expression of genes that affect specific features of the cell such as axon and dendrite growth and targeting, the topic of the next chapter.

Neurogenesis and Migration

INTRODUCTION

The epithelium lining the brain vesicles in the neural tube, which is termed the ventricular zone (VZ), is the site of primary neurogenesis in the CNS. The idea that CNS neurogenesis occurs in the thin epithelium of the embryonic brain vesicles became apparent when Fred and Mary Sauer showed that cells in the neuroepithelium contain different amounts of DNA, with diploid cells located on the ventricular surface (Sauer & Chittenden, 1959). Clear images of the pseudo-columnar character of the neuroepithelium of embryonic rat brain were achieved in ^{3}H-thymidine labeling studies of the neocortex (Berry & Rogers, 1965) and in serial scanning and electron micrographs, which showed movements of the nuclei during the principal phases of the cell cycle (Hinds & Ruffett, 1971). Cells in interphase extend processes across the thin wall of the epithelium, one cell deep at this stage, and divide at the ventricular surface. During the cell cycle, the nucleus undergoes interkinetic migration, moving from the apical surface of the ventricular zone (VZ) during G1, entering S phase as the nucleus reaches the top of the VZ, and moving back toward the ventricular surface during G2 to enter mitosis, or M phase (Sauer & Walker, 1959). A cardinal feature of the neuroepithelium is its upside-down orientation relative to epithelia of other tissues. This relates to the fact that the neuroepithelium forms a tube that orients the apical surface of neuroblasts in the epithelial sheet toward the lumen of the neural tube and their basal surface toward the pia.

The neurons of the peripheral nervous system (PNS) and CNS originate from the neural tube and the folds of the neural tube. The cells of the PNS are generated first, as they delaminate in a specialized region of the dorsal aspect of the neural tube called the neural crest. Neural crest neuroblasts migrate out into the developing nonneuronal tissues, where they will form the axon tracts of the periphery, as the progenitors of the CNS are beginning to establish the regions of the brain and spinal cord that will receive the sensory information from the PNS and establish brain circuitry. We will therefore discuss neurogenesis and migration in the PNS first, followed by patterns of neurogenesis and migration in the CNS.

DEVELOPMENT OF THE PERIPHERAL NERVOUS SYSTEM

The Neural Crest is a Migratory Cell Population That Forms Multiple Derivatives

The *neural crest* is a transient population of cells, so named because they arise on the "crest" of the closing neural tube. This cell population is unique to vertebrates and forms most of the PNS. Neural crest cells migrate extensively along characteristic pathways and give rise to diverse and numerous derivatives. All of the *dorsal root, sympathetic, parasympathetic,* and *enteric ganglia* are derived from neural crest cells. Furthermore, most *cranial sensory ganglia* receive a contribution from the neural crest, with the remaining cells derived from *ectodermal placodes.* In addition to forming neurons and glia of the PNS, neural crest cells form melanocytes, cranial cartilage, and adrenal chromaffin cells. This wide variety of cell types arises from precursors in the neural folds and neural tube that are multipotent and have stem cell properties (Bronner-Fraser & Fraser, 1988; Stemple & Anderson, 1993). See Chapter 17 for a discussion of stem cells.

The neural crest originates at the border between the neural plate and the nonneural ectoderm by an inductive interaction between these two tissues (Selleck & Bronner-Fraser, 1995) (see Chapter 13). This induction initiates during gastrulation (Basch, Bronner-Fraser, & Garcia-Castro, 2006) even though precursors with the potential to

© 2013 Elsevier Inc. All rights reserved.

form neural crest only become recognizable by expression of neural crest markers within the dorsal portion of the neural tube. This delay occurs as the result of epigenetic changes that allow transcription of neural crest marker genes at the proper time (Strobl-Mazzulla, Sauka-Spengler, & Bronner-Fraser, 2010). These premigratory neural crest cells subsequently emerge from the neural tube and embark upon defined pathways.

Cells in the neural tube are epithelial and look much like contiguous soda cans that have a defined top (apical) and bottom (basal) side. They are closely apposed to one another and are connected by various types of adhesive junctions. In contrast, migratory cells such as neural crest cells are mesenchymal, having a fibroblast-like morphology that facilitates their movement. Thus, precursor cells within the neural tube change from an epithelial to a mesenchymal morphology as they turn into migratory neural crest cells. Such an *epithelial-to-mesenchymal transition* is a common event in development during the formation of tissues and organs. The transcription factor Snail2 is expressed in premigratory and early migrating cells and represents an early neural crest marker. Snail transcription factors have been associated with epithelial–mesenchymal transitions in a number of cell types, and Snail2 function is necessary for the emigration of neural crest cells. Initiation of neural crest cell migration proceeds in a rostral-to-caudal progression along most of the neural axis, following upon the heels of the head-to-tailward closure of the neural tube. After emigration, these cells move in a highly patterned fashion through neighboring tissues and localize in diverse sites.

Initiation of Migration

As they change from epithelial to migratory mesenchymal cells, neural crest cells undergo changes in adhesive properties. While within the neuroepithelium, neural tube cells express high levels of the *cell adhesion molecules* N-cadherin and cadherin-6B. Migrating cells downregulate these cadherins during migration and upregulate cadherin-7. Upon coalescing into ganglia and ceasing migration, cadherin-7 is downregulated and N-cadherin are again upregulated (Nakagawa & Takeichi, 1998). This suggests that a shift in cell surface and adhesive properties may accompany the onset and cessation of migratory behavior. Neural crest cells also turn on RhoB during the initiation of migration.

After leaving the neural tube, neural crest cells encounter extracellular spaces that are rich in *extracellular matrix* (ECM) *molecules*, such as fibronectin, laminin, collagens, and proteoglycans. These may serve as a good migratory substrate, and, indeed, the neural crest cell surface has abundant integrin receptors that mediate adhesion to ECM molecules. Furthermore, administration of function-blocking antibodies to the *β subunit of integrin* cause severe perturbations in neural crest development in the head. They appear to prevent the migration of some neural crest cells from the cranial neural tube. In the trunk, function-blocking antibodies that interfere with the *a_4 subunit of integrin* cause defects in neural crest cell movement but fail to alter the segmental pattern of migration through the somites. These results suggest that perturbing integrin function alters the properties of migratory cells, but not their overall metameric pattern of migration. Thus, cell–matrix interactions may play a permissive role in the migration of neural crest cells through the somites but cannot play an instructive role in directing the precise patterns or pathways for crest cell migration.

Techniques for Following Neural Crest Cells

When neural crest cells emerge from the neural tube, they first enter a cell-free space in which they are easily identifiable (Fig. 15.1). Subsequently, they invade other tissues in which they are difficult to distinguish. Therefore, it is necessary to *mark* neural crest cells in order to study their migratory patterns and derivatives. A variety of techniques have emerged for this purpose, ranging from transplantation of tissue containing premigratory neural crest cells to lineage tracers and molecular markers. *Neural tube transplantations* have provided a wealth of information about neural crest migratory pathways and, in particular, derivatives arising from this population. Although this approach was widely used in amphibians for studying numerous embryonic processes, it has been applied most successfully to the analysis of neural crest migratory pathways and derivatives in avian embryos (LeDouarin & Kalcheim, 1999). Initial experiments in birds involved transplanting a neural tube from a donor labeled with the radioactive marker [^{3}H] thymidine into an unlabeled host (Weston, 1963). Neural crest cells generated from the labeled neural tube were also labeled and could be

FIGURE 15.1 A transverse section through a chick embryo showing neural crest cells initiating migration from the dorsal neural tube and into an ECM-filled space. *Courtesy of Jan Lofberg.*

identified readily in the periphery. This technique yielded important information about early stages of neural crest migration, but the label became diluted with further cell division and was not useful for looking at long-term differentiation of neural crest cells into diverse derivatives.

To circumvent this problem, LeDouarin took advantage of the ability to perform grafts between related species of birds, such that the grafted cells were indelibly marked (Fig. 15.2). This created an interspecific *chimera*, from the Greek meaning "fabulous monster," containing a donor quail portion of the neural tube and neural crest in an otherwise normal chick host embryo. Quail neural crest cells migrate away from the grafted neural tubes and can be recognized easily within the host chick embryo by staining for condensed heterochromatin, which characterizes the quail but not chick cells. This technique has been facilitated greatly by the advent of quail-specific antibodies. Recently, the availability of transgenic chickens with cell populations that are labeled with green fluorescent protein (GFP) makes it possible to perform similar grafts within the same species. Use of the these transplantation studies has made it possible to demonstrate that neural crest cell populations originating from different axial levels follow distinct migratory pathways and give rise to different progeny once they reach their destinations.

In addition to grafting experiments, antibodies that recognize neural crest cells, such as HNK-1 and NC-1 antibodies, made it possible to identify early migrating neural crest cells without the necessity of performing microsurgery. The exclusive use of neural crest antibodies has several pitfalls because these antibodies are neither entirely specific nor stain the full complement of neural crest cells. However, they do provide important confirmatory information about the pathways followed by neural crest cells. More recently, a number of other molecular markers for early neural crest populations have become available. These include the cell adhesion molecule cadherin-6B and the transcription factor Snail2, expressed in the neural folds and neural crest cells during early stages of migration, and Sox10, expressed in premigratory, early migrating neural crest cells and later in neural crest-derived glia.

One problem with using antibodies or molecular markers to follow cell migratory patterns is that these do not represent true lineage markers. Shifts in their expression patterns could just as easily reflect up- or downregulation of these molecules as changes in cell position. Therefore, approaches for labeling small groups, as well as large populations, of neural crest cells have been employed to follow individual cell movements and interactions within the population. One successful approach has been to inject the *lipophilic vital dye DiI* into the neural tube or neural folds. Because the dye is hydrophobic and lipophilic, it intercalates into all cell membranes that it contacts. Injection into the neural tube marks all neural tube cells, including presumptive neural crest cells, within its dorsal aspect. Because the time and location of injection can be controlled, this provides a direct approach for following migratory pathways. When dye injections are made focally into neural folds, this technique can be used to label very small numbers of cells. It has the further advantage of being applicable to almost all vertebrates. Similarly, the availability of green fluorescent protein (GFP)

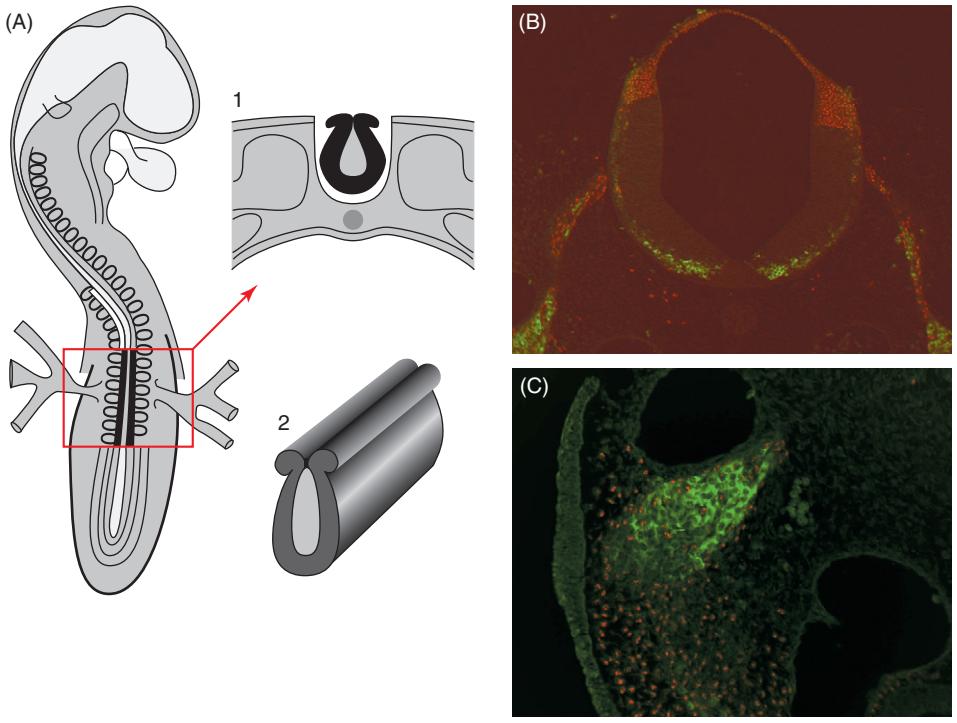

FIGURE 15.2 Procedures for grafting a fragment of the neural primordium from a donor quail into a host chicken embryo as used by LeDouarin and colleagues. (A) View of an avian embryo with anterior at the top. Neural folds are shown in black in the boxed region; this structure is removed and transplanted to a host embryo. and its variants has made it possible to label neural tube cells, including premigratory neural crest cells, by electroporating constructs encoding GFP into the neural tube lumen at various stages and axial levels. A disadvantage of these approaches, however, is that the dye or fluorophore becomes diluted with each cell division and, therefore, this approach is not useful for examining the long-term differentiation of neural crest derivatives.

Because most studies of cell migration *in vivo* look only at the beginning and end point, little is known about the dynamics of neural crest cell movement. Advances in imaging technologies have made it possible to acquire more refined images *in ovo*. Time-lapse movies of cranial neural crest migration can be generated by injecting DiI or electroporating GFP constructs (Yasuda et al., 2000) into the lumen of the chick neural tube, and high-resolution confocal images can be made of the labeled cells over time (Fig. 15.3). These movies make it possible to visualize the migratory behavior of neural crest cells as they emerge from the cranial neural tube and migrate toward the branchial arches. As the embryo develops, it is possible to follow individual cell movements within the branchial arches, which will give rise to the bone and cartilage of the jaw. Neural crest cells move in defined streams and appear to form distinct chains in which cells are oriented along the same trajectory and remain in contact via their processes. This suggests a large degree of intercommunication between migrating populations of cranial neural crest cells.

A number of different methods have proved useful for following the pathways of neural crest migration, including neural tube transplantations, vital dye labeling, GFP expression, and antibody staining. These have made it

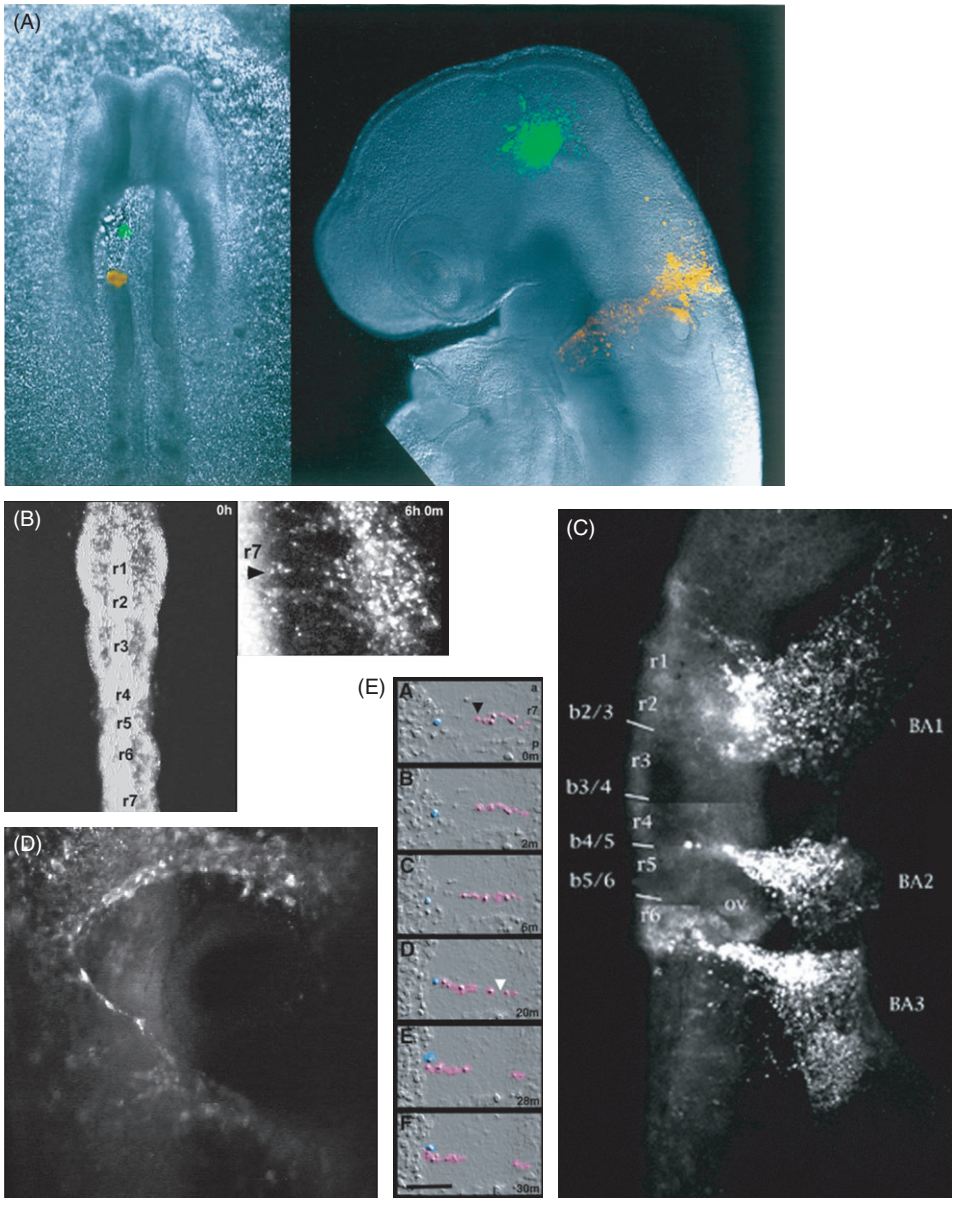

FIGURE 15.3 Labeling of neural crest cells with liphophilic tracer dyes. (A) On the left is a chick embryo viewed shortly after unilateral ablation of the neural folds of roughly half the neural tube at the level of the presumptive midbrain. A spot of DiO (green) was focally injected into the remaining neural tube, and DiI (red) was injected into the bordering intact neural folds. On the right, the same embryo after 48 h of further development. Cells that were originally in the neural tube had dispersed as migratory neural crest cells from both the green- and the red-labeled spots. (B–D) Different views of time-lapse movies of embryos in which the neural tube and premigratory neural crest cells were labeled with DiI. (B) Two views of the same embryo immediately after DiI labeling (left) and several hours after neural crest migration from the hindbrain. Rhombomeres (r1–r7) are indicated. (C) A similar embryo at a later time point by which time neural crest cells have migrated into the branchial arches (BA). possible not only to establish the various routes of neural crest migration occurring at different axial levels but also to follow the derivatives of neural crest cells arising from distinct locations.

Regionalization of the Neural Crest along the Body Axis

Despite differences in the nature of the techniques involved, transplantation experiments, molecular markers, and direct labeling have provided similar pictures of the migratory pathways followed by neural crest cells. These migratory pathways and the derivatives formed by neural crest cells are regionalized according to their original position along the anterior/posterior axis, such that cells from a given axial level give rise to a characteristic array of progeny and follow distinct pathways from those arising at other axial levels (LeDouarin & Kalcheim, 1999; Noden, 1975). The different populations of neural crest cells arising along the neural axis have been designated as cranial, vagal, trunk, and lumbosacral (Fig. 15.4). Distinct cell types differentiate from these different populations.

At cranial levels, some neural crest cells contribute to the *cranial sensory ganglia* and the *parasympathetic ciliary ganglion* of the eye, whereas others migrate ventrally to form many of the *cartilaginous elements of the facial skeleton*. One of the interesting things about neural crest-derived bones of the head is that these are the only skeletal elements in the body that are derived from ectoderm. Precise quail/chick grafting experiments have determined the regions of neural tube from which neural crest cells arise to contribute to cartilaginous elements and cranial ganglia (Noden, 1975). Neural crest cells originating in the midbrain migrate primarily as a broad, unsegmented sheet under the ectoderm; they contribute to derivatives ranging from the skeleton around the eye, connective tissue and membranous bones of the face, to the ciliary ganglion and trigeminal ganglia (LeDouarin & Kalcheim, 1999). Neural crest cells arising in the hindbrain migrate ventrally and enter the branchial arches to form the bones of the jaw.

Vagal neural crest cells migrate long distances to form the *enteric nervous system*, which also receives a contribution from the lumbosacral neural crest. Within the gut, the earliest generated crest cells move as a wave from anterior to posterior to populate the bowel, which they appear to populate in sequence such that the anterior portions are populated by neural crest cells first and the cells move to progressively more posterior sites. Mice bearing a "lethal spotted" mutation lack neural crest cells in a portion of their bowel. This leads to a lack of innervation in the region called aganglionic bowel. As a consequence, food waste fails to move through this portion of the bowel, leading to a disorder called "mega-colon." A similar defect is observed in humans leading to "Hirschsprung's disease." This disorder arises from a defect in molecules

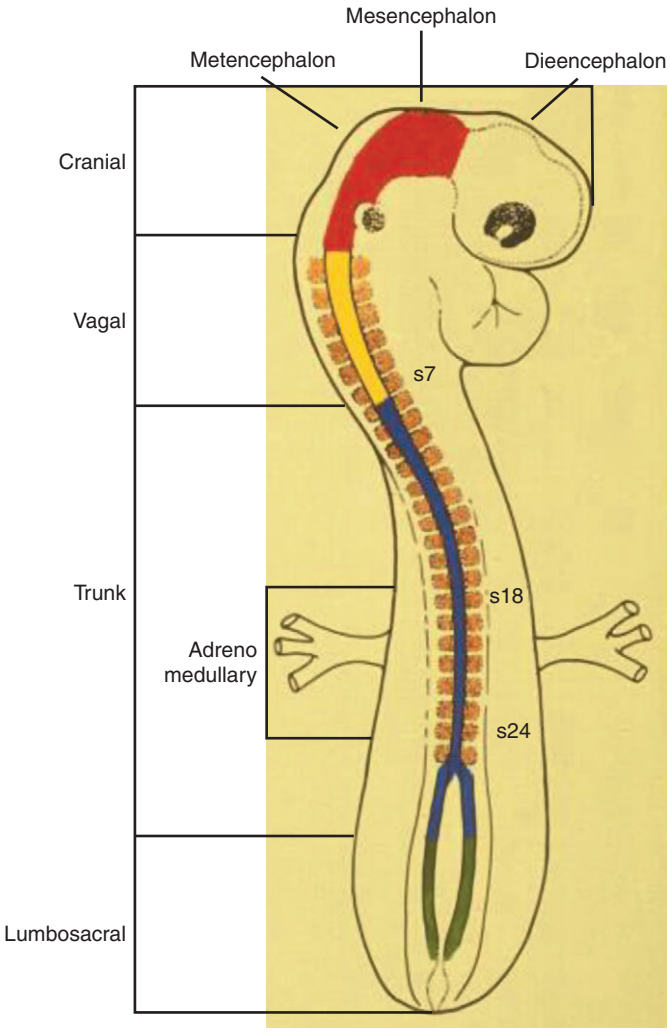

FIGURE 15.4 Schematic diagram showing different levels of the neural axis from which neural crest cells arise. From anterior to posterior, the neural axis can be divided into cranial, vagal, trunk, and lumbosacral levels. Each gives rise to distinct derivatives. *Drawing provided by Dr. M. Bronner.*

called endothelins and their receptors. The failure of neural crest migration in the aganglionic bowel of lethal spotted mutant mice is caused by a defect in mesenchymal components of the gut, whereas the neural crest cells themselves are normal.

Trunk neural crest cells follow two primary migratory pathways (Fig. 15.5): a *dorsolateral pathway* between the ectoderm and the somite and a *ventral pathway* through the rostral half of each sclerotome, the mesenchymal portion of the somite, which will go on to form the vertebrae. Cells following the dorsolateral stream give rise to *melanocytes*. Those cells following the ventral pathway give rise to the PNS of the trunk, including the chain of *sympathetic ganglia* and *dorsal root ganglia*, as well as *chromaffin cells* of the adrenal medulla. In addition to these neurons, these cells generate *glia* of the peripheral ganglia and *Schwann cells* that ensheathe and myelinate peripheral axons.

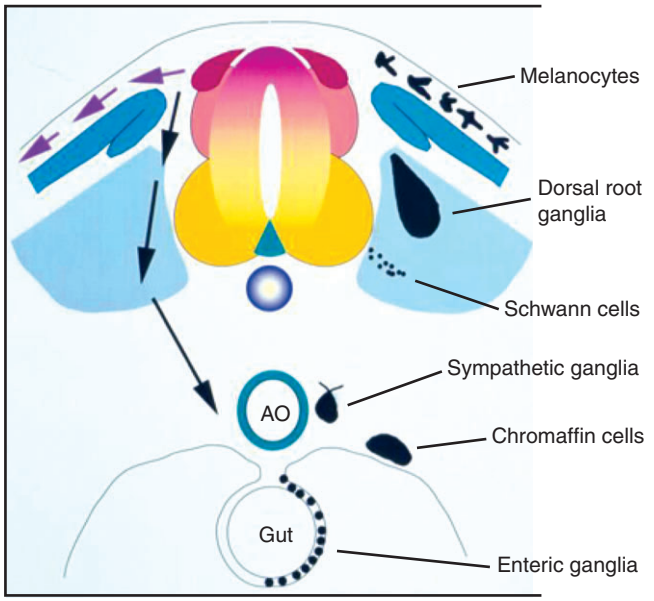

FIGURE 15.5 Schematic diagram of an idealized embryo in cross section showing pathways of neural crest migration in trunk and derivatives formed. Neural crest cells migrate along two primary pathways: dorsally under the skin or ventrally through the sclerotome. Dorsal migrating cells form pigment cells, whereas ventrally migrating cells give rise to dorsal root and sympathetic ganglia, Schwann cells, and cells of the adrenal medulla. *Drawn by Mark Selleck.*

The neural crest can be subdivided into specific subpopulations based upon their level of origin along the neural tube. Different populations follow different migratory pathways and form characteristic types of derivatives. For example, cranial bone and cartilage only arise from the cranial neural crest.

Grafting of Neural Crest Cells to New Locations—Intrinsic Versus Extrinsic Cues?

Neural crest cells that arise and migrate at different axial levels assume different fates. Thus, it is possible that they are specified at early times to take on particular fates. For example, one possibility is that neural crest cells are preprogrammed by their axial level to populate specific derivatives; alternatively, neural crest cells might be multipotent and migrate naively into available locations, where local cues provide them with instructions about their fates. To test the role of migratory pathways in choice of fate, neural tubes from particular axial levels have been grafted to new locations. This is referred to as a "heterotopic" graft. These experiments have revealed, for example, that when vagal neural crest cells are grafted to trunk regions, they form normal trunk derivatives (dorsal root ganglia, sympathetic ganglia, etc.) and normal vagal derivatives (enteric ganglia of the gut) (Fig. 15.6). The gut is immediately ventral to the trunk region and is connected to it by a narrow piece of tissue called the dorsal mesentery. Despite their close proximity, trunk neural crest cells

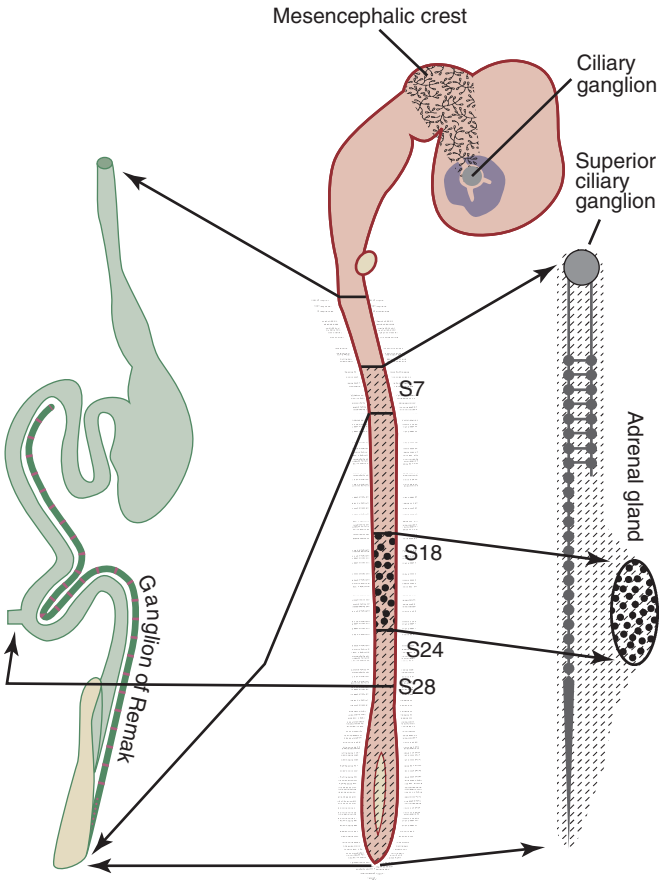

FIGURE 15.6 Neural crest cells at different levels along the anterior–posterior axis give rise to distinct autonomic and adrenomedullary derivatives in avian embryos. In the cephalic region (center), mesencephalic crest cells populate the ciliary ganglion. Ganglia of the sympathetic chain (right), including the superior ciliary ganglion, are formed from spinal neural crest cells originating caudal to somite 5. Cells of the adrenal medulla (right) originate exclusively from neural crest cells between somites 18 and 24. Vagal neural crest cells generated between somites 1 and 7 form enteric ganglia (left), whereas cells of the ganglion of Remak (left) are derived from the lumbosacral neural crest posterior to somite 28. *Drawing provided by Dr. M. Bronner.*

normally fail to invade the gut where enteric ganglia form. When vagal neural tubes are grafted in place of trunk neural tubes, however, donor vagal neural crest cells do invade the gut and form enteric ganglia. Therefore, these cells can respond to normal trunk neural crest migratory pathways, but, in addition, some cells behave in a "uniquely vagal" fashion and migrate directionally to the gut. This indicates some intrinsic differences between the two populations. Along similar lines, when cranial neural tubes are grafted in place of the trunk neural tube, donor cranial neural crest cells form some normal derivatives in the trunk-like dorsal root and sympathetic ganglia. Other cells, however, fail to migrate and instead differentiate into ectopic cartilage. In the reciprocal experiment, avian trunk neural crest cells grafted to the head region appear unable to generate cartilage at all, although they

can participate in the formation of elements of the cranial ganglia (LeDouarin & Kalcheim, 1999) (Fig. 15.6).

These experiments suggest two things: (1) environmental factors can influence neural crest cells from different axial levels to express a broader range of fates than they would normally express when left *in situ*, and (2) some neural crest cells undergo their intrinsic program even when grafted to an ectopic site. Thus, some combination of *intrinsic and extrinsic information* is likely to govern neural crest cell fate decisions. The migratory pathways taken by neural crest cells are likely to play an important regulatory role in cell fate specification. Indeed, different migratory pathways contain different distribution patterns of important inducing factors. A number of factors, including BMPs, neuregulins, and glucocorticoids, have been demonstrated to influence the choice of neural crest cells into neural, glial, or chromaffin lineages (see Chapter 18). When added to multipotent neural crest stem cells in culture, these factors can drive these cells into neural, glial, or chromaffin lineages, respectively. Accordingly, BMP-7 is present in the dorsal aorta adjacent to the location where trunk neural crest cells differentiate into sympathetic neurons. Similarly, glucocorticoids are produced by the adrenal cortex, which surrounds the adrenal medullary cells.

In addition to specific growth factors, the timing of emigration may play an important role in eventual neural crest cell fate decisions. Neural crest cells exhibit an orderly pattern in the timing of migration, with cells initially following the ventral pathway and later contributing to progressively more dorsal derivatives. Although early and late migrating cranial neural crest cells appear to have a similar developmental potential, it is likely that the cell population does undergo a change in the range of fates that the cells can assume. For example, the last emigrating trunk neural crest cells in the bird give rise to pigment cells and appear to have a limited capacity to form sympathetic neurons. However, *stem cells* appear to persist in the neural tube and retain the potential to form neural crest. Well past the normal time of neural crest cell emigration, cells with the full range of neural crest potential can be isolated from the ventricular zone of the developing spinal cord (Sharma, Korade, & Frank, 1995). In the embryo, these late-emigrating cells appear to contribute to a subpopulation of neural crest derived cells in the dorsal root ganglia.

Summary

Neural crest cells are somewhat plastic with respect to their prospective fates. When put into a new environment, they sometimes behave according to their new location. However, some cells act according to their original location and thus have some "intrinsic" information. With time, the developmental potential of neural crest populations becomes restricted, although a subpopulation of "stem cells" may remain until late stages.

SEGMENTAL MIGRATION OF NEURAL CREST CELLS

A hallmark of the developing peripheral nervous system is its inherent *segmentation.* After neural crest cells migrate from the neural tube and through the somites, they condense to form segmentally arranged sensory and sympathetic ganglia. For each somite, a single sensory and sympathetic ganglion forms. This exquisite and reproducible pattern suggests the presence of some inherent segmental information in the embryo that is responsible for segmental migration and gangliogenesis of neural crest cells. In longitudinal sections through early embryos, it is clear that neural crest cells migrate in a metameric pattern, moving exclusively through the rostral half of each somite while failing to enter the caudal half (Fig. 15.7).

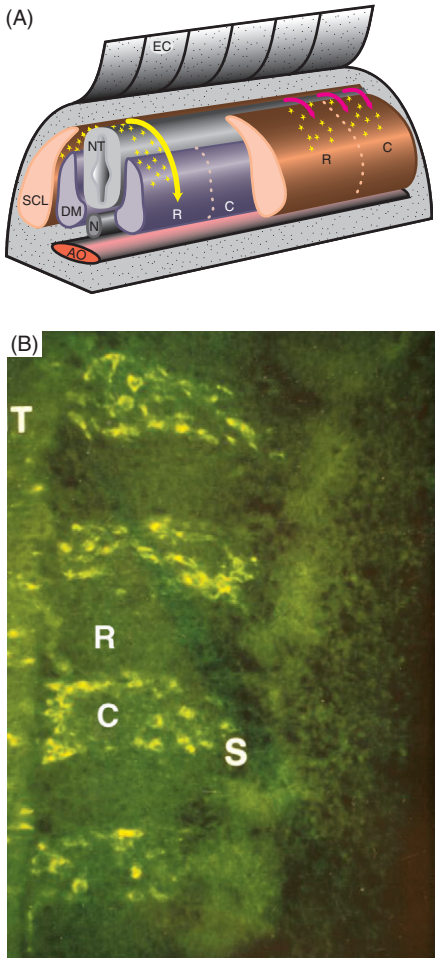

FIGURE 15.7 Trunk neural crest cells migrate in a segmental fashion. (A) Schematic diagram demonstrating that neural crest cells migrate through the sclerotomal portion of the somites, but only through the rostral half of the sclerotome. (B) In longitudinal section, neural crest cells (green) can be seen migrating selectively through the rostral half of each somitic sclerotome (S). *From Bronner-Fraser (1986).*

Such a segmental pattern of migration could be caused by inherent cues within the neural tube that direct neural crest cells to migrate segmentally. Alternatively, tissues through which neural crest cells migrate may contain patterning information that results in segmental migration. The relationship between neural crest cells and their surrounding tissues has been explored by manipulating the neural tube and/or somites in a series of grafting experiments. Removal of the somites results in the formation of huge, unsegmented neural crest–derived ganglia, suggesting that somites are necessary for the segmental migration of neural crest cells. However, inversion of the segmental plate in the rostrocaudal dimension reverses the pattern of neural crest migration such that neural crest cells migrate through the half of the rotated sclerotome that was originally rostral but is now caudal. Motor axons, which also traverse the rostral sclerotome in normal animals, exhibit similar behavior to neural crest cells after segmental plate rotation. This suggests that the information necessary to guide neural crest cells and motor axons is intrinsic to the somites. Furthermore, these experiments show that the rostrocaudal polarity of the somites is already established at the segmental plate stage.

Other experimental manipulations demonstrate that the caudal half of each somite is inhibitory, whereas the rostral half somite is permissive for neural crest migration and motor axon guidance. If somites are constructed to contain only caudal sclerotome tissue, neural crest cells and motor axons fail to migrate altogether. Conversely, an all-rostral somite results in the absence of segmentation for both neural crest cells and motor axons. Taken together, these findings demonstrate that the segmental migration of both neural crest cells and motor axons is due to cues inherent in the somite. These cues may be caused by attractive cues in the rostral-half sclerotome, inhibitory cues in the caudal-half sclerotome, or a combination of both. The finding that somites containing all caudal-half sclerotomes cannot support neural crest migration strongly suggests that some of the guidance cues are inhibitory. This segmentally arranged stream of migrating neural crest cells in turn results in the segmental organization of the neural crest–derived ganglia of the PNS.

Although it was suggested that Eph/ephrin signaling might direct the pattern of trunk neural crest migration (Krull et al., 1997; Wang & Anderson, 1997), the Eph and ephrin mutant mice that have been examined fail to exhibit trunk neural crest migration defects (Oriolli et al., 1996; Wang, & Anderson, 1997). Another receptor expressed by neural crest cells is Neuropilin-2 (Npn2), which is expressed in premigratory and migratory neural crest in both chick and mouse. Strikingly, trunk neural crest cells no longer migrate segmentally through the somites of *Npn-2* mutants and are distributed equally in rostral and caudal sclerotome. These defects are the result of Npn2/Semaphorin3F (Sema3F) signaling, as *Sema3F* mutants

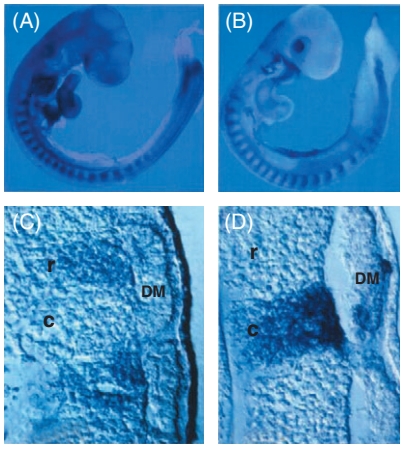

FIGURE 15.8 Distribution of Eph receptors (A and C) on neural crest cells in the rostral sclerotome and ephrin ligands in the caudal sclerotome (B and D) of chick embryos. Eph receptors are on neural crest cells in the rostral half of each somite, whereas inhibitory ephrin ligands are expressed in the caudal halves of each sclerotome. *From Krull et al. (1997).*

have an identical phenotype. These results demonstrate that Npn-2/Sema3F signaling is necessary to restrict neural crest migration to the rostral somite (Gammill, Gonzalez, Gu, & Bronner-Fraser, 2006). Interestingly, metameric dorsal root ganglia still form in Npn-2 mutants in the absence of segmental neural crest migration, suggesting that segmental migration may be separable from ganglion formation. However, mice lacking both *Npn1* and *Npn2* form abnormally fused ganglia, suggesting that Npn-1 is required for the later segregation of neural crest-derived ganglia (Fig. 15.8) (Gammill et al., 2006).

As in the trunk, the migration of neural crest cells in the hindbrain is also segmented. Three broad streams of migrating cells are found adjacent to rhombomere 2 (r2), r4, and r6, whereas no neural crest cells are apparent adjacent to r3 and r5. Focal injections of DiI at the levels of r3 and r5 have demonstrated that both of these rhombomeres generate neural crest cells and that the apparent segmental pattern results from the DiI-labeled cells that originated in r3 and r5 deviating rostrally or caudally and failing to enter the adjacent preotic mesoderm or otic vesicle region.

Trunk neural crest cells move in a segmental pattern, which is controlled by inhibitory molecules present in the caudal half of each somite. Neural crest cells have Npn2 receptors on their surface. When they encounter Sema3F ligands in the caudal somite, they are diverted from this location, leading to selective migration through only the rostral-half somite.

Cessation of Neural Crest Migration

Neural crest cells exhibit an orderly pattern in their migration. Whereas the first cells to migrate tend to move

most ventrally, later migratory cells contribute to progressively more dorsal derivatives. The different destinations of neural crest derivatives are therefore populated in a sequential order during development. One possibility is that the early migrating cells "fill" the more ventral sites, effectively clogging up the pathway. Alternatively, the sites themselves may change with time so that they can no longer support migration.

Surprisingly little is known about how neural crest cells know that they have reached the appropriate destination and stop their migration. This is in marked contrast to the developing CNS, where a number of mutations affect the ability of neuroblasts to cease migrating. It is clear that cell adhesion molecules such as N-cadherin and N-CAM are upregulated after cells reach their final sites and condense to form peripheral ganglia. However, there is no evidence for a causal role for cell adhesion molecules in this process.

Neurogenesis in the PNS

Some of the factors and signaling cascades that result in neurogenesis in the developing PNS are beginning to be understood (see Chapter 16). Many neural crest cells appear to be multipotent and not yet committed to a neural fate. However, particular external factors can influence their fate decisions. For example, clonal populations of neural crest cells become neural in the presence of BMPs and glial in the presence of glial growth factor. Similarly, activation of Notch signaling promotes gliogenesis at the expense of neurogenesis in neural crest cells and their derivatives. Certain transcription factors may bias cells toward certain fates; for example, while Mash-1 is essential for sympathetic neuron formation, Neurogenins are essential for sensory fates (Christiansen, Coles, & Wilkinson, 2000).

An interesting contrast between the developing PNS and the CNS is that migrating neural crest cells proliferate as they move. In fact, even after exhibiting defined neuronal characteristics, some neural crest derivatives continue to divide. For example, in the developing sympathetic ganglia, neural crest-derived cells express neurotransmitters and other proteins characteristic of sympathetic neurons but remain actively mitotic. However, other neural crest cells, such as sensory neurons, appear to withdraw from the cell cycle well before they express neuronal traits.

Summary

Neural crest cells migrate over long distances throughout the body to form diverse cell types, including neurons, glia, melanocytes, and cells of the adrenal gland. The migratory pathways of neural crest cells vary along the rostrocaudal body axis, and the local environments through which cells migrate and eventually differentiate play an important role in phenotypic specification. The migration of neural crest cells is guided by both positive (attractive or permissive) and inhibitory (repulsive) cues that are found in the environment.

CELL MIGRATION IN THE CNS

The emergence of the laminar architecture of the mammalian neocortex depends on neurogenesis in germinal zones, migration of postmitotic neurons (Caviness, 1982; Del Rio, Martinez, Auladell, & Soriano, 2000; McConnell, Ghosh, & Shatz, 1994; Wood, Martin, & Price, 1992; Zecevic & Rakic, 2001), formation of transverse zones of transient neurons (the preplate, cortical plate, marginal zone, and subplate) (Caviness, 1982; Del Rio et al., 2000; Marin-Padilla, 1998), and assembly of postmigratory cortical neurons into six neuronal layers. The columnar organization of cortical regions of the CNS develops from the radial glial scaffold, which provides a substrate for directed cell migrations of the primary output neurons of the neocortex in early periods of development, and generates neurons in later stages of development. Although the anatomists Retzius, Kolliker, and Magani described a system of radial glial cells in the nineteenth century, the influence of radial glial cells on cortical histogenesis did not become apparent until the late twentieth century. The spatiotemporal pattern of neurogenesis and migration during the formation of neural layers in developing cortex emerged from the pioneering work of Richard Sidman (1970) on thymidine "birthdating." The broad application of this approach to different brain regions and times of development demonstrated the spatiotemporal pattern of neurogenesis in the vertebrate CNS. The discovery of directed neuronal migration along glial fibers by Pasko Rakic in the 1970s (Rakic, 1972; Sidman & Rakic, 1973) set the stage for a period of intense focus on the process of neuronal migration in cortical histogenesis (Sidman & Rakic, 1973) (Fig. 15.10). Cell and molecular studies of identified neurons from the cerebellar cortex and hippocampal formation provided real-time imaging that defined the mode of movement of neurons migrating along glial fibers (Edmondson & Hatten, 1987; Gasser & Hatten, 1990a).

Studies on the architectonics of human cortical malformations (Barkovich et al., 1996; Dobyns & Truwit, 1995) revealed populations of heterotopic cells and suggested that pathogenic processes disrupted normal glial-guided neuronal migration (Rakic, 1988). The hypothesis that cortical malformations resulted from migration defects became even more attractive with the analysis of spontaneously occurring neurological mutations. All of these studies underscore the critical role of neuronal migration in brain development.

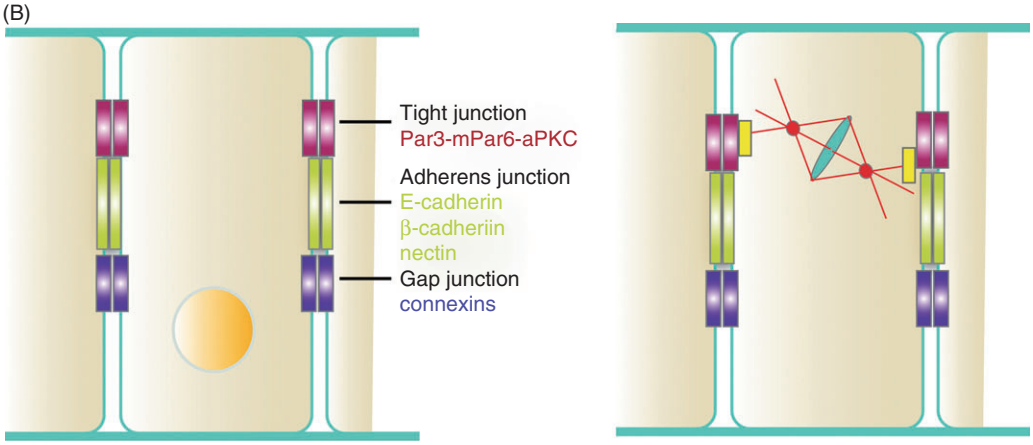

FIGURE 15.9 (A) *The Ventricular Zone Forms a Pseudostratified Columnar Epithelium*. Here neural progenitor cells have been visualized in the cerebral vesicle of a hamster embryo using scanning electron microscopy. Neuroepithelial cells are elongated bipolar cells that, at this early stage of development (E9.25), span the entire wall of the cerebrum. Some of the cells at the ventricular surface (bottom) appear spherical; these cells have retracted their cytoplasmic processes and are presumably rounding up in preparation for mitosis. Other rounded cells at the external surface (top) may be young neurons beginning to differentiate. (Inset) A low-power view of the hamster cerebral vesicle, corresponding roughly to that of a human embryo at the end of the first month of gestation.(B) *Polarity Proteins and Vertebrate Epithelia*. Three classes of cell-cell junctions form between cells in a vertebrate epithelium. Conserved polarity proteins function in the formation of tight junctions (red). The cadherin and nectin cell adhesion proteins are required to form adherens junctions (green) and connexins form gap junctions (purple). During cell division in the neuroepithelium, the mPar6 polarity complex positions the spindle of the dividing cell (see text for details). *From Sidman and Rakic (1973).*

Cortical Histogenesis: Formation of the Basic Embryonic Zones

During corticogenesis, early-born, polymorphic neurons settle in a narrow zone above the VZ, termed the preplate (PP) (Caviness, 1982; Del Rio et al., 2000; McConnell et al., 1994; Wood et al., 1992; Zecevic & Rakic, 2001) (Fig. 15.11). Preplate neurons include Cajal-Retzius cells, GABAergic interneurons, and future subplate projection neurons (Caviness, 1982; Del Rio et al., 2000; Marin-Padilla, 1998). During the preplate stage, preplate neurons pioneer the first axon projections of the neocortex, with some preplate neurons extending descending axons to subcortical targets and others extending corticocortical axons to targets in the ipsilateral or contralateral hemisphere via the anterior commissure. As the preplate matures, extensive cell movements occur across the dorso-ventral (DV) plane of the neuroaxis. At late preplate stages, preplate neurons undergo changes in polarity, shifting from a random orientation into a radial orientation (Schneider, Gulacsi, & Hatten, 2011). Thereafter, the preplate separates into a superficial marginal zone (MZ) of Cajal-Retzius cells and small neurons, the cortical plate (CP) (Rakic & Zecevic, 2003), and a deeper layer called the subplate (SP) (Fig. 15.11).

Studies on the genetics of cortical development underscore the importance of preplate separation to the

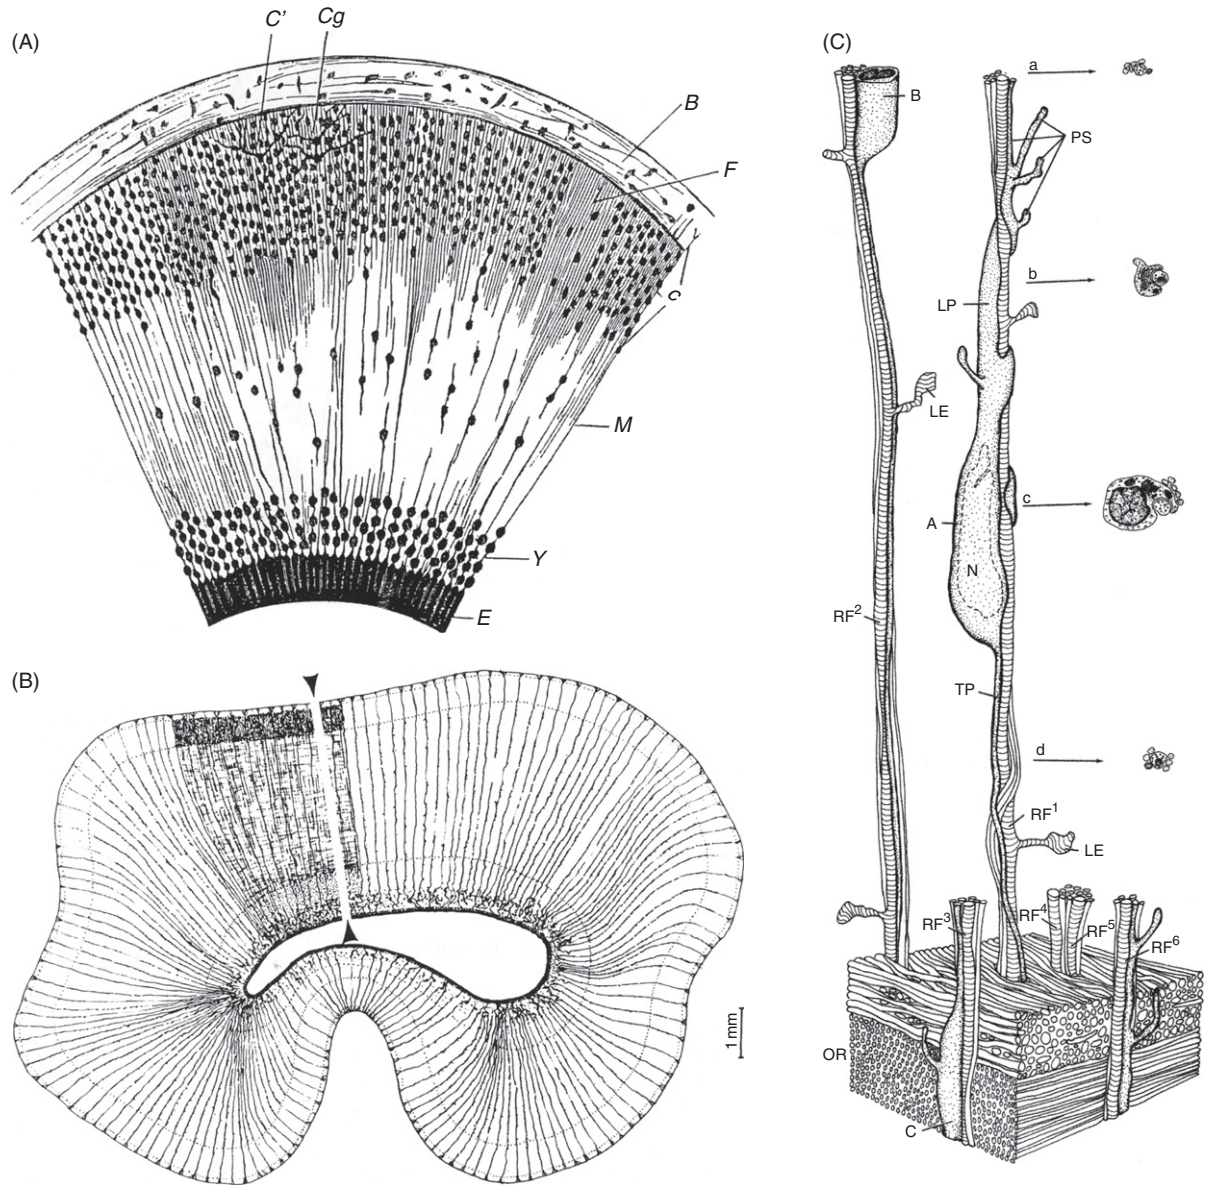

FIGURE 15.10 Radial Glial Cells Provide a Pathway for Neuronal Migration. (A) In the late nineteenth century, the Italian histologist G. Magini used Golgi impregnation methods to visualize a system of glial fibers that spanned the cortical wall. He proposed that the glial fibers provided a scaffold for neuronal migration. (B) In the late twentieth century, Rakic and Sidman again used the Golgi impregnation method to map radial glial cells in the developing primate neocortex. As described below, they used electron microscopy (EM) to visualize the relationship of young neurons to the glial fiber system. (C) Three-dimensional reconstruction of serial EM sections of a migrating neuron in the intermediate zone of the primate neocortex illustrate the cytology and neuron-glia relationships of migrating neurons *in vivo*. The cell soma of the migrating cell apposes radial glial fibers (striped vertical shafts, RF1-6), which extend short lamellate expansions (LE). Nuclei (N) of migrating neurons are elongated, and their leading processes (LP) are thicker and richer in organelles than their trailing processes (TP). The lower part of the diagram depicts the numerous parallel axons of the optic radiations (OR). These axons have been deleted from the upper portion of the figure to reveal the radial glial fibers. The leading process extends several pseudopodial endings (PS), which appear to explore the territory through which the neuron is migrating. In cross-section (a–d), a migrating neuron partially encircles the shaft of the radial glial fiber. *From Sidman and Rakic (1973).*

development of cortical laminae. During corticogenesis in *reeler* mutant mice, the segregation of preplate neurons into two zones and formation of the cortical plate do not occur and subsequent cortical lamination fails (Caviness & Rakic, 1978; Goffinet, 1984; Tissir & Goffinet, 2003). Cell movements involved in the subdivision of the preplate into the MZ and SP and formation of the CP are also critical to the formation of cortical synaptic circuits. As first proposed by Shatz and colleagues, subplate neurons extend pioneer axons during the establishment of thalamocortical architecture and function (Dupont, Hanganu, Kilb, Hirsch, & Luhmann, 2006; Ghosh & Shatz, 1992, 1993; Ghosh,

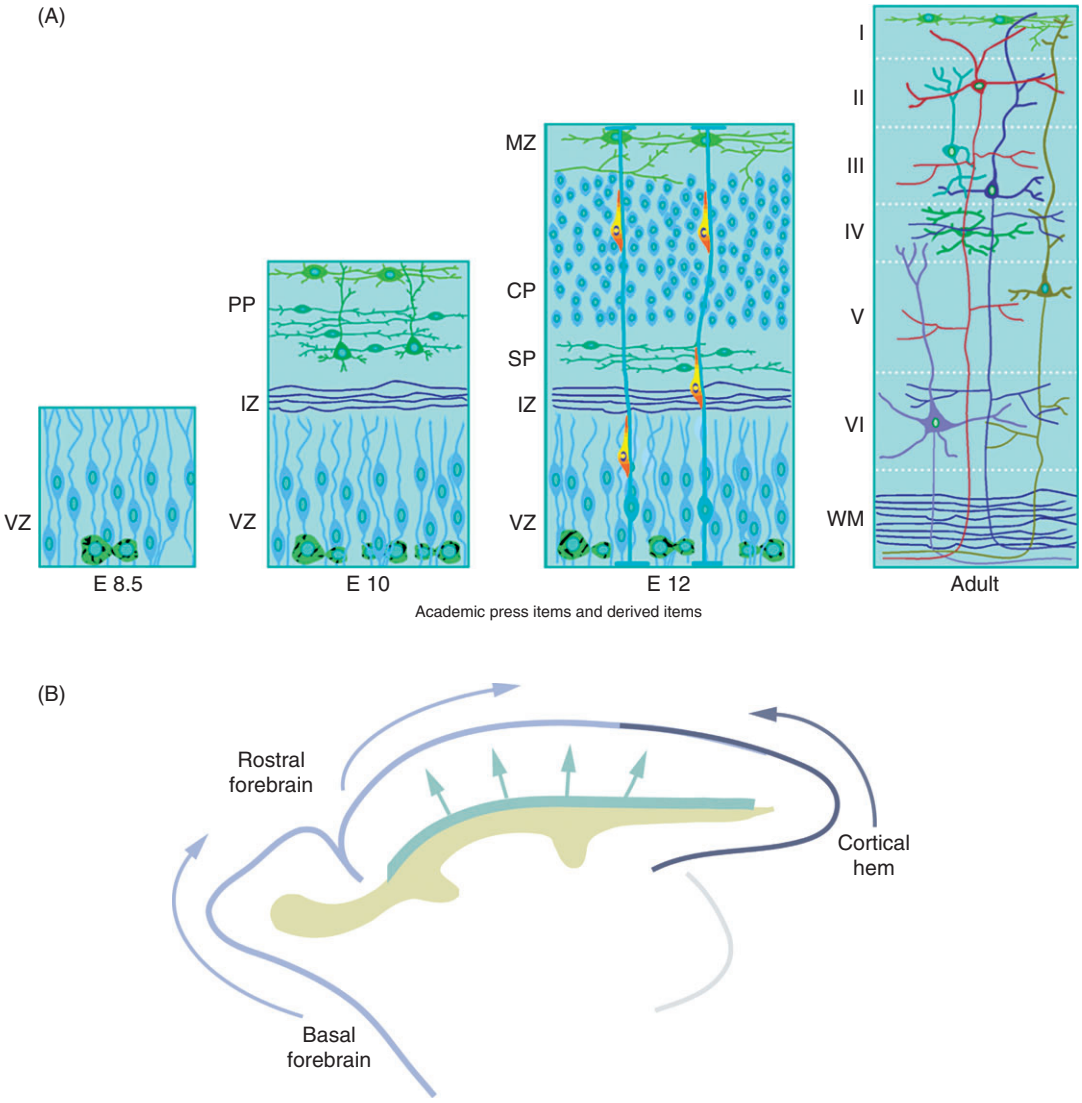

FIGURE 15.11 Development of the Cerebral Cortex. (A) *Formation of the Fundamental Layers*: The ventricular zone (VZ) contains the progenitors of neurons and glia. The first neurons to be generated establish the preplate (PP); their axons, as well as ingrowing axons from the thalamus, establish the intermediate zone (IZ). The subsequently generated neurons of cortical layers II–VI establish the cortical plate (CP), which splits the preplate into the marginal zone (MZ), or future layer I, and the subplate (SP), a transient population of neurons. After the completion of neuronal migration and differentiation, six cortical layers are visible overlying the white matter (WM) and the subplate has largely disappeared. Neural precursors in the subventricular zone (SVZ) continue to generate neurons that migrate rostrally into the olfactory bulb, even during postnatal life. (B) *Emerging Complexity of the Origin of Layer 1 Neurons*. Recent experiments in rodents and primates reveal multiple origins and migratory pathways of the precursor neurons in layer 1 of the developing neocortex. As discussed above, the neocortical VZ is a primary source of preplate neurons, which contains layer 1 cells. However, subsets of layer 1 neurons also arise in the rostral aspect of the neocortex, the basal forebrain, and the cortical hem. The latter progenitor cells migrate along the surface of the emerging brain from their sites of origin into the superficial layer of the neocortex. (This population of cells migrates several days before progenitors destined to become cortical interneurons). See text for details.

Antonini, McConnell, & Shatz, 1990; Kanold, Kara, Reid, & Shatz, 2003; Lein, Finney, McQuillen, & Shatz, 1999; Price et al., 2006). They form some of the first synapses in cortex (Blue & Parnavelas, 1983a, 1983b; Chun & Shatz, 1988; Konig & Marty, 1981; Konig, Roch, & Marty, 1975; Kostovic & Rakic, 1980; Molliver, Kostovic, & van der Loos, 1973) and provide a transient scaffold for the organization of thalamocortical projections. Thus, the neuroepithelium develops from a single layer of dividing cells to five embryonic zones, a VZ of proliferating progenitors, an intermediate zone (IZ) of immature axons, an SP containing a subset of preplate neurons, the cortical plate containing immature pyramidal cells born after embryonic day 13 (E13), and a superficial marginal zone (MZ), which contains Cajal-Retzius cells and small interneurons (Fig. 15.11).

Cortical Neurogenesis

Detailed cell cycle analyses by Takahashi and Caviness (Caviness et al., 2003) demonstrate that the murine neocortex is generated over an epoch of 11 cell cycles. Time-lapse imaging studies in cortical slices by McConnell and colleagues first suggested that progenitor cells can divide asymmetrically during the period of neurogenesis and that cleavage orientation of dividing precursors predicts the fate of the daughters (Chenn & McConnell, 1995). These studies proposed that vertically oriented divisions are symmetric, generating two identical daughters, whereas horizonal divisions are asymmetric, generating one daughter that differentiates into a neuron and another that reenters the cell cycle. The asymmetric inheritance of Notch and Numb proteins may also contribute to the control of symmetric versus asymmetric cell divisions during cortical neurogenesis. The polarity protein Numb is expressed in early phases of cortical histogenesis (Petersen, Zou, Hwang, Jan, & Zhong, 2002), and colocalizes with EGFR by a process that is actin-dependent (Sun, Goderie, & Temple, 2005). The loss of *Numb* and *Numbl* causes premature progenitor cell depletion and malformations of the neocortex (Petersen, Zou, Krauss, & Zhong, 2004), suggesting that *Numb*-mediated asymmetric cell divisions provide a general mechanism for cell cycle control during cell fate allocation events in the developing mammalian brain (Petersen et al., 2004).

At the cortical plate stage, two classes of neural stem and progenitor cells, the apical and basal progenitors (Farkas & Huttner, 2008; Gotz & Huttner, 2005; Noctor et al., 2002; Pinto & Gotz, 2007) are defined by their position in the cortical wall. The apical progenitors located in the VZ include the neuroepithelial cells (NECs) (Fig. 15.9) and radial glial cells (RGCs). RGCs are a specialized form of glial cell, recognized by their expression of the RC2 or BLBP antigen, that extend long radial processes toward the overlying cerebral wall (Gadisseux & Evrard, 1985; Kriegstein & Gotz, 2003; Noctor et al., 2002). As discussed below, these radial processes presage the basic columnar plan of development, providing a scaffold "in plane" with the layer of dividing cells for a subpopulation of neurons to migrate away from the primary germinal matrix. RGCs undergo symmetric divisions at early stages of cortical development, then shift to asymmetric divisions later, generating an RGC and either a neuron or a basal progenitor cell (also called an intermediate progenitor cell; IPC) that in turn divides in a more basal location, the subventricular zone (SVZ), and in most cases generates two neurons (Box 15.1, Fig. 15.14) (Farkas & Huttner, 2008; Gotz & Huttner, 2005; Kriegstein & Parnavelas, 2006; Zhong & Chia, 2008).

Cell Movements within the Primary Proliferative Matrix

The columnar organization of the cerebral cortex led to the hypothesis that progenitors in the neuroepithelium form a protomap for cortical organization. Two experimental approaches provided evidence for widespread tangential movements within the neuroepithelium. First, live imaging of dye-labeled cells in slices of embryonic cortex revealed extensive movements of the neuroblasts within the neuroepithelium. Labeled cells move intermittently within the plane of the epithelium at speeds between 10 and 100 μm/h (Fishell, Mason, & Hatten, 1993). Second, experiments using retroviral markers to follow the dispersion of clonally related cells in the developing brain demonstrated widespread dispersion of cells within the developing cortex (Walsh & Cepko, 1992). Thus, widespread movements occur in the neuroepthelial germinal zone of the CNS and across the plane of the outer embryonic zones of the neocortex.

Molecular Mechanisms of Cell Motility: General Features

Neuronal motility in the developing CNS, like that of all metazoan cells, occurs in response to a migration-promoting signal(s), which polarizes the cell and induces the extension of protrusions in the direction of migration (Ridley et al., 2003). These protrusions can be large, broad lamellipodia or spike-like filopodia driven by actin polymerization and microtubule dynamics, and stabilized by adhering to the extracellular matrix (ECM) in the case of migrating neural crest cells or adjacent to radial glial cells or to bundles of axons in the case of radial, glial-guided migrations and tangential migrations. Adhesions serve as traction sites during forward translocation of the cell soma (Fig. 15.13).

As key regulators of the actin and microtubule cytoskeletons, the Rho family of small GTPases plays an integral part in the morphological changes, polarization, and locomotion of migrating cells. When bound to GTP, they stimulate downstream effector molecules to regulate actin and microtubule dynamics to reorganize the cytoskeleton, as well as control cell-cycle progression, gene expression, and vesicle transport. The best-studied Rho GTPase family members are Rac, Cdc42, and RhoA. In many cell types, Rac stimulates the formation of the veil-like lamellipodial protrusions involved in membrane extension, Cdc42 promotes the formation of the thin filopodial microspikes that sense the surrounding environment, and RhoA regulates cell contractility. All three of these GTPases play a role in cell adhesion (Ridley et al., 2003). Cdc42 also has a conserved role in regulating cell polarity, along with homologs of the *C. elegans* polarity signaling complex Par6, and together they orient the nucleus, centrosome, and Golgi apparatus in the direction of migration (Burakov, Nadezhdina, Slepchenko, & Rodionov, 2003; Etienne-Manneville & Hall, 2001; Etienne-Manneville & Hall, 2003; Gomes, Jani, & Gundersen, 2005). The Rho GTPases orchestrate general and specific structural and functional

BOX 15.1

ADULT NEUROGENESIS

Adult neurogenesis refers to the process of generating new neurons in the adult mammalian brain (Gage, 2000). For over a century, it was believed that adult mammalian brains had no capacity to produce new neurons and that the neurons damaged in the adult brain were lost forever. However, this dogma has been challenged by the discovery of neural stem cells (NSCs) in the adult brain and by intensive research on adult neurogenesis over the past two decades. These studies of adult neurogenesis can be dated back to the 1960s, when Joseph Altman and colleagues observed [^{3}H]-labeled neurons in brains of adult rodents injected with [^{3}H]-thymidine, a marker for proliferative cells and their progeny (Altman & Das, 1965). A second breakthrough in the study of adult neurogenesis did not occur until the early 1990s, however, with the discovery of adult NSCs that are able to self-renew while producing daughter cells with a potential to differentiate into neurons (Reynolds & Weiss, 1992). Two discrete neurogenic niches that harbor NSCs have been consistently identified across mammalian species in vivo—the subventricular zone (SVZ) of the lateral ventricle and the subgranular zone (SGZ) in the dentate gyrus of the hippocampus. NSCs in the SVZ give rise to neuronal precursors that migrate through the rostral migratory stream and differentiate into interneurons in the granular cell layer and the periglomerular layer in the olfactory bulb. In the SGZ, most of the progeny of NSCs differentiate and integrate locally as dentate granule cells. Adult neurogenesis in the hippocampus can also be observed in human brains (Eriksson et al., 1998), suggesting a therapeutic potential for utilizing adult-born neurons for treatment of neurodegenerative disease and repair of injured neural tissues in adulthood.

Adult neurogenesis starts with the proliferation of NSCs. Some progeny of NSCs remain undifferentiated as NSCs; others differentiate into neurons and glia. The newly born neurons undergo a lengthy process of morphological and physiological maturation and eventually integrate into the corresponding neural circuitry. During the differentiation and maturation processes, a significant fraction of newborn neurons are lost before their final integration. Therefore, the rate of neurogenesis is regulated at levels of NSC proliferation, neuronal fate determination, and the survival of newborn neurons. Numerous molecular factors take part in the regulation of adult neurogenesis, including growth factors, neurotrophins, morphogens, cytokines, and hormones. Moreover, distinct from embryonic neurogenesis, adult neurogenesis can also be modulated by the animals' experiences and behaviors. For example, voluntary exercise, environmental enrichment, and hippocampus-dependent learning can enhance SGZ neurogenesis. Conversely, hippocampal neurogenesis is reduced in stressed or aged animals. Olfactory stimulus enrichment results in enhanced SVZ neurogenesis.

Because of the region-specific network integration of newborn neurons, it is postulated that SGZ neurogenesis may play a role in hippocampus-related functions, such as learning and memory and affective regulation, and SVZ neurogenesis may contribute to olfactory function. This hypothesis is supported by many studies demonstrating a positive correlation between levels of neurogenesis and performance in specific behavioral tasks. While a causal relationship between adult neurogenesis and its functions is the subject of intense investigation, current studies using a combination of molecular, cellular, genetic, system, and behavioral approaches are striving to elucidate the exact roles of newborn neurons in hippocampal and olfactory functions.

Wei Deng and Fred H. Gage

changes required for directed motility of nonneuronal cells and neurons, as well as growth cones.

A large number of actin regulatory molecules act downstream of Rac and Cdc42 signaling to regulate the formation of lamellipodia and filopodia, respectively, during motility. Rac induces actin filament uncapping, actin polymerization, and filament branching during lamellipodial extension, and Cdc42 induces the actin polymerization of parallel bundles of actin filaments that make up filopodia. Cdc42 and Rac localize Wiskott–Aldrich syndrome protein (WASP) family members and WASP-family verprolin-homologous protein (WAVE) complexes, respectively, at the cell surface to activate the actin-related protein-2/3 (ARP2/3) complex. Arp2/3 is an actin-nucleating complex that binds to the sides or tip of a preexisting actin filament and induces the formation of a new daughter filament that branches off the mother filament (Heasman & Ridley, 2008; Ridley et al. 2003). Protrusive force by actin polymerization is generated by an "elastic Brownian ratchet" mechanism, in which thermal energy bends nascent short actin filaments, pushing the membrane forward. Thus, actin polymerization and unbending a growing actin filament against the leading edge of the cell provides a driving force for the motility of nonneuronal cells, neural crest cells and extending axons. Local activation of the Arp2/3 complex induces lamellipodial extension in a particular direction, providing the basis for directional migration.

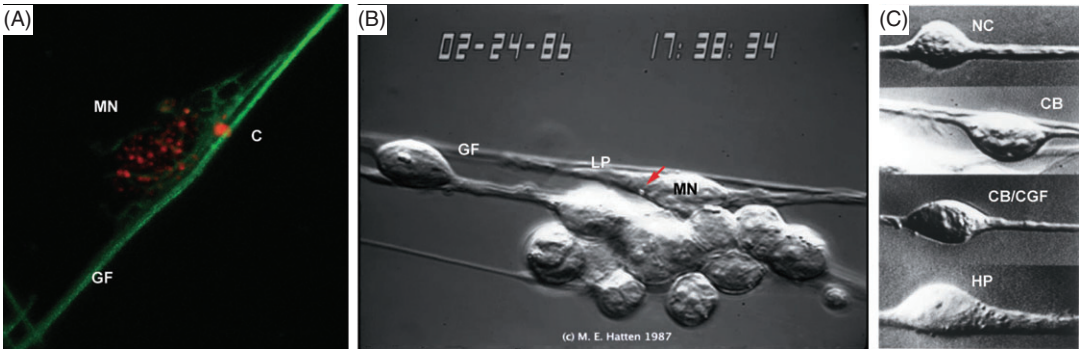

FIGURE 15.12 Live Imaging of Glial-Guided Neuronal Migration. Live imaging of cells with video-enhanced differential contrast (VEC-DIC) optics. The cytology and neuron-glial relationship of a cerebellar granule neuron migrating on a glial fiber. With live imaging of neuronal migration along glial fibers, the granule neuron closely apposes the cell glial fiber (GF) along the length of the soma of the migrating neuron (MN) and extends a leading process (LP) in the direction of migration along the glial guide. The nucleus is in the posterior aspect of the cell during periods of movement, the centrosome (C) is just forward of the neuronal nucleus. (A) In migrating neurons, apparently antibodies against dynein intermediate chain (red) label the centrosome and dynein on the surface of the nucleus. Antibodies against tubulin (green) reveal a perinuclear "cage" of tubulin in migrating neurons. (B) Live imaging of a cerebellar granule neuron migrating on a glial fiber (red arrow indicates centrosome). (C) Cytology of cerebellar and hippocampal neurons migrating along homotypic and heterotypic astroglial fibers: cerebellar granule neuron migrating along a hippocampal glial fiber (CB/HP), a cerebellar granule neuron migrating on a cerebellar glial fiber (CB/CB), a hippocampal neuron migrating along a cerebellar glial fiber (HP/CB) or a hippocampal neuron migrating on a hippocampal glial fiber (HP/HP). In heterotypic co-cultures, migrating neurons have a stereotyped cytology, extending their cell soma along the glial guide and extending a leading process in the direction of migration.

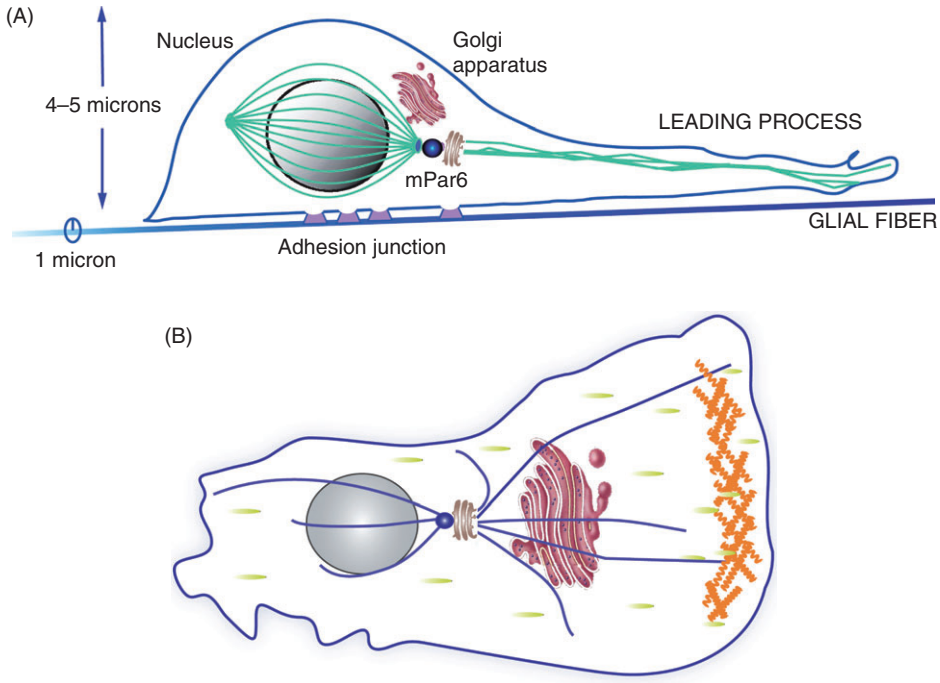

FIGURE 15.13 *Comparison of the cellular organization of neurons migrating on glial fibers (A) and fibroblasts migrating in vivo (B).* As the neuron migrates, the polarity complex mPar6, and signaling pathways, polarize the migrating cell. mPar6 localizes to the centrosome (blue) and paces the timing of the movement of the neuron along the glial fiber via Myosin IIB-mediated contraction of F-actin in the proximal aspect of the leading process. A perinuclear cage of tubulin (green) positions the nucleus in the posterior aspect of the cell. Microtubules (green) grow out of the centrosome into the leading process and support vesicle transport during movement. As the neuron moves, it forms attachments beneath the cell soma (purple), which provide traction for neuronal locomotion along the fiber. (B) The model shown represents a polarized cell that has distinct leading and trailing edges. This is a common feature of fibroblastic motility. The leading edge points in the direction of movement and is driven by actin-polymerization-mediated protrusion. Green spots represent points of interaction of the cell with the substrate. Other structures depicted include the nucleus (grey), the Golgi apparatus (brown) and the microtubule-organizing center (MTOC) (blue), from which the microtubule network (blue) radiates, as well as an actin-rich lamellipodium at the front (orange).

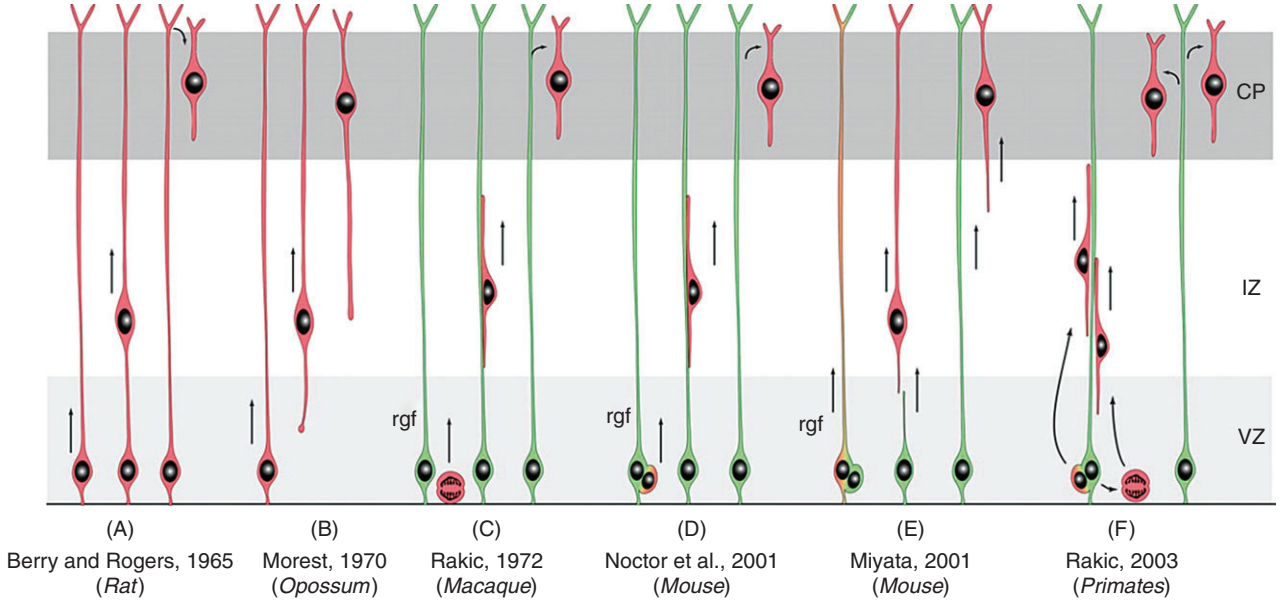

FIGURE 15.14 Schema of the Evolving Concepts of the Relationship between Radial Glial Cells and Migrating Neurons in the Developing Mammalian Cerebral Cortex. As discussed in the text, initial theories of neuronal migration ignored the glial cells. In the early 1970s, Sidman and Rakic proposed that neurons migrate along glial fibers. Live imaging of labeled radial glia and migrating neurons revealed that during the epoch of migration, glial cells produce neuronal progeny, which immediately or after several rounds of division use the mother glial cell as a guide for their migration. As indicated in the diagram, there are some differences in this process among vertebrate species. Neurons, red; radial glial cells, green. *Reprinted from Rakic (2003).*

Neuronal Migration along Radial Glial Fibers

Radial glial cells are a transient population of cells that provide a primary pathway for neuronal migrations. The histologists Albert Kölliker and Wilhelm His used silver impregnation methods to reveal the development of glial cells in the late nineteenth century. In a series of EM and Golgi studies, Rakic and Sidman provided evidence that neurons are closely apposed to radial glial fibers during the period of neuronal migration (Rakic, 1972; Sidman & Rakic, 1973) (Fig. 15.10). Rakic and Sidman postulated that the radial glia guide the migrations of young neurons from the VZ to the neural layers, in a spatiotemporal order that positioned the youngest born neurons in the most superficial layers. This "inside-out" model relied upon coordinating ^{3}H-thymidine labeling of neuroblast proliferation in the VZ with light and EM analysis (Sidman, 1970). Cells born at successively later times after administration of labeled ^{3}H-thymidine would be lighter than those born the day of the injection (their "birthday"), due to dilution of the label with continued proliferation.

Experiments by Nowakowski and Rakic (1979) on the developing hippocampus provided the most compelling argument for glial guidance of migration, as young neurons in the hippocampal formation followed the undulating paths of the glial fibers, rather than a straight radial line, during their migrations. Real-time imaging of the migration of identified neurons, purified from cerebellum, hippocampus, and neocortex, on glial processes provided critical support for this model (Edmondson & Hatten, 1987), and revealed the dynamics of cell movement along the glial guide described above. Cell-based assays further showed that neurons from one brain region could migrate freely on glia from other brain regions, suggesting that the glial fibers were a generic "monorail" system, rather than a track that specified the duration and direction of migration (Gasser & Hatten, 1990a, 1990b; Hatten, 1999) (Fig. 15.12).

Live imaging studies of neuronal migration along glial fibers revealed unique features of migrating neurons that are distinct from features of general cell and axon motility. These unique features include the extension of a highly polarized leading process in the direction of migration, the assembly of an interstitial adhesion junction beneath the cell soma (Gregory, Edmonson, Hatten, & Mason, 1988), localization of acto-myosin contractile motors in the proximal portion of the leading process (Solecki et al., 2009), and the formation of a perinuclear cage of tubulin to maintain the posterior positioning of the nucleus (Fig. 15.13). Migration involves a cycle of steps that include forward movement of the centrosome into the proximal portion of the leading process, translocation of the neuronal nucleus (Edmondson & Hatten, 1987; Solecki, Model, Gaetz, Kapoor, & Hatten, 2004), activation of acto-myosin motors in the proximal aspect of the leading process (Solecki et al., 2009), and the release of the adhesion junction. Thereafter, the neuronal cell soma glides forward along the glial fiber until a new adhesion forms.

During glial-guided neuronal migration, Cdc42 likely polarizes migrating neurons, while Rac regulates leading process formation and protrusion. A decrease in RhoA levels and activity are required for radial migration; however, low levels likely persist to regulate actomyosin contractility to generate force during motility (Govek, Hatten, & Van Aelst, 2011). Recent studies show that two additional Rho GTPase proteins, Rnd2 and Rnd3/RhoE, inhibit RhoA signaling during radial migration to control distinct steps of the migratory process (Heng et al., 2008; Pacary et al., 2011). Thus, tight regulation of Rho GTPase levels and activity are required for proper neuronal migration, and the Rho GTPases act within multiple signaling pathways, including those associated with cortical malformations, to regulate different steps of the migration cycle.

During migration, a dynamic rearrangement of the actin cytoskeleton occurs in the proximal region of the leading process, where Myosin II motors localize. Myosin II activity, which is regulated by the conserved mPar6α polarity complex, is required for both centrosomal and somal motility (Solecki et al., 2004, 2009). The microtubule cytoskeleton is further regulated by cytoplasmic dynein and its cofactors LIS1 and Doublecortin (DCX) to couple centrosomal and nuclear movement (Coquelle et al., 2002; Faulkner et al., 2000; Mesngon et al., 2006; Smith et al., 2000; Tai, Dujardin, Faulkner, & Vallee, 2002; Tsai, Bremner, & Vallee, 2007; Tsai, Chen, Kriegstein, & Vallee, 2005; Umeshima, Hirano, & Kengaku, 2007).

Several adhesion receptor systems function in glial-guided neuronal migration, including Astrotactin (ASTN1), Neuregulin/ErbB4, and BDNF. The neuronal protein ASTN1 is a well-studied adhesion receptor for neuronal migration along glial fibers (Edmondson, Liem, Kuster, & Hatten, 1988; Fishell & Hatten, 1991) that is expressed by neurons in both the cerebellum and cerebral cortex (Zheng, Heintz, & Hatten, 1996). Mice lacking ASTN1 have slowed cerebellar granule neuron migration, a decrease in neuron-glial binding, and abnormal Purkinje cell development compared with wild-type littermates (Adams, Tomoda, Cooper, Dietz, & Hatten, 2002). Recent studies have identified a second member of the Astrotactin receptor family, ASTN2, which regulates the cell surface expression and trafficking of ASTN1 critical for granule cell migration (Wilson, Fryer, & Hatten, 2010). The importance of receptor trafficking to neuronal migration is further highlighted by the finding that inhibition of endocytosis by the small molecule dynasore reversibly arrests migration (Wilson et al., 2010; Zhou et al., 2007). Neuregulin binds ErbB4 on the glial surface and provides signals that maintain glial process formation (Anton, Marchionni, Lee, & Rakic, 1997; Rio, Rieff, Pelmin, & Corfas, 1997), and BDNF stimulates granule neuron migration (Borghesani et al., 2002). Surprisingly integrin-based adhesions, which are essential for most types of cell migration, are not required for glial-guided neuronal migration in the developing brain (Belvindrah, Hankel, Walker, Patton, & Muller, 2007; Fishell & Hatten, 1991).

As methods became available to culture acute slices of developing brain, it became feasible to acquire real-time images of neurons migrating in the complex setting of developing brain tissue. Lipophilic dyes (Rivas & Hatten, 1995), retroviral transfection, and *in vivo* electroporation of constructs that tag the cells with fluorescent markers such as EGFP (Bhatt, Tomoda, Fang, & Hatten, 2000) in the embryonic neocortex, followed by the generation of acute slices several days later, made it possible to follow particular cohorts of developing neurons and their fates in the emerging neocortex (Zhang, Campbell, Ting, & Tsien, 2002). Moreover, this approach facilitated real-time imaging of cells with altered levels of gene expression, achieved by the introduction of cDNAs to overexpress genes or small hairpin RNAs (shRNAs) to knockdown gene expression, in order to test the function of proteins associated with human cortical malformations (Bai et al, 2003; Tsai et al., 2005), transcription factors (Hand et al., 2005), polarity proteins (Solecki et al., 2004), cytoskeletal proteins (Tsai et al., 2005), and components of downstream signaling pathways. Methods for real-time imaging, such as spinning disc confocal imaging, and for imaging cells deep in living tissue with multiphoton systems are evolving rapidly, providing neurobiologists with the tools to study the molecular regulation of CNS migrations. These experiments have occurred in parallel with cell biological studies of the fundamental mechanisms of metazoan motility, described briefly above.

Lineage Analysis of Radial Glial Cells: Glia Generate Neurons in Late Phases of Cortical Development

During the past decade, real-time imaging of labeled radial glial cells and genetic experiments on the lineal descent of radial glia have shown that a large number of neurons are descended from glial progenitor cells. In the developing neocortex, imaging experiments (Noctor et al., 2002; Kriegstein & Noctor, 2004) revealed the surprising finding that radial glial cells can also generate neuronal precursors, which immediately, or after several rounds of cell division, migrate along the radial processes of the glial mother cells that stretch across the expanding cerebral wall (Fig. 15.14). Genetic studies by Anthony and Heintz (Anthony, Klein, Fishell, & Heintz, 2004) used Cre/loxP fate mapping and clonal analysis to demonstrate that radial glia throughout the CNS serve as neuronal progenitors and that radial glia within different regions of the CNS pass through their neurogenic stage of development at distinct time points. Thus, radial glial populations within different CNS regions are not heterogeneous with regard to their potential to generate neurons versus glia. They went on to show that the promoter region of the radial glial cell marker gene *Blbp* (Feng, Hatten, & Heintz, 1994) contains a binding site for the Notch effector CBF1

that is essential for *Blbp* transcription in radial glia (Anthony, Mason, Gridley, Fishell, & Heintz, 2005). These results identified *Blbp* as the first predominantly CNS-specific Notch target gene. Their results also confirmed earlier studies by Gaiano and Fishell (Gaiano & Fishell, 2002) who showed that Notch signaling regulates radial glial differentiation in the neocortex.

Tangential Migration Pathways: Cortical Interneurons, Cajal-Retzius Cells, the Rostral Migratory Stream, and the Cerebellar System

CORTICAL INTERNEURONS

Although radial migration was once thought to be the primary mode of CNS migrations in cortical regions of vertebrate brain, we now realize that a small subset of the total population of neurons in the murine neocortex migrate from the neocortical VZ to form the layers of the mature cerebral cortex (Tan et al., 1995, 1998). These neurons are the large output neurons, the pyramidal cells (Parnavelas, Barfield, Franke, & Luskin, 1991), and a subpopulation of cortical interneurons. The majority of cortical interneurons originate in the basal forebrain and migrate into the neocortex (Fig. 15.15). The importance of this ventral to dorsal mode of migration is evidenced by the rather remarkable fact that the GABAergic neurons are only about 20% of the total neuronal population in the cortex of rodents (the number is far lower in humans). A detailed view of the migratory routes of cells migrating from the basal forebrain into the neocortex emerged from genetic and transplantation studies. Initial experiments with mice lacking the transcription factors *Dlx1/2* suggested that cortical interneurons originate in the medial ganglionic eminence (MGE) (Anderson, Eisenstat, Shi, & Rubenstein, 1997; Tamaki, Fujimori, & Takauji, 1997). More detailed transplantation and fate mapping studies refined this original view, providing support for the general model that the majority of cortical interneurons originate in the MGE and migrate into the neocortex (Polleux, Whitford, Dijkhuizen, Vitalis, & Ghosh, 2002; Xu, Cobos, De La Cruz, & Rubenstein, & Anderson, 2004). The lateral ganglionic eminence (LGE) likely contributes a small population of interneurons to the cortical interneuron population, but current experiments show that the many LGE cells migrate into the olfactory bulb intermingling with cells that migrate from the cortical SVZ.

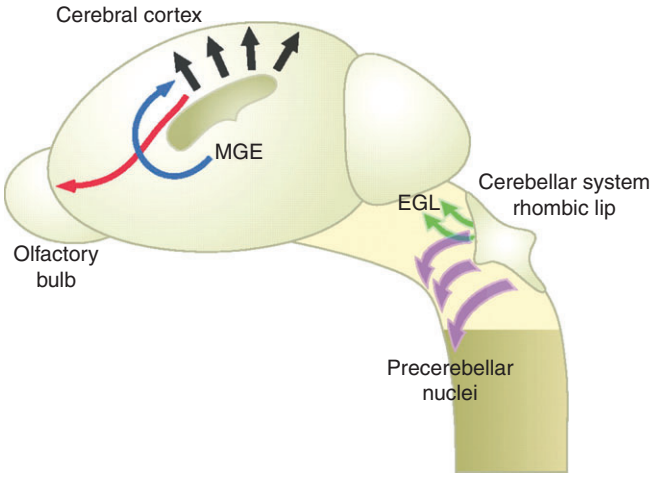

FIGURE 15.15 Non-Radial Pathways of Neuronal Migration. Over the past decade, a number of tangential migratory pathways have been described, in addition to radial pathways (black), including the migration of interneurons from the basal forebrain into the developing neocortex (blue), the migration of neurons from the SVZ to the olfactory bulb along the rostral migratory stream (red), and migrations of progenitors from the rhombic lip to cerebellar cortex (green) and the pre-cerebellar nuclei of the brainstem (purple). (EGL, external granule layer; MGE, medial ganglionic eminence; SVZ, subventricular zone) *Reprinted from Hatten (2002).*

Another tangential migratory pathway occurs in the marginal zone of the neocortex. Although the cells of the MZ were long assumed to be the earliest generated neurons in the cortical VZ, recent evidence from genetic and molecular genetic studies supports the view that a subpopulation of MZ cells originate in the rostral forebrain (or even the basal forebrain) (Meyer, Soria, Martinez-Galan, Martin-Clemente, & Fairen, 1998), while others emerge from the cortical hem, and migrate across the surface of the developing cortex (Garcia-Moreno, Lopez-Mascaraque, & De Carlos, 2007; Meyer, 2007). Support for this view came from studies on gene expression patterns in EGFP-BAC transgenic mice from the GENSAT project (Gong et al., 2003), which showed that cells marked by the gene *Pde1c* migrate from the rostral forebrain back over the surface of the emerging neocortex. Similarly, studies on *Wnt3a positive* cells showed that cells of the cortical hem also contribute to the preplate via a superficial migratory pathway across the surface of the neocortex (Louvi, Yoshida, & Grove, 2007).

THE ROSTRAL MIGRATORY STREAM

The rostral migratory stream (RMS) is another major pathway for tangential migrations (Fig. 15.5). Between E12.5 and E14 in the mouse (E14-16 in the rat), a secondary proliferative zone is formed along the third ventricle of the forebrain (Pencea & Luskin, 2003). This progenitor zone, known as the subventricular zone (SVZ), persists in the adult, where it continues to generate neurons. The subventricular zone has been the subject of intense interest, because it continues to generate new neurons into adulthood, providing GABAergic neurons for the olfactory bulb (Luskin, 1998). As a renewable population of partially committed CNS precursors, the cells from the RMS are an ideal system for studying adult neural "stem" cells (as indicated, they are not "stem cells" in the strict definition of the term). RMS cells differentiate into interneurons when transplanted into the wide variety of target areas, including the septum, thalamus, hypothalamus, and

midbrain of embryonic brain (Alvarez-Buylla, Herrera, & Wichterle, 2000). Thus, many labs are studying the molecular mechanisms that control the differentiation of these cells when placed in ectopic positions, especially in the adult brain.

RMS neurons migrate from the SVZ to the olfactory bulb by a unique mechanism. As the neurons move, they use other migrating neurons in the stream as a substrate (Lois & Alvarez-Buylla, 1994; Lois, Garcia-Verdugo, & Alvarez-Buylla, 1996). This mode of neuronal migration is termed "chain migration" because the neurons form chains within glial sheaths. Recent experiments by Muller and colleagues show that neuroblasts express integrins containing the ß1 and ß5 subunits (Belvindrah et al., 2007). Using genetic and cell biological approaches, they demonstrated that ß5 integrins are dispensable for chain migration, whereas ß1 integrins promote cell–cell interactions that link neuroblasts into chains. The ß1 integrin ligand laminin is recruited to the cell surface of migrating neuroblasts and induces chain formation in SVZ explants and the aggregation of purified neuroblasts. Thus, ß1 integrins and their laminin ligands promote the formation of cell chains in the adult RMS (Belvindrah et al., 2007).

Several secreted signaling molecules are thought to guide the migration of RMS neuroblasts to the olfactory bulb, including the diffusible chemoattractants Netrin-1 (Murase & Horwitz, 2002), the glial cell line–derived neurotrophic factor (Paratcha, Ibanez, & Ledda, 2006), and the chemorepellent Slit1/2 (Nguyen-Ba-Charvet et al., 2004; Wu et al., 1999). In addition, receptor tyrosine kinases of the Eph families and their ephrin ligands (Conover et al., 2000), and Neuregulin and Erb-B ligands (Ghashghaei et al., 2006) apparently guide neuronal migration in the RMS.

CEREBELLAR SYSTEM

A final example of widespread tangential migrations can be found in the cerebellar system, where migrations from the rhombic lip (RL) contribute to both cerebellar histogenesis and the formation of the precerebellar nuclei of the brainstem, which project afferent connections to the cerebellar nuclei or receive efferent connections from the cerebellum (Fig. 15.5). During embryogenesis, the cerebellar territory arises from rhombomere 1, delineated by the expression of Hoxa2 (posterior) and Otx2 (anterior). In the mouse, between embryonic (E) day E9.0 and E9.5, the pontine flexure creates an area along the border of the mesencephalon and metencephalon, where the neural tube fails to close, called the RL (Harkmark, 1954). The embryonic RL is a specialized germinative epithelium that arises relatively late in development at the interface between the neural tube and the roofplate of the fourth ventricle. The rostral (cerebellar) and hindbrain domains of the RL form a continuous proliferative epithelium, which contains overlapping pools of progenitor cells that express combinatorial patterns of transcription factors. Lineage tracing experiments demonstrate that progenitor cell populations in the RL generate both cerebellar granule cells and neurons of the cerebellar nuclei (Rodriguez & Dymecki, 2000), the lateral pontine nucleus, and the cochlear nucleus (Machold & Fishell, 2005; Wang, Rose, & Zoghbi, 2005). Moreover, lineage tracing experiments define the neurons of the precerebellar nuclei that project afferent axons to cerebellar neurons (Rio et al., 1997). Thus, experiments on the allocation of cell fate among rhombic lip (RL) precursors destined for the cerebellar cortex, the cerebellar nuclei and the pre-cerebellar nuclei of the chick and mouse (Landsberg et al., 2005) illustrate the complex migrations that generate the nuclear and cortical regions of the cerebellum (Morales & Hatten, 2006). These patterns include both radial and tangential migratory pathways.

Summary

During CNS development, a remarkable range of neuronal migrations set forth the architectonics of the brain. In general, these migrations can be seen as dorso-ventral (DV) or anterior-posterior (AP) migrations, pathways thought to be prominent in lower organisms but not in vertebrates. Indeed, genes discovered in *C. elegans* and *Drosophila* provide molecular cues for guiding migrations in higher vertebrates, and conserved polarity proteins and their signaling pathways play a key role in sensing directional cues, polarizing cellular extrusions, and generating forces required to propel cells along pathways defined by specific adhesions and/or chemoattractants. The relationship of cell migrations to the establishment of the neuronal layers and brain circuitry will ultimately require novel insights into the role of the transient scaffolding systems of cortical development, the preplate, subplate, and cortical plate, which appear to pattern the connections between laminar, cortical areas of the brain, subcortical nuclei, and the formation of sensorimotor pathways.

CHAPTER

16

Growth Cones and Axon Pathfinding

Approximately 100 years ago, Ramón y Cajal described the trajectories taken by nerve cell processes as they extend toward their intermediate and final targets, and he inferred that multiple influences likely guide growing axons. Ramón y Cajal (1890) also observed for the first time the growing tips of axons and named them "growth cones." In an unparalleled feat of scientific conjecture based on morphological observations of fixed material, he described their behavior:

> From the functional point of view, one might say that the growth cone is like a club or battering ram endowed with exquisite chemical sensitivity, rapid ameboid movements, and a certain motive force allowing it to circumvent obstacles in its path, thus coursing between various cells until reaching its destination.

Decades later, Harrison and Speidel demonstrated using cell culture techniques the truth of Cajal's description of a highly motile, ameboid specialization at the tips of growing axons. Viewed in real time, growth cone shape changes very slowly, at a rate just detectable by an observer. Viewed with modern time-lapse techniques, however, the dynamism of their ever-changing morphology as they crawl forward is striking. These pioneering studies identified the growth cone as the key decision-making component in the elaboration of axonal pathways.

The growth cone at the distal tip of an axon extending in tissue culture is flattened into a thin fan-shaped sheet with many long, very thin spikes radiating forward (Fig. 16.1). The fan-shaped sheets are called lamellipodia, and the spikes are called filopodia, or microspikes. Many growth cones growing *in situ* have a similar appearance, but it is not unusual to observe spindle-shaped growth cones with tufts of forward-directed filopodia within axon bundles. More complex growth cone shapes are often characteristic of slowly extending growth cones choosing between possible routes of extension, whereas simpler morphologies are characteristic of rapidly extending growth cones coursing along permissive tracts.

GROWTH CONES ARE ACTIVELY GUIDED

Growth cones crawl forward as they elaborate the axons trailing behind them, and their extension is controlled by cues in their outside environment that ultimately direct them toward their appropriate targets. What is the nature of these guidance cues and how do they affect growth cone behavior? One view to account for the ability of the nervous system to wire itself, already implicit in Ramón y Cajal's writings, held that axonal growth is highly directed, with each class of axons navigating along a distinctive prescribed pathway to reach its target. For example, during neural development, spinal commissural axons extend seemingly unerringly toward the ventral-most region of the spinal cord, cross to the contralateral side, and then extend rostrally to targets in the brain (Fig. 16.2A). These neurons could be influenced by a variety of repulsive and attractive cues at different points along their trajectory, with each portion of the journey directed anew by distinct guidance mechanisms (Fig. 16.2B). An alternative view for wiring the nervous system postulated that axonal growth involves a random wandering of axons throughout the embryonic environment with connections appropriate for proper functioning of the nervous system somehow being maintained and reinforced at the expense of inappropriate connections.

A number of experiments provided evidence supporting directed axon growth, including the classic experiments of Sperry demonstrating highly specific targeting

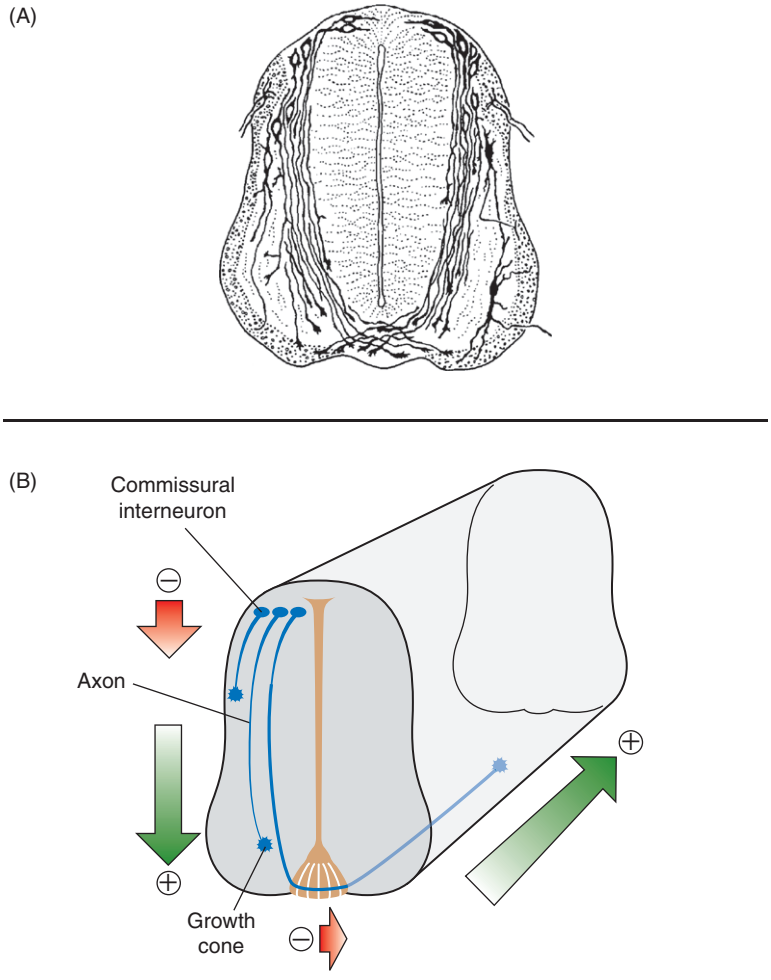

FIGURE 16.2 **Multiple guidance cues direct spinal cord commissural axons during neural development**. (A) This original drawing by Cajal illustrates neuronal pathways in the developing chick spinal cord, showing several commissural axons extending to the ventral spinal cord and crossing the floor plate. Note the distinct growth cone morphologies observed at different portions of the pathway, with growth cones at or crossing the midline exhibiting complex and expanded morphologies. From Ramón y Cajal (1890). (B) At least four classes of guidance cues are now known to instruct commissural axons during development: repellents from the dorsal spinal cord, initially directing commissural axons on a ventral course; attractive cues emanating from the ventral spinal cord guiding commissural axons toward the ventral spinal cord; repulsive cues in the ventral spinal cord, facilitating midline crossing and preventing recrossing; and attractants that guide postcrossing commissural axons anteriorly toward targets in the brain.

of regenerating retinal ganglion cell axons to the optic tectum (Sperry, 1963). The application of axonal tracing techniques has made it possible over the past 35 years to observe in multiple species a variety of different classes of axons en route to their targets. These studies show that the establishment of complex neural wiring patterns occurs through a combination of initial neuronal activity-independent guidance events and subsequent refinement of connections requiring electrical signaling among neurons (Goodman & Shatz, 1993). When projecting to the vicinity of their target field, axons grow along very stereotyped trajectories, making few projection errors. This growth is highly directed, and selection of the target cell is equally precise. A good example is the highly stereotyped and reproducible extension of individual axons arising from defined insect neurons as they grow within the central and peripheral nervous systems (Bastiani, du Lac, & Goodman, 1986; Caudy & Bentley, 1986; Raper, Bastiani, & Goodman, 1984). Neuronal ablation experiments demonstrate that individual neurons show selective affinity for certain axon bundles and in the absence of these targets fail to extend upon alternative neuronal, or nonneuronal, substrates (Fig. 16.3). Therefore, neurons appear programmed to connect with specific targets even before they contact them, an idea supported by the finding that axons of vertebrate motoneurons that have been surgically moved to abnormal nearby locations can reach their normal and appropriate targets even when they must traverse unusual routes to do so (Lance-Jones & Landmesser, 1980). Thus, guidance to target fields occurs prior to, and is independent of, neuronal circuit function. However, once many similar axons arrive at a target field containing numerous similar target cells, as occurs when groups of motor axons all innervate many muscle fibers in a single muscle or when thalamic neurons receiving input from both eyes establish overlapping axonal arborizations in the visual cortex, neuronal function does come into play. In these circumstances, individual axons initially arborize widely within the target field and contact many target cells, only later refining their pattern of connections in a process that depends on the precise patterns of electrical activity in these neurons and their target cells. The rest of this chapter focuses on the first step in the formation of connections: the directed growth of axons to target fields. The selection of target cells and the role of electrical activity in this process are discussed in Chapters 18, 20, and 22.

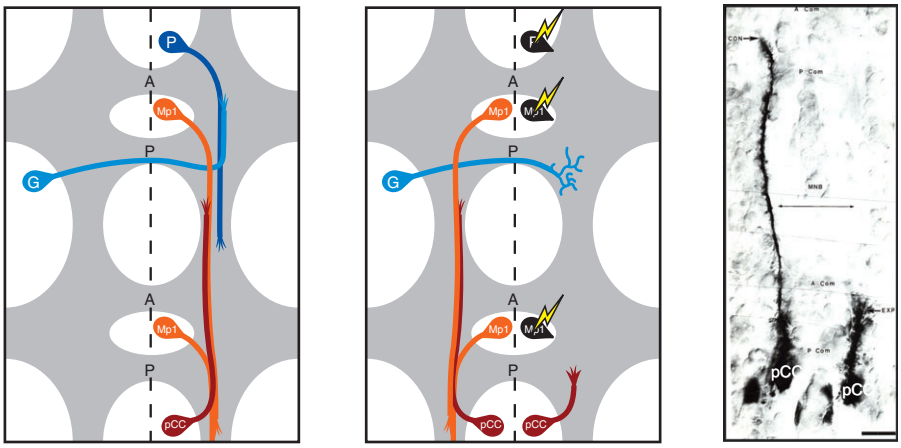

FIGURE 16.3 **Extending axons demonstrate exquisite selectivity in choosing their pathways during neural development.** (A) A simplified diagrammatic representation of the embryonic grasshopper central nervous system shows the establishment of two distinct axon pathways (or fascicles): the joining of the G neuron with the P trajectory, and the joining of the pCC neuron with the MP1 pathway. The G neuron extends across the CNS midline (dotted line) within the posterior commissure ("P") and selectively joins (or fasciculates) with axons from the P neurons (one of which is shown here), extending anteriorly along these descending P axons. The pCC neuron does not cross the midline and instead extends anteriorly along descending MP1 axons. (B) Ablation of neurons that contribute the P or MP1 pathways results in the inability of the G or pCC neurons, respectively, to extend anteriorly; these neurons do not fasciculate with numerous other axon pathways present very close by at this stage of development (not shown), and they instead stall at the point where they would have selectively fasciculated with their axonal targets. (C) Dye filling of pCC neurons on the experimental (right) and control (left) sides of a grasshopper embryo shows that when pCC does not encounter descending MP1 neurons, which are absent on the right side owing to ablation of these neurons, its growth cone stalls near the point where normally this contact would take place and no directed extension on alternative substrates occurs. *Source: From Bastiani et al. (1986) and Raper et al. (1984).*

GUIDANCE CUES FOR DEVELOPING AXONS

How do axons succeed in navigating through the embryonic environment to targets that in some cases can be many centimeters away? The trajectories of many axons appear to be broken up into short segments, each perhaps a few hundred micrometers long. The daunting task of reaching a distant target is then reduced to the simpler task of navigating each of these successive segments. This is illustrated by the projections of commissural neurons in the spinal cord, depicted in Figure 16.2. The pathway of these axons can be divided into discrete segments, each bounded by a specific cell, or group of cells, that marks the end of one segment and the beginning of the next. Such cells, forming an intermediate target for the axons, are sometimes termed "guidepost" cells. For example, commissural axons initially grow from the dorsal spinal cord to a set of guidepost cells at the ventral midline termed "floor plate cells," which serve as an important intermediate target. Commissural axons cross the midline at the floor plate, then turn and extend alongside the midline before eventually leaving the midline to seek out their ultimate targets. In mice, genetic ablation of floor plate cells results in profound misrouting of the axons when they reach the midline (Matise, Lustig, Sakurai, Grumet, & Joyner, 1999). Evidence for the existence of such guidepost cells harboring important guidance information has been obtained throughout the animal kingdom (Caudy & Bentley, 1986; McConnell, Ghosh, & Shatz, 1994).

The appreciation that axonal trajectories are formed in small segments pushes the question back one step: How do axons navigate each small segment of their trajectory? Axons appear to be guided along their appropriate trajectories by their responses to selectively distributed molecular signals within the developing embryo. Studies over the past three decades have led to the view that axon guidance involves the coordinate action of four types of cues: short-range (or local) cues and long-range cues, each of which can be either positive (attractive) or negative (repellent) (Fig. 16.4). The operations of short- and long-range guidance mechanisms and of attraction and repulsion are not mutually exclusive. Rather, axons may generally be guided over each individual segment of their trajectories by several different types of mechanisms acting in concert to ensure reproducible and high-fidelity guidance. Many experiments show that axons may navigate short segments by using several and, in some cases, even all four types of cues (Fig. 16.4): a repellent from behind the axons to "push," a corridor marked by a permissive local cue and bounded by an inhibitory local cue to "hem in" growth, and an attractant at the end of the corridor to "pull" (Tessier-Lavigne & Goodman, 1996). Push, pull, and hem—these forces working together can ensure accurate guidance.

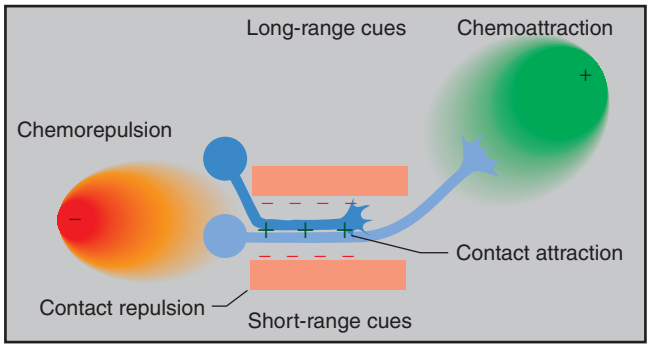

FIGURE 16.4 **Axons are guided by the simultaneous and coordinate actions of four types of guidance mechanisms:** contact attraction, chemoattraction, contact repulsion, and chemorepulsion. Individual growth cones might be "pushed" from behind by a chemorepellent, "pulled" from in front by a chemoattractant, and "hemmed in" by attractive and repulsive local cues (cell surface or extracellular matrix molecules). Push, pull, and hem: these forces act together to ensure accurate guidance. *Source: Adapted from Tessier-Lavigne and Goodman (1996).*

The identification of signaling molecules that function as guidance cues has depended primarily on three experimental approaches: (1) pairing biochemistry and *in vitro* tissue culture assays to detect proteins with either attractive or repellent properties, (2) using forward genetics to identify mutations that affect axon trajectories *in vivo*, or (3) using genetic and tissue culture approaches to characterize the functions of molecules with distributions or molecular structures that make them attractive candidate guidance cues.

Studies over the past decade and a half have, in this way, led to the identification of several prominent families of signaling molecules that function as instructive guidance cues (Kolodkin & Tessier-Lavigne, 2010). A first wave of studies in the 1990s identified four major families that have well-established and widespread roles in axon guidance: netrins, semaphorins, slits, and ephrins (Fig. 16.5A). These are sometimes referred to as the "classic" axon guidance molecules. More recently, two additional classes of molecules initially identified in other contexts were shown to function as guidance cues as well: proteins that are usually classified as morphogens (including members of the Bone Morphogenetic Protein, Hedgehog, Vascular Endothelial Growth Factor, and Wnt families), as well as some proteins initially identified as growth factors (Fig. 16.5B). The identification and characterization of these cues and their receptors have led to several important generalizations about guidance mechanisms (Dickson, 2002; Tessier-Lavigne & Goodman, 1996). First, guidance cues come

	Neurotrophins	Trks	+

FIGURE 16.5 Multiple families of molecules serve as guidance cues. (A) Structures of the "canonical" axon guidance cues: netrins, semaphorins, slits, ephrins, and their receptors. Netrin receptors include members of the DCC and UNC5 family. There are seven classes of semaphorins (two invertebrate and five vertebrate). Of the ~20 mammalian semaphorins, 5 are secreted (class 3) and the others are divided into four families of transmembrane or GPI-linked proteins (represented here by a single diagram). Semaphorin receptors include plexins (of which nine are known in mammals, divided into classes A–D) and neuropilins (two in mammals). Class 3 semaphorin signaling is mediated by complexes of neuropilins (which serve as binding moieties) and plexins (signaling moieties). Slit receptors are members of the Roundabout (Robo) family. The receptors for Ephrins are members of the Eph family. Ephrin-As are GPI-anchored and predominantly bind EphAs, whereas Ephrin-Bs are transmembrane proteins and preferentially bind EphBs. *Adapted from Winberg et al. (1998) and Chisholm and Tessier-Lavigne (1999).* (B) Morphogens (members of the Wnt, Hedgehog, and BMP families) and various growth factors listed here also serve to guide neuronal processes. Known receptors functioning to mediate their effects in guidance are indicated.

in families that may, in some cases, comprise both diffusible members that can function in long-range axon guidance and nondiffusible members functioning at short range. Second, many guidance cues are multifunctional, attracting some axons, repelling others, and sometimes controlling axonal branching or arborization. Different axons may respond to the same cue differently because they express a distinct complement of surface receptors or contain particular components of the relevant signal transduction pathways. Third, many (although not all) cues are evolutionarily conserved between vertebrates and simpler invertebrate organisms, with species homologues often performing similar axon guidance roles. Higher vertebrates typically have many more members within a given family of guidance cues, and these cues are likely to have overlapping functions.

These different families of guidance cues are discussed briefly to illustrate features of wiring mechanisms. We

start by reviewing each of the four families of "classic" guidance cues before briefly describing the roles of morphogens and growth factors in guidance. We also focus specifically on members of the Immunoglobulin Gene (Ig) Superfamily, which have diverse roles as ligands and receptors in axons guidance.

Netrins

The netrin family (Fig. 16.5A) comprises about half a dozen members identified in vertebrates. The first vertebrate members were identified in studies on the guidance of commissural axons in the spinal cord. As described above, these axons project from the dorsal spinal cord to floor plate cells at the ventral midline (Fig. 16.6A). Experiments in tissue culture using microdissected pieces of rat spinal cord showed that floor plate cells secrete a diffusible outgrowth-promoting and chemoattractive activity for commissural axons, and netrins were identified as proteins that can mimic these activities (Serafini et al., 1994; Tessier-Lavigne, Placzek, Lumsden, Dodd, & Jessell, 1988). In the spinal cord, netrin is present in a dorsal-to-ventral increasing gradient (Figs. 16.6Ai and ii) and appears to provide guidance information to commissural axons, guiding them to the floor plate. In support of this view, netrin-1 can attract commissural axons from dorsal spinal cord pieces in culture, deflecting dorsal-ventral projections laterally when cells secreting recombinant netrin-1 are placed alongside the dorsal spinal cord pieces (Fig. 16.6B). Further, removal of netrin-1 function, which occurs in a *netrin-1* knockout mouse, results in significant misrouting of commissural axons, with many failing to reach the floor plate (Fig. 16.6C). Interestingly, a few axons do reach the floor plate even in the absence of netrin-1 (Fig. 16.6C), showing that one or more additional cues must collaborate to guide the axons. The collaboration of multiple guidance cues even over short segments of an axonal trajectory helps reduce the risk of guidance errors and contributes to the high degree of accuracy of wiring of the nervous system.

In addition to attracting commissural axons, netrins have been shown to function in attracting other subsets of axons to various targets in the retina and brain. Remarkably, netrin-1 also appears to function as a long-range repellent, providing a push from behind for a group of axons in the hind-brain that grow away from the midline, thus illustrating guidance cue bifunctionality.

Strikingly, netrins are vertebrate homologues of the UNC-6 protein of the nematode *Caenorhabditis elegans*, a protein similarly involved in both attracting some axons toward the nervous system midline and in repelling others away from it (Fig. 16.6Aiii) (Wadsworth, Bhatt, & Hedgecock, 1996). Netrin homologues are also expressed at the *Drosophila melanogaster* nervous system midline, where they contribute to attracting axons. In all of these organisms, netrin attraction is mediated by receptors of the DCC family, members of the immunoglobulin gene superfamily (Fig. 16.5) (Kolodkin & Tessier-Lavigne, 2010), and mutations in these receptors impair guidance to the midline in all species. This is true even in humans, since inherited loss-of-function mutations in the gene encoding DCC result in "mirror movements," a neurological syndrome in which voluntary movement of one extremity (e.g., the left arm) is accompanied by an involuntary mirror movement of the other (the right arm). This syndrome apparently results from miswiring of the nervous system, as corticospinal projections partially fail to reach and cross the midline at the pyramidal decussation so that each cerebral hemisphere is connected to both sides of the spinal cord, not simply the contralateral side as in unaffected humans (Srour et al., 2010). Netrin repulsion, in contrast, requires receptors of the UNC5 family, which are also members of the immunoglobulin gene superfamily (Figs. 16.5A) (Kolodkin & Tessier-Lavigne, 2010). In fact, as first shown in *C. elegans*, and illustrated for a vertebrate neuron in Figure 16.7, it is possible to convert

FIGURE 16.6 **Netrins are phylogenetically conserved axon attractants.** (A) Distribution and function of Netrins in axon guidance. (i) Diagram of a cross section through the embryonic vertebrate spinal cord depicting the role of Netrin-1 (here and in all subsequent schematic figures shown in green) in guiding commissural axons from the dorsal spinal cord to the ventral midline. (ii) A ventral to dorsal gradient of Netrin protein in the developing mouse spinal cord visualized using an immunohistochemical stain. *From Kennedy, Wang, Marshall, and Tessier-Lavigne (2006).* (iii) Diagram of a cross section through the developing nematode *C. elegans* illustrating the role of the Netrin/UNC-6 in guiding axons along a dorso-ventral trajectory. (B) Attractive effect of Netrin-1 on rodent commissural axons in an *in vitro* assay for chemoattraction. Pieces of the dorsal half of the spinal cord, viewed from the side, were placed in culture for 40 hours with either control COS cells or COS cells secreting Netrin-1. In control conditions (left), all the commissural axons grow from their cell bodies at the top (dorsal) side of the explants along a vertical (dorso-ventral) trajectory (shown in diagrammatic form at the top, and visualized within the spinal cord explants using an immunohistochemical axonal marker (red) at bottom). In the presence of cells secreting Netrin-1, however, the axons within ~150 μm of the cells (arrowheads) turn toward the Netrin source. Dots mark the boundary between COS cells and spinal cord tissue. In the presence of Netrin-1 axons can be seen invading the Netrin-secreting COS cell clump. *From Kennedy, Serafini, de la Torre, and Tessier-Lavigne (1994).* (C) Netrin-1 is required for guidance of commissural axons to the ventral midline. Shown are cross-sections through the spinal cord of embryonic day 11.5 mice. Left: wild-type (control); right: Netrin-1 knockout mouse. Axons are visualized with an axonal marker. Normally (left), commissural axons (c) extend along a smooth dorsal-to ventral trajectory to the floor plate (fp) at the ventral midline. In the absence of Netrin-1 (right), they extend normally in the dorsal half of the spinal cord, but when their trajectory through the ventral half is profoundly perturbed, with many projecting medially or laterally, only a very few axons reach the floor plate. *From Serafini et al. (1996).*

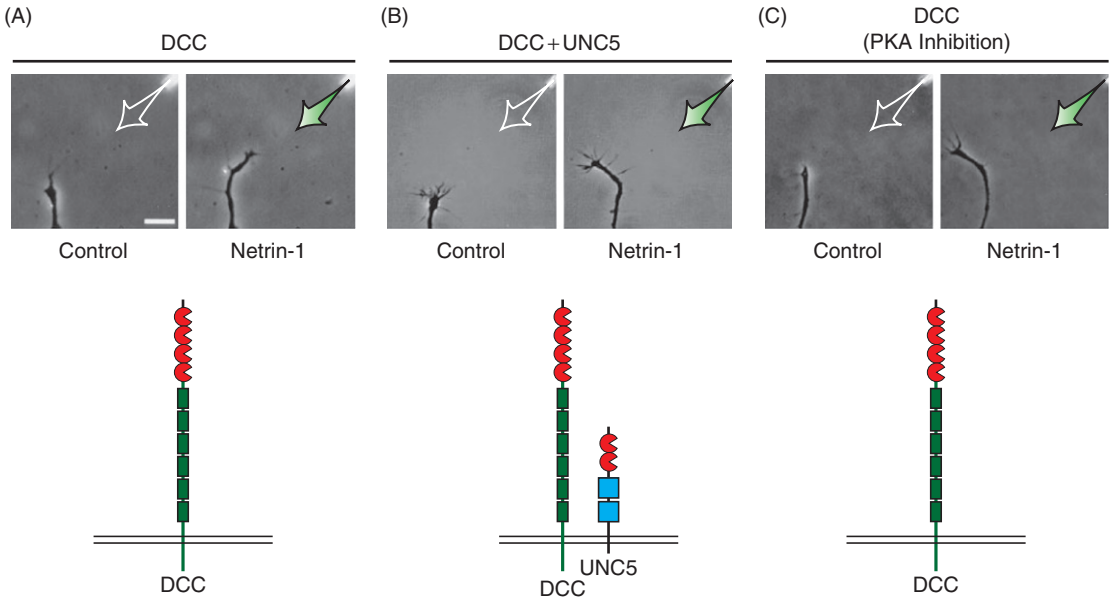

FIGURE 16.7 **Netrin bifunctionality depends upon both receptor composition and intracellular signaling.** (A) Single *Xenopus* spinal neurons in culture are attracted and steer along an increasing gradient of Netrin-1 originating from a micropipette (hollow arrow, upper right: green arrow, Netrin; white outlined arrow, control). These neurons express DCC on their surface. (B) If a *Xenopus* neuron expresses both DCC and UNC5 receptors, these proteins form a signaling complex which now interprets Netrin-1 as a repellent, and they steer down the gradient. (C) Inhibition of cAMP-mediated signaling using a protein kinase A (PKA) inhibitor also converts Netrin-1 attraction to repulsion, even though these neurons only express DCC. *From Ming et al. (1997) and Hong et al. (1999).*

netrin attraction, mediated by DCC, to repulsion by introducing an UNC5 family member into the neuron (Hamelin, Zhou, Su, Scott, & Culotti, 1993; Hong et al., 1999). These findings on netrins and their receptors vividly illustrate both guidance cue bifunctionality and the remarkable evolutionary conservation of axon guidance mechanisms.

The signaling mechanisms mediating attraction and repulsion are currently the subject of intense investigation (Bashaw & Klein, 2010). Several observations suggest that the signaling machinery within growth cones is organized to allow rapid switching from attractive to repulsive responses. For example, the responses of growth cones that are attracted to netrin-1 can be converted to repulsive responses through pharmacological manipulations that result in a reduction in cyclic AMP (cAMP) signaling (for instance, incubation with a membrane permeable inhibitor of the cAMP effector protein kinase A (PKA)) (Fig. 16.7) (Ming et al., 1997). How cAMP signaling modulates the netrin response is not fully understood, but it is clear that the growth cone turning machinery is organized to facilitate such switching.

Although netrins are capable of long-range attraction, the extent to which netrins can diffuse appears to be regulated so that in some circumstances they function as local cues, as shown in the nematode *C. elegans*, in the vertebrate retina, and at the *Drosophila* midline (Brankatschk & Dickson, 2006; Deiner et al., 1997; Wadsworth et al., 1996). Thus, like the distinction between attractive and repulsive cues, there is not a hard and fast distinction between local and long-range cues.

Semaphorins

The semaphorin family of proteins includes many secreted and membrane-associated proteins (Raper, 2000). The first known semaphorin was grasshopper Semaphorin 1a, a transmembrane protein required for correct pathfinding of pioneer axons in the developing limb (Kolodkin et al., 1992). The first vertebrate semaphorin, semaphorin 3A (Sema3A, originally called collapsin-1), was identified utilizing an *in vitro* axon repulsion assay to facilitate the biochemical purification of axonal repellents from brain extracts (Fig. 16.8A) (Luo, Raible, & Raper, 1993). There are approximately 20 distinct semaphorin family members in higher vertebrates, and all contain the family's signature semaphorin domain, a ~500 amino acid domain that is the key extracellular signaling domain of these proteins (Fig. 16.5A). Semaphorin biological specificity is in part determined by a relatively short stretch of amino acids within the semaphorin domain.

Most semaphorins have the capacity to act as potent inhibitory cues for neuronal or nonneuronal cells, and *in vitro* have been shown to repel very specific subsets of cultured axons. *In vivo* genetic analyses in invertebrates and vertebrates demonstrate conclusively that semaphorins serve as key axon repellents during neural

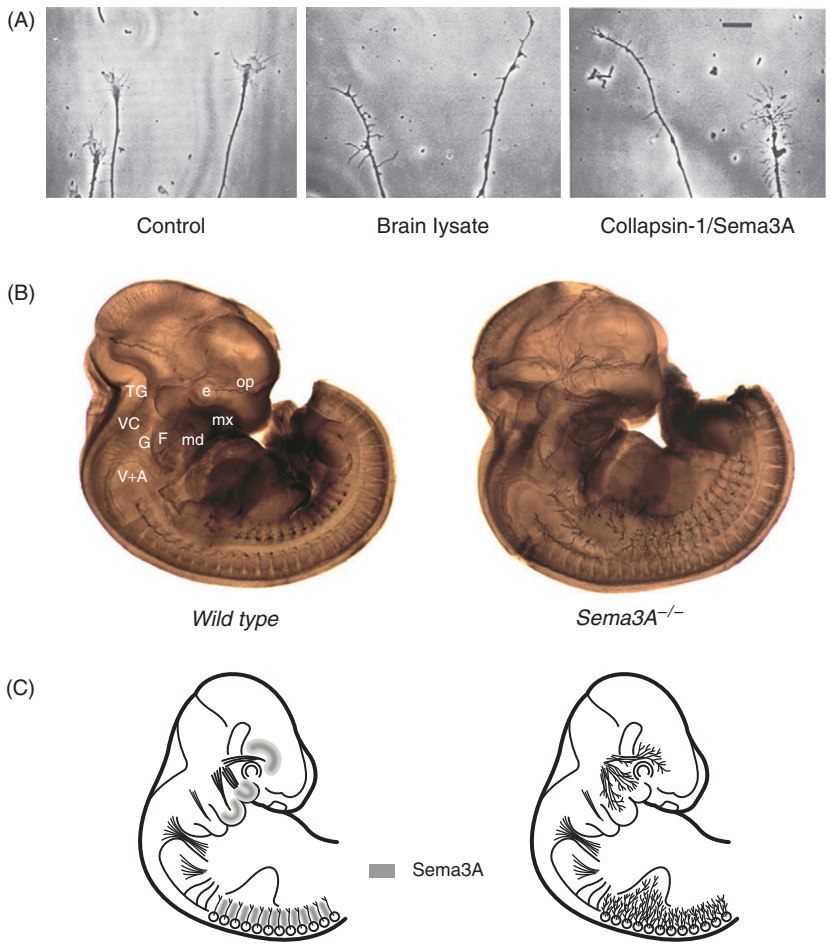

FIGURE 16.8 Secreted semaphorins are potent repellents. (A) Dorsal root ganglion neurons in culture exhibit a dramatic collapse when exposed to biochemically enriched fractions derived from chick brain lysates or to conditioned medium from tissue culture cells engineered to express recombinant Sema3A/collapsin-1. Medium from control non-transfected cells has no effect on DRG growth cone morphology. From Luo et al. (1993). (B) Mouse whole mount, embryonic day 11.5, wild-type and Sema3A mutant embryos immunostained for neurofilaments to illuminate spinal and cranial peripheral nerve projections. In Sema3A mutants, cranial nerves, including the trigeminal nerve (TG), are dramatically defasciculated, extend branches into ectopic locations, and overshoot their normal target regions. Spinal nerves, too, are defasciculated and extend into intersomitic regions they normally avoid (cranial nerves: ophthalmic, op; maxillary, mx; mandibular, md; facial, F, glossopharyngeal, G; vestibulocochlear, VC; vagus and accessory, V+A. Eye, e. Spinal nerves, arrow). Observations first reported by Taniguchi et al. (1997); whole-mount photographs courtesy of J. Merte and D. Ginty. (C) Schematic of whole mount embryos in B showing cranial and spinal nerve projections, and also Sema3A localization (gray).

development (Tran, Kolodkin, & Bharadwaj, 2007). For example, dramatic axon guidance defects are observed in *Sema3A* mutant mice (Fig. 16.8B) (Taniguchi et al., 1997). How does Sema3A-mediated repulsion contribute to normal axon guidance? Through various permissive cues expressed on axons or substrates upon which they extend promote axon outgrowth, repellents in the surrounding tissue constrain axon outgrowth—a process termed "surround repulsion." For example, Sema3A is expressed in tissues surrounding many peripheral nerves and acts as a repellent for sensory and motor axons. In *Sema3A* mutants, many peripheral nerves are defasciculated, extending and branching excessively into regions where normally Sema3A would inhibit their growth (Fig. 16.8B and C). Transmembrane semaphorins expressed on axons within fascicles also serve as repellents, but rather than providing "surround repulsion," they counter attractive axon-axon interactions, allowing axons to respond to other cues and defasciculate from main bundles in order to extend toward specific targets (Tran et al., 2007).

The major receptors for semaphorins are members of the plexin family, transmembrane proteins that include nine different receptors in higher vertebrates (Fig. 16.5A) (Tamagnone & Comoglio, 2000). Many transmembrane and some secreted semaphorins bind plexins directly. However, several secreted vertebrate semaphorins, including Sema3A, do not. Instead, these secreted semaphorins bind to the obligate co-receptors neuropilin-1 or neuropilin-2 that, together with a plexin family member, form an active receptor complex (Fig. 16.5A) (Tran et al., 2007). Plexin receptor activation initiates a series of intracellular signaling events that results in the local disassembly of growth cone cytoskeletal components and substrate attachments, ultimately producing inhibition of axon outgrowth or repulsive steering (Bashaw & Klein, 2010). Semaphorins also include both attractants and repellents, and the same semaphorin may under certain circumstances serve both functions. For example, the secreted semaphorin Sema3B in the mouse embryo functions as an attractant for one subset of axons in the developing anterior commissure tract in the brain and as a repellent for a different subset of axons in this same tract (Falk et al., 2005). Sema3A can act as both an attractant and a repellent for distinct neural processes extending from mouse cortical pyramidal neurons, and in a neuronal culture paradigm Sema3A repels

cortical pyramidal neuron axons but attracts dendrites from these same neurons (Polleux, Giger, Ginty, Kolodkin, & Ghosh, 1998; Polleux, Morrow, & Ghosh, 2000). Like netrin-1, Sema3A repulsive steering of isolated growths *in vitro* is also modulated by cyclic nucleotide signaling, but cGMP signaling plays a key role in switching Sema3A repulsion to attraction (Song et al., 1998).

Semaphorins facilitate the formation of central and peripheral axon pathways by regulating axon pathfinding and fasciculation, but semaphorins have also been implicated in targeting axons to the specific locations of their synaptic partners, in directing the pruning of exuberant projections, and in regulating the morphology of cortical pyramidal neuron dendrites (Pasterkamp & Giger, 2009).

Slits

Slits are large secreted proteins (Fig. 16.5A) that are also multifunctional. They were identified as axonal repellents through studies of chemorepellent factors in *Drosophila* and in vertebrates (Brose et al., 1999; Kidd, Bland, & Goodman, 1999; Li et al., 1999), and as stimulators of axon branching through studies of sensory axon arborization in vertebrates (Wang et al., 1999). A single Slit gene is found in *Drosophila* and in *C. elegans*, whereas there are three in mammals. Extensive studies in all three organisms demonstrate key roles for Slit-mediated repulsion in guidance of many axonal classes, including a variety of axons in the mammalian forebrain, as well as guidance at the midline of the spinal cord (discussed below). The branching activity of Slits has been observed in vertebrates (Ma & Tessier-Lavigne, 2007) and has been implicated in regulating dendritic branching (Whitford, Dijkhuizen, Polleux, & Ghosh, 2002).

In all species, the repulsive actions of Slit proteins are mediated by receptors of the Roundabout or Robo family (Kidd et al., 1998) (Fig. 16.5A), which, like the DCC and UNC5 families of netrin receptors, are also members of the immunoglobulin superfamily. Interestingly, whereas in the case of netrins different receptors mediate attraction and repulsion, for Slits it appears that both repulsion and branching are mediated by Robo family receptors, presumably activating distinct downstream effectors within the axons.

Ephrins

The fourth family of "classic" guidance cues consists of the ephrins, cell surface signaling molecules that play important roles in a large number of developmental events, including axon guidance (Klein, 2004). There are two subfamilies (Fig. 16.5A). Eight class A ephrins are tethered to the cell surface via GPI linkages, and six class B ephrins are transmembrane molecules. Ephrins must be clustered together to activate their receptors and do not appear to be active if released from the cell surface, so they are thought to function exclusively as short-range guidance cues. These ligands bind receptor tyrosine kinases of the Eph family. Class A ephrins interact with various degrees of selectivity with five class A Eph receptors, whereas class B ephrins interact with three class B Eph receptors (Fig. 16.5A). Ephrins have been shown to play an essential role in organizing topographic projections that connect, for example, retinal ganglion cells in the eye with their target cells in the appropriate portion of the optic tectum in lower vertebrates, or the lateral geniculate nucleus of the thalamus in higher vertebrates (see below). These mapping functions demonstrate the versatility of ephrins, which can function as attractants for some axons and repellents for others, and as either positive or negative regulators of axonal branching. In addition to topographic mapping, ephrins are implicated as short-range attractants and repellents in the guidance of a variety of central and peripheral axons, and they also play key roles in synapse development (see Chapter 18).

Morphogens and Growth Factors

The "classic" guidance cue families do not account for all axon guidance. Though certainly additional classes of guidance cues remain to be discovered, studies over the past decade reveal that various morphogens and growth factors have also been co-opted to guide axons (Fig. 16.5B). We are still learning how widely these molecules are used in this role.

Morphogens are proteins that function to specify cell fates at earlier stages of embryonic development; the term refers specifically to factors that can induce different fates in a dose-dependent fashion. Three key families of developmental morphogens have been implicated in axon guidance as well: members of the Hedgehog (Hh), Bone Morphogenetic Protein (BMP), and Wnt families. Most of these families were introduced in Chapter 14 in the discussion of cell fate determination. The evidence implicating these factors and their receptors in axon guidance is growing and is particularly well established in the vertebrate spinal cord. Here, members of all four families collaborate with classic guidance cues of the netrin and slit families (see below). Outside the spinal cord, evidence for guidance functions of BMP and Hedgehog proteins is still limited. Examples have been noted in *C. elegans* (involving the BMP family member UNC-129) and in the vertebrate retina (involving Sonic Hedgehog), but just how widely these factors function as guidance cues remains to be determined.

The evidence implicating Wnt family members in guidance is, however, quite extensive; they play key roles in axon guidance along the longitudinal (anterior-posterior) axis in *C. elegans*, *Drosophila*, and vertebrates, and they function in retinotectal topographic mapping (Schmitt et al., 2006). A list of these factors, and the receptors that mediate their guidance functions, is provided in Figure 16.5B.

Whereas morphogens that function at early stages of development have been co-opted to guide axons at later stages, various growth factors initially known for their functions at later stages of nervous system development—particularly in regulating the survival of neurons (Chapter 19)—also play earlier axon guidance roles. So far, these factors are all implicated as attractants: Hepatocyte Growth Factor (HGF), Fibroblast Growth Factors (FGFs), and Glial Cell-derived Neurotrophic Factor (GDNF) for subsets of motor axons, Neurotrophins (BDNF and NT3) for sensory axons, Neuregulins for thalamocortical axons, and Vascular Endothelial Growth Factor A (VEGFA) for commissural axons (Fig. 16.5B). In each case, the factors have been implicated in guidance of just one subset of axons and just in vertebrates. Thus, it remains an open question how widely growth factors are used to guide axons, and whether they can also function as repellents *in vivo*. There is, however, already considerable evidence that many of these factors function to stimulate branching of diverse classes of axons at their targets (for example, the neurotrophin NGF regulates branching of sensory axons at their targets, whereas BDNF regulates branching of thalamocortical axons in the cortex).

The following sections of this chapter explain how the guidance cues discussed above are deployed *in vivo* to affect accurate guidance. However, we first discuss one family of proteins, already mentioned above, that has diverse roles in regulating nervous system wiring, the Ig Superfamily proteins.

Ig Superfamily Proteins: Cell Adhesion Molecules, Guidance Cue Receptors, and Repellents

Initial work directed toward understanding nervous system connectivity in part focused on identifying factors that promote neuronal adhesion to substrates. In the 1980s, several cell adhesion molecules (CAMs) were identified, including a protein called Neural Cell Adhesion Molecule (NCAM) that was shown to mediate *in vitro* adhesive interactions in a homophilic (like-binds-like) fashion. NCAM contains a large extracellular domain structure that includes multiple repeats of an immunoglobulin (Ig)-C2 motif, and also several fibronectin type II repeats (Edelman, 1986). In cell culture NCAM can regulate axon-axon associations, but mice harboring mutations in *NCAM*, or in other vertebrate Ig superfamily adhesion molecules such as L1, do not exhibit guidance defects indicative of these proteins playing major instructive roles in nervous system wiring. However, the *Drosophila* cell adhesion molecule fasciclin II (FasII), the fly orthologue of NCAM, provides insight into how selective CAM expression can contribute to more subtle aspects of nervous system wiring—namely fasciculation (or bundling) of axons. FasII is expressed on a defined subset of fascicles in the developing insect CNS and PNS. Axons that contribute to FasII-expressing pathways still extend in approximately correct directions in *FasII* mutant fly embyros. However, ultrastructural analysis reveals in *FasII* mutants that axons that normally express FasII on their surface and maintain very close contact now fail to bundle together and instead proceed independently (Lin, Fetter, Kopczynski, Grenningloh, & Goodman, 1994).

A myriad of different Ig superfamily proteins is expressed in developing neurons, including CAMs and receptors for classic guidance cues (such as DCC, Robo, and Unc5; see above). However, a novel repulsive function for homophilic interactions involving the CAM Dscam (Downs Syndrome CAM) in *Drosophila* neural development have been observed (Schmucker et al., 2000; Zipursky & Sanes, 2010). Dscam is distinguished from all other Ig superfamily members by its genomic structure; alternative splicing of numerous exons has the capacity to result in the generation of close to 40,000 different Dscam isoforms. Homophilic Dscam interactions only occur between identical Dscam isoforms; a difference of even a few amino acids in otherwise identical isoforms precludes homophilic association. This astounding molecular diversity, coupled with expression of only a few isoforms in any one neuron, has the potential to allow individual neuronal processes, including axon branches or dendrites, to distinguish between self and nonself. This is because it is extremely unlikely that any two neurons will express the same complement of Dscam isoforms. Indeed, in the mushroom body of the *Drosophila* brain, isoform-specific Dscam interactions are required for axon branches from the same neuron to separate from one another and bifurcate at a single choice point (Zhan et al., 2004). Further, the elaboration of individual sensory neuron dendritic arborizations with nonoverlapping branches (called "tiling," which allows for an even distribution of sensory endings), also requires homophilic interactions between identical Dscam isoforms (Zipursky & Sanes, 2010). Therefore, Dscam isoform diversity allows neuronal processes emanating from a single neuron to be repelled from one another while simultaneously maintaining contact with processes from other neurons. Though in vertebrates Dscam is not extensively alternatively spliced, in the mammalian retina DSCAM plays a key role in

regulating self-avoidance among neurites of amacrine cell subtypes (Fuerst, Koizumi, Masland, & Burgess, 2008). Several other vertebrate neuronal proteins and families of proteins, including protocadherins, have the potential to provide extensive molecular diversity. Therefore, the employment of extreme protein isoform diversity in the service of distinguishing neuronal process uniqueness may be generally applicable across species (Zipursky & Sanes, 2010).

Summary

Several prominent classes of guidance cues have been identified: the four families of "classic guidance cues" (netrins, semaphorins, slits, ephrins) whose functions in guidance are widespread and well established, three families of morphogens (Hedgehogs, BMPs, and Wnts) whose functions are still being defined, a growing set of growth factors implicated in select attractive guidance events, and members of the Ig superfamily that, beyond their roles as receptors for other guidance cues, are implicated in axon fasciculation repulsion. These guidance cues can function in long-range or short-range axon guidance. Many guidance cues are multifunctional and can particpate in attraction, in repulsion, or in regulating branch formation. Furthermore, many cues are conserved evolutionarily, both in structure and in function, between vertebrates and invertebrates. In addition to these molecules, yet other molecules appear to contribute to guidance; these include a range of extracellular matrix components, transmembrane phosphatases, and cadherins.

GUIDANCE CUES AND THE CONTROL OF CYTOSKELETAL DYNAMICS

Guidance cues are signaling molecules that influence the cell biological mechanisms by which growth cones extend, turn, and retract. The forward-crawling motion of a growth cone depends on its own intrinsic motile mechanism interacting with a permissive outside environment, often in the context of instructive guidance cues. The extension and withdrawal of the leading edge and filopodia are an intrinsic property of a healthy growth cone. Once the leading edge has extended, an appropriate substratum on which it can attach and become stabilized must be present. Once attached, an inherent traction-generating mechanism within the growth cone causes tension to develop. Unattached or poorly attached processes are withdrawn, whereas tension exerted against attached processes helps draw the body of the growth cone forward. The continuous repeated cycling of extension, attachment, retraction of poorly attached processes, and tension generation produces net forward extension. In principle, guidance cues could act at any one of these steps to affect the direction in which growth cones extend.

Actin Cycle, Microtubules, and Axon Growth

Within growth cones the distribution of actin and microtubules is dramatically segregated, with microtubules primarily occupying the axon shaft and the central domain of the growth cone, and actin residing in the peripheral domain (Fig. 16.9). One way in which guidance cues can affect the direction of growth cone advance is by controlling the actin polymerization that helps drive protrusion of the leading edge of the growth cone. A dense meshwork of fibrillar actin (F-actin) is concentrated at the leading edge of the growth cone. New actin polymerization just behind the leading edge effectively helps push it forward, while, on average, F-actin is simultaneously depolymerized at an equal rate more centrally.

A second important component of growth cone motility is a continuous rearward flow of polymerized actin away from the leading edge toward the central domain. This actin flow can be visualized in cultured growth cones with the aid of a drug that blocks actin polymerization (Forscher & Smith, 1988). Actin monomers generated by depolymerization in the body of the growth cone are recycled to the front, polymerized again at the leading edge, and swept rearward, where they are depolymerized once again. This continuous rearward flow of polymerized actin is called "treadmilling," and it results from the action of myosin-based motors driving F-actin toward the growth cone central domain (Lin, Espreafico, Mooseker, & Forscher, 1996) (Fig. 16.10A). In the absence of adhesive contacts with the substratum, a steady state arises whereby the actin polymerization–depolymerization cycle and treadmilling do not contribute to growth cone advance. If polymerized F-actin is linked to a permissive substratum through cell surface receptors, however, growth cone actin dynamics advance the leading edge and withdraw the trailing edge (Fig. 16.10B). Cell surface receptors that bind permissive substratum molecules must in turn be linked to the cellular cytoskeleton. Indirect linkages between the cytoskeleton and members of the integrin, cadherin, and immunoglobulin families give the cytoskeleton traction upon the substratum and facilitate growth cone advance (Fig. 16.11B). This traction can be modulated by several signaling events, including the phosphorylation of specific cytoplasmic proteins (Dent, Gupton, & Gertler, 2010).

The linkage of F-actin to the substratum generates tension within the growth cone and causes processes that are poorly attached to the substratum to shrink or withdraw. When the retrograde movement of actin is impeded by a relatively strong attachment between the actin cytoskeleton and the surface substratum, not only

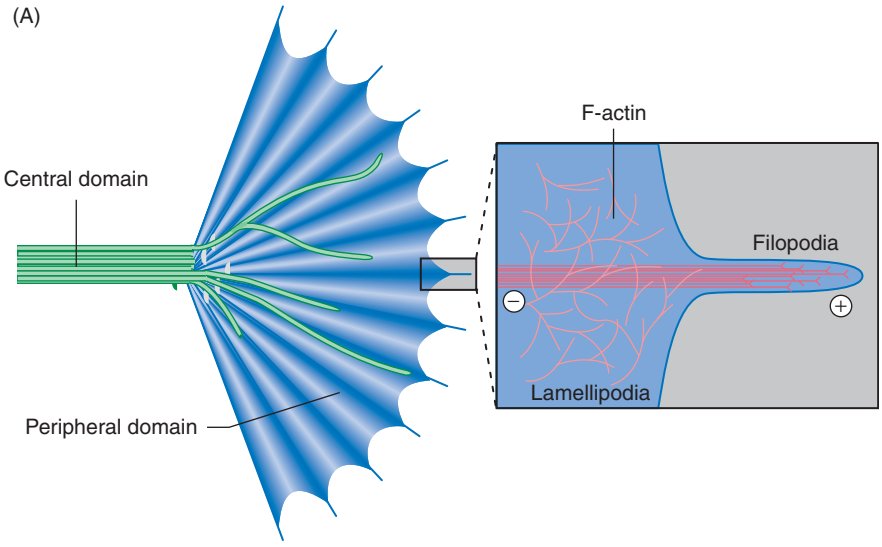

FIGURE 16.9 Distributions of microtubules and fibrillar actin in a neuronal growth cone. Microtubules and fibrillary actin are highly compartmentalized within growth cones. Microtubules (green) are a key structural component of the axon and though tightly bundled with the axon shaft, a dynamic subpopulation of microtubules actively explores the peripheral domain of the growth cone by extending along filopodia. All of the growing ends of microtubules are pointed toward the leading edge. In contrast, actin (red) is highly concentrated in the filopodia and in the leading edges of lamellae. Within filopodia, actin fibrils are oriented with their growing tips pointed distally. The same is true of many fibrils within lamellae, although many additional fibrils are oriented randomly and form a dense meshwork. *Modified from Lin, Thompson, and Forscher (1994).* (B) The organization of cytoplasmic domains and cytoskeletal components in an *Aplysia* bag cell growth cone. Fluorescent labeling of microtubules (green) and fibrillar actin (red) shows their segregation within the growth cone central and peripheral domains, respectively. Note the extension of a small number of microtubules into the actin-rich peripheral domain. *From Suter and Forscher (2000).*

is the leading edge of the growth cone advanced, but microtubules tend to be drawn forward. In the axon shaft and proximal region of the growth cone's central domain, microtubule polymers are bundled and relatively stable. However, toward the peripheral region a highly dynamic population of microtubule polymers extends individually toward the leading edge along filopodia. The strong attachment of individual filopodia to appropriate cellular targets induces additional localized actin accumulation in the contacting process, and these processes are preferentially invaded by dynamic microtubules. In this way filopodia act as scouts for less advanced portions of the growth cone: either seizing hold of permissive substrata or avoiding nonpermissive or inhibitory substrates, thereby reorienting subsequent process extension to define the location of the newly generated trailing axon shaft.

Particular representatives of several proteins families provide permissive substrata for growth cone extension. Among these are extracellular matrix (ECM) molecules such as laminin-1 and fibronectin, and also specialized cell surface molecules from the Ig superfamily and cadherin families. These molecules are bound by specific cell surface molecules on the growth cone, including

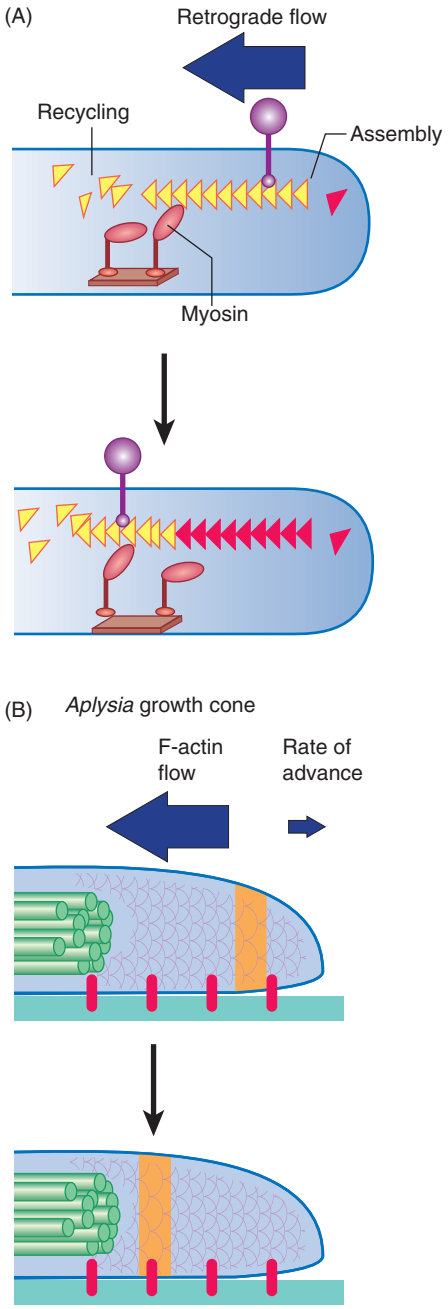

FIGURE 16.10 **Actin dynamics regulate growth cone advance.** (A) A schematic representation of a growth cone filopodium, depicting polarized assembly and disassembly of actin monomers at the distal (red triangles) and proximal (yellow triangles) ends of a fibrillar actin filament. Retrograde flow (large arrow) of fibrillar actin polymers occurs through the action of nonmuscle myosin. This can be visualized by the proximal translocation of a particle that is linked to the actin cytoskeleton (sphere), which fails to occur if myosin function is inhibited. *Modified from Lin et al. (1996).* (B) Linkage of the actin cytoskeleton to a permissive surface is required for forward advance. Actin polymerized at the leading edge of the growth cone (right) is swept toward the rear. If the actin meshwork is not linked to cell surface receptors that bind permissive molecules on adjacent cell surfaces, the actin cycles from front to rear but does not advance the growth cone. However, when the actin meshwork becomes attached to these receptors and thereby linked to the substrate, the meshwork remains in place and newly polymerized actin helps advance the leading edge. *Modified from Lin et al. (1994).*

members of the integrin, Ig, and cadherin superfamilies. While these proteins provide potent permissive substrates for cultured neurons, it is still unknown whether they or other classes of molecules are the major permissive factors for axon growth *in vivo*. At least two of the sets of "classic" guidance cues, the netrins and semaphorins, are known to include members that have a permissive role for axon growth *in vivo*. Interestingly, ECM components, including laminin-1 and select proteoglycans, can exert modulatory effects on classic guidance cue signaling, influencing the sign of the steering response (Höpker, Shewan, Tessier-Lavigne, Poo, & Holt, 1999; Kantor et al., 2004; Van Vactor, Wall, & Johnson, 2006).

Interactions Between the Cytoskeleton and Guidance Receptors

How do cues such as semaphorins, netrins, slits, and ephrins tap into these mechanisms for growth cone extension to affect guidance? Attractive and repulsive signals could promote the extension of the leading edge by increasing the local rate of actin polymerization in the preferred direction or by decreasing its rate of depolymerization in other directions. Guidance cues could also modulate the rate of myosin-mediated F-actin translocation, thereby stimulating or inhibiting filopodia and leading edge retraction. It is therefore reasonable to expect that many signaling pathways activated by guidance cues ultimately converge on actin dynamics. Studies on the receptor mechanisms for the guidance cues described above show that activation of these receptors often directly or indirectly alters the activity of small Rho family GTPases such as Rac and Rho, which are key regulators of actin dynamics and impact on cell motility in a large variety of cell types (Bashaw & Klein, 2010; Lalli & Hall, 2010). For example, the netrin receptor DCC activates Rac, whereas activation of certain semaphorin receptors results in activation of Rho through the action of an adaptor protein that associates with the cytoplasmic domain of Plexin receptors and stimulates the exchange of GDP for GTP on the Rho GTPase. Activation of both Eph and Robo receptors can also modulate Rho GTPases through the action of distinct adaptor proteins that associate with these receptors and either stimulate, or inactivate, Rho GTPases. In addition to modulating signaling cascades that regulate actin dynamics, guidance cue receptor activation can also directly regulate microtubule dynamics through activation of microtubule binding proteins that either promote or inhibit microtubule extension (Dent et al., 2010).

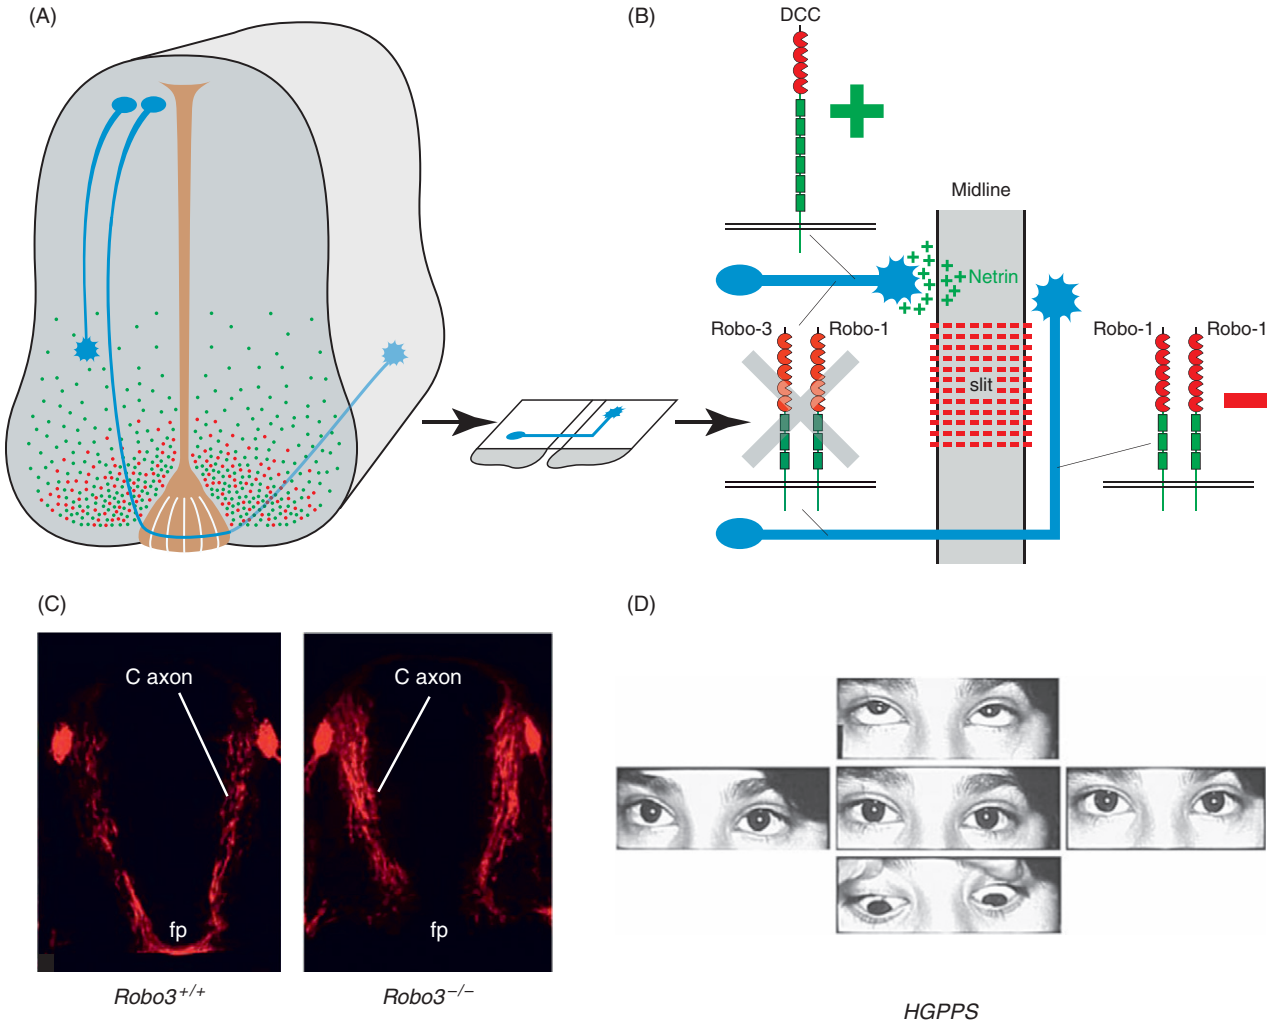

FIGURE 16.11 A switch from attraction to repulsion allows commissural axons to enter then leave the CNS midline. (A) Schematic of a cross section through the mammalian spinal cord (as in Figure 16.1), illustrating the trajectory of commissural axons from the dorsal spinal cord to, and across, the ventral midline. The axons cross the midline at the floor plate; upon exiting the floor plate, they make a sharp right-angle turn and project in a rostral (anterior) direction. A long-range gradient of Netrin-1 protein (green dots) and a shorter-range gradient of Slit protein (red dots) are shown. Right: Illustration of the "open-book" configuration, in which the spinal cord is opened at the dorsal midline and flattened, which helps to visualize the crossing and turning behavior of the axons at the midline. (B) As the axons project to the midline ("precrossing"), they are attracted by Netrin-1 acting on the attractive Netrin receptor DCC. They are insensitive to the repulsive action of Slit proteins despite expression of the repulsive Slit receptors (Robo1 and Robo2) because they also express Robo3, a Slit receptor that suppresses the activity of Robo-1 and Robo-2. This enables these axons to enter the midline upon reaching it. However, upon crossing the midline, commissural axons downregulate expression of Robo3 and increase expression of Robo1 and Robo2 (not shown), which allows them to sense the repulsive action of Slits and results in their expulsion from the midline. (C) In Robo3 mutant mice, the precrossing commissural axons are prematurely sensitive to Slits, which prevents them from entering the midline. Shown are cross sections through a normal E11.5 mouse embryo (left) and a stage-matched Robo3 mutant embryo (right), illustrating the inability of commissural axons in the mutant to cross the midline. *From Sabatier et al. (2004)*. (D) Human patients with Horizontal Gaze Palsy and Progressive Scoliosis (HGPPS) carry mutations in the human ROBO3 gene. They are capable of coordinated eye movements along the vertical axis (center), but not along the horizontal axis (left and right panels are attempts by this HGPPS patient to look left and right). The deficits in horizontal gaze result from a defect in neuronal connections across the midline in the hindbrain, which is presumed to arise from aberrant axon guidance during development, since a similar defect is observed in Robo3 mutant mice. *From Jen et al. (2004)*.

Summary

Growing axons utilize an intrinsic, actin-based treadmilling mechanism to extend filopodia and advance the leading edge of the growth cone. Growth cone extension requires an appropriate substratum for attachment and stabilization, which allows an inherent traction-generating mechanism within the growth cone to generate tension. This tension results in the withdrawal of poorly attached processes and the growth of processes that form attachments with the substratum. Net forward extension results from repeated cycles of extension, attachment, and the retraction of poorly attached processes. Cell surface

receptors that bind substratum molecules are linked indirectly to the cellular cytoskeleton, and these linkages can be modulated by the activation of signaling pathways. The binding of extracellular guidance cues to receptors on the growth cone surface modulates axon growth through several mechanisms, including regulation of actin polymerization, F-actin treadmilling, linkage between the growth cone cytoskeleton and the substrate, and modulation of microtubule dynamics. Many guidance receptors directly or indirectly modulate the activity of small Rho family GTPases, which are key regulators of actin polymerization.

GUIDANCE AT THE MIDLINE: CHANGING RESPONSES TO MULTIPLE CUES

How are guidance cues interpreted by growth cones *in vivo*, and how do they direct appropriate nervous system wiring? The guidance of an axon from its inception through its acquisition of a target is a complex process that can be broken down into a series of discrete decisions. Single guidance cues probably rarely, or never, act by themselves, and the integration of several simultaneously active cues is required for most, if not all, guidance decisions. This can be illustrated by interactions between the activities of many different guidance cues at the midline of the developing nervous systems in both invertebrates and vertebrates. These interactions have been elucidated through genetic, biochemical, and embryological studies in rodents, *Drosophila*, and *C. elegans*. Focusing on the mammalian spinal cord, we describe four important regulatory mechanisms that are required for reaching, crossing, and leaving the midline: initial attraction; switching on of repulsion; switching off of attraction; and prevention of premature repulsion. These mechanisms involve both classic guidance cues, illustrated in Figure 16.11, and morphogens, illustrated in Figure 16.12.

Initial Attraction

As mentioned earlier, in both vertebrates and invertebrates, the so-called commissural axons are attracted to the nervous system midline by members of the netrin family, which activate receptors of the DCC family (Kolodkin & Tessier-Lavigne, 2010; Tessier-Lavigne & Goodman, 1996). We also mentioned that netrins do not function alone in guiding commissural axons to the midline. In the mammalian spinal cord, the morphogen Sonic Hedgehog is also made by floor plate cells at the ventral midline and collaborates with netrin-1 to attract the axons to the midline (Fig. 16.12); recent work shows that the morphogen vascular endothelial growth factor A (VEGFA) serves a very similar function. In addition, BMP morphogens are made at the dorsal midline (by so-called "roof plate cells") and function as

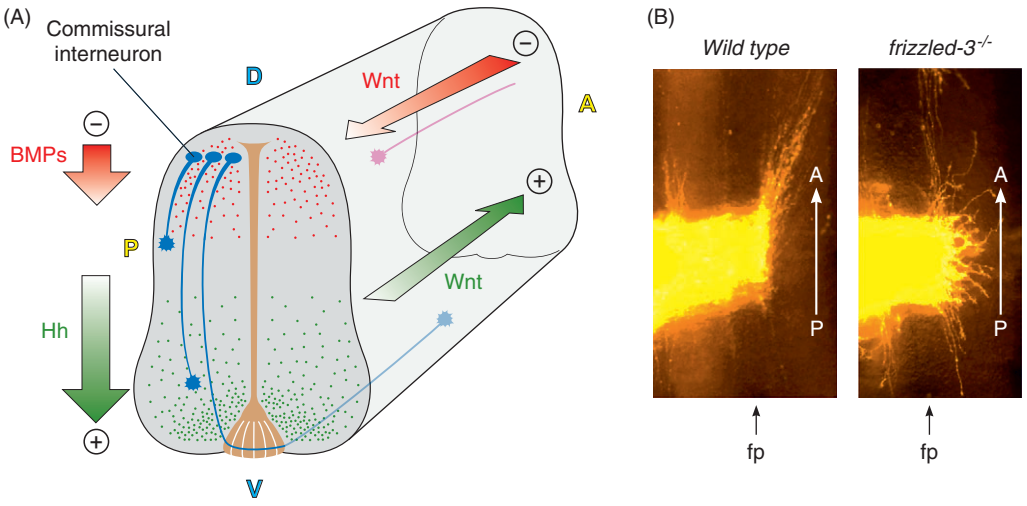

FIGURE 16.12 Morphogens help direct pre- and postcrossing commissural axon trajectories. (A) Diagram of the roles of morphogens in commissural axon guidance to the midline and beyond. BMP proteins made at the dorsal midline repel the axons from the dorsal spinal cord, providing a "push from behind," whereas Sonic Hedgehog (Shh) made by floor plate cells attracts the axons, providing a "pull from afar" in collaboration with Netrin-1 (see Fig. 16.11). After midline crossing, the axons turn in a rostral (anterior) direction in response to an attractive rostral-to-caudal decreasing gradient of Wnt protein. In contrast, cortical spinal tract (CST) axons extending caudally in the dorsal spinal cord are repelled by different Wnt family members. (B) The rostral Wnt signal is mediated by the Frizzled3 (Fz3) receptor. The trajectory of commissural axons at the midline is examined in the "open-book" configuration (Fig. 16.13A), with the axons visualized by labeling with the fluorescent dye DiI. In wild-type mice (left), commissural axons cross the midline, then turn rostrally (up), whereas in Frz3 knockout mice (right), the axons are disorganized after crossing (Lyuksyutova et al., 2009).

repellents for commissural axons, providing a "push from behind" to help set them out on their initial ventral trajectory. Thus, even over a relatively simply trajectory, multiple cues collaborate to ensure accurate guidance of axons.

Switching on Repulsion

The midline is not, however, the final destination for commissural axons: upon reaching it, axons cross the midline, then they turn at right angles and project alongside the midline to other levels of the embryo, and finally they leave the midline area altogether to reach their eventual targets (Fig. 16.11A). This behavior immediately raises a paradox: if the midline is such an attractive environment for the axons, how can they leave it? The answer is that midline cells, in addition to making attractive netrin proteins, also make repellents of the slit family (and, in vertebrates, of the semaphorin family) (Fig. 16.11A) (Kidd et al., 1999; Zou, Stoeckli, Chen, & Tessier-Lavigne, 2000). Axons can approach and then cross the midline a first time because they are initially insensitive to these repellents and thus respond only to netrin-mediated attraction. However, and quite remarkably, upon crossing the midline the axons become responsive to the repellents by increasing the expression or function of receptors for the repellents, including upregulating expression of the slit receptors of the Robo family on their surfaces (Fig. 16.11B) (Kidd et al., 1998; Zou et al., 2000). What causes this dramatic change in receptor expression and function is not yet known, but its net effect is to make the axons interpret the midline as a repulsive environment, which helps expel the axons from the midline and move on to the next leg of their trajectory.

Switching Off Attraction

The upregulation of responsiveness to midline repellents is only half of the equation, however: to be efficiently expelled from the midline, it would be desirable for the axons to stop being attracted. Indeed, the attractive response of these axons to netrins is switched off (silenced) as the axons cross the midline. There is evidence that the silencing of netrin attraction is caused by activation of the slit receptor Robo: activation of Robo by slit causes a specific region of its cytoplasmic domain to bind a specific region of the cytoplasmic domain of the netrin receptor DCC and to prevent it from transducing an attractive response to netrin (Stein & Tessier-Lavigne, 2001). Together, these two mechanisms (upregulation of a response to midline repellents and silencing of the attractive receptor) ensure that the growth cones perceive a once attractive environment, the midline, as unambiguously repulsive.

Preventing Premature Repulsion

For guidance at the midline to occur accurately, it is essential that the switch from attraction to repulsion be carefully choreographed. In particular, it is essential that growth cones upregulate responses to repellents only after crossing the midline, and not before, or the axons would not be able to enter the midline. It is perhaps not surprising, then, that there are mechanisms that ensure these axons do not become responsive to repellents too soon. One mechanism that regulates the switch, already mentioned, is that the Robo receptors are expressed only at low levels before crossing and are upregulated only after crossing. In *Drosophila*, this appears to involve regulated trafficking of the receptor to the neuronal cell surface under the control of a protein called Commissureless. However, the low level of Robo receptor that is present on the axons before crossing appears to be capable, nonetheless, of transducing a repulsive Slit signal that can prevent midline crossing and that must be silenced. In vertebrates, this is achieved by a more divergent member of the Robo family called Robo3 (also known as Rig1). Robo3 is expressed on commissural axons before and during crossing, and it silences the repulsive Slit signal mediated by other Robo receptors, allowing the axons to cross (Sabatier et al., 2004). Thus, in *Robo3* knockout mice, which lack Robo3 function, the axons can sense Slit repulsion before midline crossing. As a result, commissurals fail to cross the midline in these mutant mice, resulting in a dramatic "commissureless" phenotype (Fig. 16.11C).

Remarkably, a similar midline crossing defect is caused by mutations in the human *ROBO3* gene, found in patients with a syndrome known as "Horizontal Gaze Palsy with Progressive Scoliosis" (HGPPS) (Jen et al., 2004). These patients are unable to move their eyes in a coordinated fashion along the horizontal axis (horizontal conjugate gaze), a behavior that requires the function of commissural interneurons linking the two sides of the hindbrain (Fig. 16.11D). Imaging and evoked potential studies have shown that, as in *Robo3* knockout mice, there is a failure of midline crossing by axons in the hindbrains of these patients. Thus, the role of Robo3 proteins in allowing midline crossing is conserved in humans.

Guidance at the midline has also shed light on the mechanisms involved in longitudinal guidance (i.e., along the anterior-posterior axis). Upon crossing the midline, commissural axons turn either anteriorly or posteriorly; in particular, the earliest born commissural axons in the mammalian spinal cord turn in an anterior direction. This anterior turn appears to be directed by an anterior-to-posterior gradient of Wnt protein in the spinal cord, which the growth cones sense as an attractive cue (Fig. 16.12A) (Lyuksyutova et al., 2003). Transduction of the attractive Wnt signal involves a receptor called Frizzled 3 (Fz3), so that loss of Fr3 function in a

Fz3 knockout mouse causes the growth cones to become misrouted after midline crossing, unable as they are to sense the Wnt gradient (Fig. 16.12B). Anterior-posterior gradients of Wnt proteins provide a mechanism conserved between vertebrates and invertebrates to guide a variety of classes of axons along the longitudinal axis. Some axons, like the spinal commissural axons just described, respond to the Wnts with an attractive response and extend up the gradient. Others have repulsive responses and therefore grow downgradient. This has been shown for cortico-spinal tract axons, which navigate in the opposite direction to commissural axons (Fig. 16.12A) (Liu et al., 2005).

Summary

The study of the growth of commissural axons to and beyond the midline exemplifies how guidance of axons *in vivo* involves the simultaneous interpretation of multiple cues, including classic guidance cues and morphogens, and how dynamic changes in axon responsiveness enable axons to navigate successive intermediate targets. Before reaching the midline, commissural axons are guided through the combined actions of repellent BMPs, providing a "push from behind," and the attractive effects of netrin-1, Sonic Hedgehog, and VEGFA from the ventral midline. Just as important, these axons are insensitive to midline repellents, which allows them to enter and cross the midline; this is achieved in part by Robo3, expressed on the axons before crossing, which prevents them from sensing repellent midline Slits. Upon reaching the midline, the axons acquire responsiveness to repellent molecules, including Slits, through upregulation of repellent receptor function, including Robo receptors for midline Slits. They concomitantly *lose* responsiveness to the midline attractants. This coordinated switch from attraction to repulsion ensures that the axons can move on from the midline. Finally, the precise positioning of the axons in axon tracts after midline crossing involves a code of Robo proteins, and the anterior turn by commissural axons is directed by a Wnt gradient.

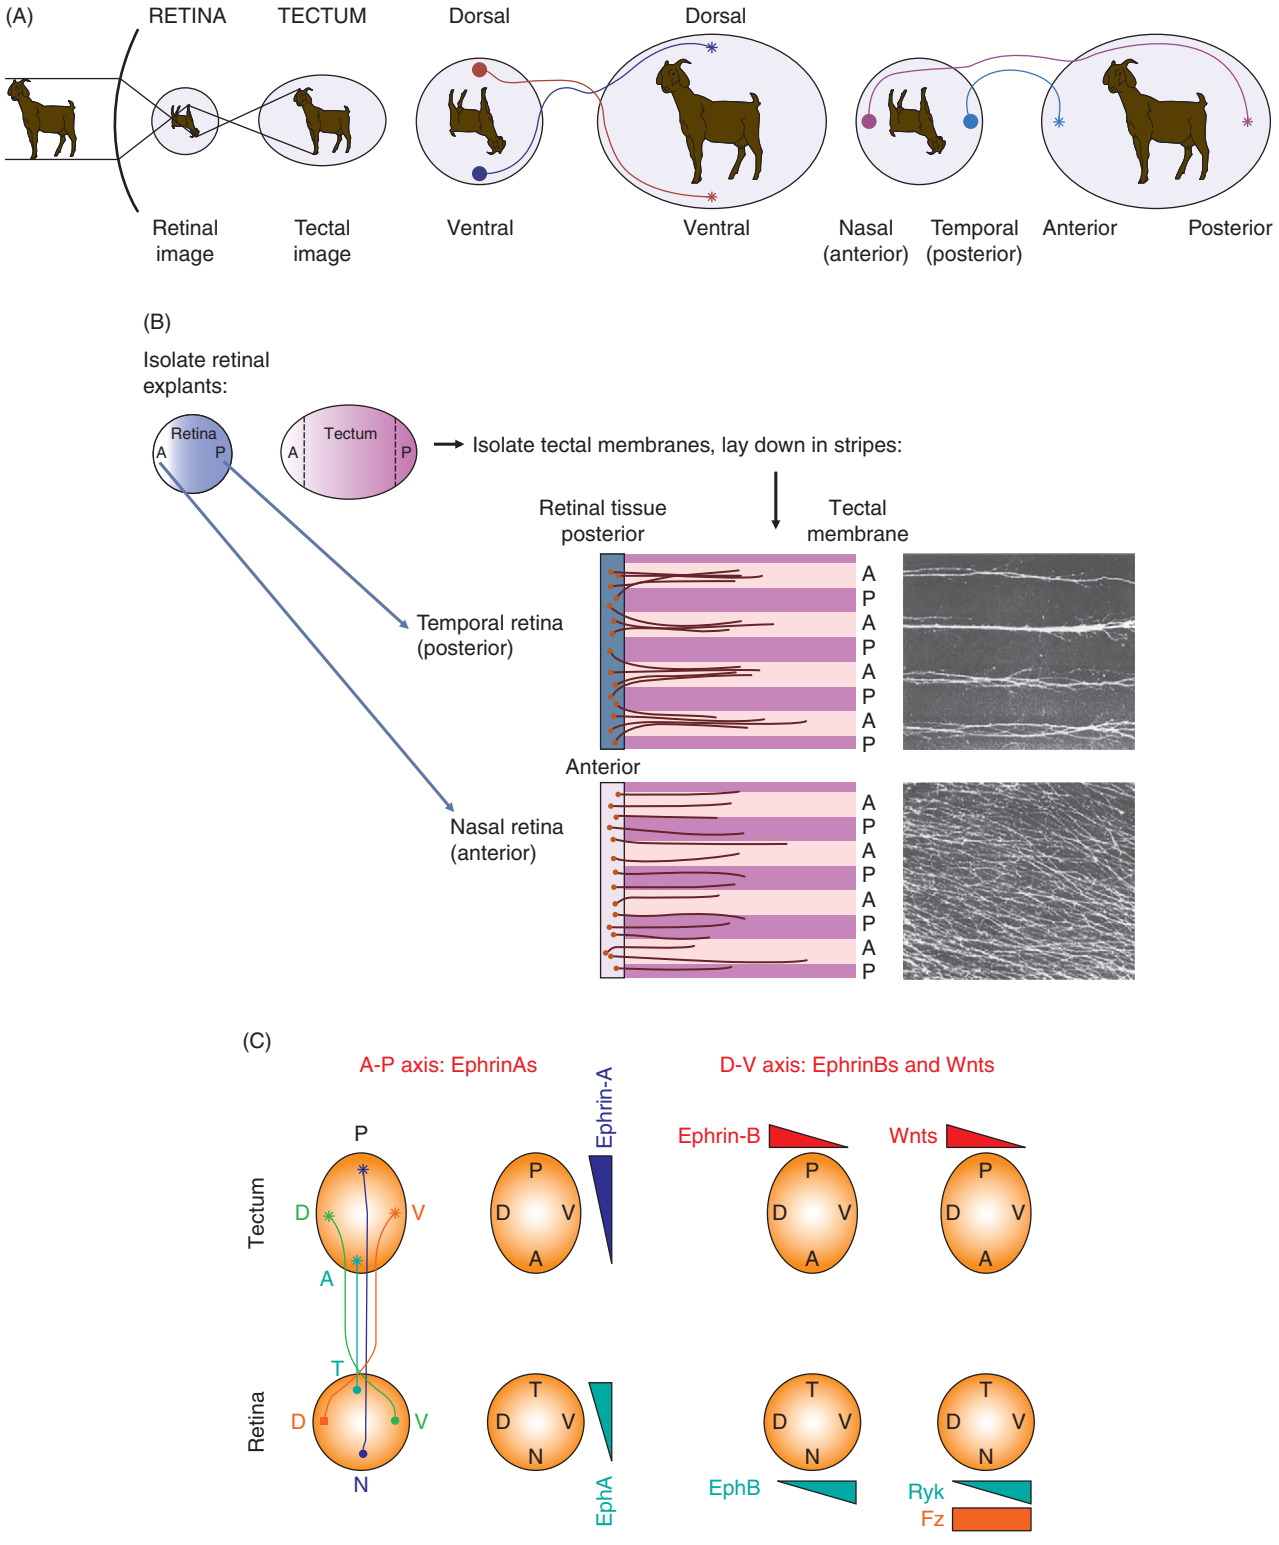
TOPOGRAPHIC MAPPING

So far, we have discussed the discrete trajectories of individual growth cones that navigate a succession of intermediate targets. We now close this chapter with a discussion of the mechanisms that contribute to the development of topographic projections.

In many parts of the nervous system, fields of neurons must project to their targets while maintaining their neighborhood—or "topographic"—relations. A classic example of this behavior is provided by the million or so retinal ganglion cells (RGCs), which are arranged in a two-dimensional sheet within the retina at the back of the eye, and which project to various subcortical targets including the superior colliculus or "optic tectum" in the midbrain. This "retinotectal" projection is topographic, as neighboring neurons in the retina project to neighboring neurons in the target field. It is also inverted along both the anterior-posterior (A-P) and the dorso-ventral (D-V) axes: for example, neurons in the anterior (nasal) retina project to the posterior tectum, while those in the anterior (temporal) retina project to the posterior tectum; similarly dorsal RGCs project to ventral tectum and vice-versa. In this way, the two-dimensional image of the visual world that is projected onto the retina is preserved, albeit inverted, on the tectum (Fig. 16.13A). Topographic projections occur throughout the nervous system and are particularly evident in ascending sensory and descending motor projections.

How do these topographic projections form? In the mid-twentieth century, Roger Sperry (1963) studied the regeneration of the retinotectal projection after optic nerve transection in some amphibians (which, unlike birds and mammals, can regenerate their retinal axons) and found that regenerating axons grow back to their appropriate topographic target regions in the tectum even when the system was perturbed in a variety of ways (e.g., when the eye was rotated in its socket, or part of the retina or tectum was deleted). Impressed with the apparent "hard-wiring" of these projections,

FIGURE 16.13 Topographic mapping of retinal projections in the visual system. (A). The projection of retinal ganglion cells (RGCs) to the optic tectum is topographic. A map of the visual world on the tectum or superior colliculus (left) is inverted with respect to that on the retina because axons from dorsal and ventral retina project to ventral and dorsal tectum, respectively (middle), and axons from anterior (nasal) and posterior (temporal) retina project to posterior and anterior tectum, respectively (right). *Adapted from Tessier-Lavigne (1995).* (B) An *in vitro* assay demonstrates topographically appropriate recognition of tectal membranes by some retinal axons. Small slivers of nasal and temporal retina (top left) are placed on carpets of membranes from tectal cells and allowed to grow. The carpets have alternating stripes of anterior and posterior tectal membranes. In these experiments, the posterior (temporal) retinal axons show an appropriate preference for growth on membranes derived from their correct target (anterior tectum) (Walter et al., 1987b). Other experiments showed that this is due to avoidance of a repellent activity, due to EphrinA ligands, that is enriched in posterior tectum. Note that in this experiment, anterior (nasal) axons do not show the expected preference for posterior tectal membranes, which represents a limitation of the assay; more refined assays are, however, able to demonstrate this. (C) A model for topographic mapping by gradients of guidance molecules and their receptors. Along the A-P axis, retinal neurons have a graded expression of EphA receptors, which enables them to interpret a decreasing posterior-to-anterior gradient of EphrinA ligands on the tectum to select their appropriate target on that axis. Mapping on the D-V axis, in contrast, involves gradients of EphrinB and Wnt ligands that are read by graded distributions of cognate receptors (EphB and Frizzled, respectively; Wnt ligands are also detected by Ryk, which has a nongraded distribution). *Adapted from Flanagan (2006).*



he postulated that a molecular code was likely used to match neurons in each retinal region to the appropriate target region in the tectum. He argued further that it would be difficult to achieve this matching using completely distinct molecular cues for each region, and that instead the guidance information was likely to be present in *gradients* of appropriate recognition molecules. Thus, he conceived that *"an orderly cytochemical mapping in terms of two or more gradients . . . would stamp each cell with its appropriate latitude and longitude expressed in a kind of*

chemical code with matching values between the retinal and tectal map."

In vitro experiments in the 1980s succeeded in demonstrating specificity in the interactions of neurons from particular regions of the retina with appropriate tectal cells, and, in later experiments, even with crude membrane preparations derived from these cells (Walter, Kern-Veits, Huf, Stolze, & Bonhoeffer, 1987a). In a particularly dramatic example, retinal axons were forced to grow on alternating "stripes" of membranes derived from anterior tectal cells and posterior tectal cells (Fig. 16.13B). Remarkably, axons derived from neurons in the temporal (posterior) retina chose to grow on membranes from anterior tectal cells—their appropriate target—rather than posterior tectal membranes (Fig. 16.13B). It was then found that posterior axons choose anterior membranes not because they are specifically attracted to those membranes, but rather because they avoid the posterior membranes, which were shown to contain an activity that is selectively repulsive to temporal axons (Walter, Henke-Fahle, & Bonhoeffer, 1987b). Biochemical analysis showed that the repulsive activity in posterior membranes was mediated by several members of the EphrinA subfamily of axon guidance molecules (introduced earlier in this chapter; Fig. 16.5A), which are present in an increasing anterior to posterior gradient along the tectum—a gradient of repulsion (Fig. 16.13C) (Cheng, Nakamoto, Bergemann, & Flanagan, 1995; Drescher et al., 1995).

These initial observations were eventually generalized to show that topographic mapping along the A-P axis involves recognition of an increasing EphrinA gradient along that axis in the tectum, with neurons at distinct positions along the A-P axis of the retina showing a preference for particular concentrations of EphrinAs by virtue of their graded expression of EphA receptors (Hansen, Dallal, & Flanagan, 2004). Interestingly, topographic mapping along the D-V axis also appears to involve gradients, but of different factors—specifically, countergradients of attractive EphrinBs and repulsive Wnts (Fig. 16.13C). Another interesting twist is that topographic projections can also be generated using other cellular strategies, such as the growth of all axons across a target field followed by the later pruning back of axons in a topographically appropriate manner, with the topographic pruning controlled by similar molecular gradients (e.g., of EphrinAs) (Feldheim & O'Leary, 2010).

Summary

Analysis of the retinotectal system has shown how spatial gradients of axon guidance molecules across a target field can be used to establish topographic projections. The specific cellular strategies can vary, with the recognition molecules either repelling or attracting, or triggering axon branching or pruning, but in all cases the maps are established as a result of neurons responding in a topographically appropriate manner to gradients of guidance cues.

CHAPTER

17

Synapse Formation

A fundamental issue in neurobiology is defining the mechanisms by which neurons form synapses with their targets. The development of appropriate synaptic connections requires a series of steps including the specification and generation of neurons and their target cells (Chapters 13, 14, and 15), the guidance of axons to their targets, the selection of appropriate targets, the formation of orderly and specific projections within the target (Chapter 16), and ultimately the induction of a specialized presynaptic terminal and postsynaptic membrane (this chapter). The first section of this chapter focuses on neuromuscular synapses that form between motor neurons and muscle cells in the peripheral nervous system. The second section summarizes current views of how neuron–neuron synapses in the central nervous system are assembled.

DEVELOPMENT OF THE NEUROMUSCULAR SYNAPSE

Once axons have arrived at their appropriate target destination, synapse formation ensues. Much of our understanding about the mechanisms of synapse formation arises from studies of the neuromuscular synapse. These studies have benefited from (1) the relative ease of experimentally manipulating developing and regenerating neuromuscular synapses *in vivo*, (2) cell culture systems for both motor neurons and skeletal muscle cells, (3) the *Torpedo* electric organ, an abundant and homogeneous source of neuromuscular-like synapses (Box 17.1), and (4) transgenic and mutant mice for studying and altering gene expression. Consequently, we have a good, although incomplete, understanding of the mechanisms that lead to the formation of the neuromuscular synapse.

The assembly of neuromuscular synapses is a multistep process. It requires coordinated interactions between motor neurons and muscle fibers, which eventually lead to the formation of a highly specialized postsynaptic membrane and a highly differentiated nerve terminal. As a consequence, acetylcholine receptors (AChRs) become highly concentrated in the postsynaptic membrane and arranged in perfect register with active zones in the presynaptic nerve terminal, ensuring fast, robust, and reliable synaptic transmission. Because neuromuscular synapses control all voluntary movement as well as respiration, the formation and function of this synapse are essential for survival. Disruption of this synapse, caused by axon withdrawal and motor neuron death, is responsible for amyotrophic lateral sclerosis (ALS). A large number of proteins contribute to the process of synapse formation, several of which play fundamental roles: (1) Agrin, a motor neuron-derived ligand essential to stabilize nascent synapses; (2) Lrp4, the receptor for Agrin; (3) MuSK, the receptor tyrosine kinase that transduces the Agrin signal; (4) Dok-7, an adaptor protein that is recruited to activated MuSK; and (5) Rapsyn, the AChR-associated protein that anchors AChRs at synapses. Defects in this signaling pathway, which lead to a reduced number of AChRs at synapses, are responsible for a variety of congenital neuromuscular disorders, termed congenital myasthenia, and autoantibodies to AChRs, Lrp4 or MuSK are responsible for myasthenia gravis. Here, we describe the structure of the neuromuscular synapse and the molecules and mechanisms responsible to assemble this structure.

Substructural Organization of the Neuromuscular Synapse

An adult myofiber, a syncitial cell containing hundreds to thousands of nuclei, is innervated by a single

BOX 17.1

TORPEDO ELECTRIC ORGAN

The majority of proteins known to be localized to neuromuscular synapses were first identified in postsynaptic membranes isolated from the electric organ of the marine ray *Torpedo*. Indeed, this specialized tissue has been essential for the identification and purification of AChR, AChE, Rapsyn, Syntrophin, Agrin, MuSK, and several synaptic vesicle proteins. The electric organ is a particularly homogeneous and abundant source of pre- and postsynaptic membranes that are similar in structure and function to those at neuromuscular synapses. The biochemical advantages of the electric organ are evident from its anatomy. The postsynaptic cell, which differentiates initially as a syncitial skeletal muscle fiber but subsequently loses its contractile machinery, is termed an electroplaque. Each electroplaque is a thin, elongated cell (1 cm × 1 cm × 10 μm) that is so densely innervated that nearly one-half of the electrocyte membrane is studded by nerve terminals. In contrast, nerve terminals occupy less than 0.1% of the cell surface of a skeletal myofiber. Because of this dense innervation and because the electric organ from a moderate size ray weighs several kilograms, it is possible to obtain several mg of purified postsynaptic proteins from a single electric organ.

Innervation is restricted to the ventral surface of the electroplaque, whereas the dorsal surface is enriched for the sodium/potassium ATPase that maintains the resting potential. Because the electroplaque lacks action potentials, activation of AChRs on the innervated ventral surface results in a voltage drop across the innervated but not the noninnervated membrane of the electrocyte. Since thousands of electroplaques are stacked closely one upon another, the potential difference across a single electrocyte is summated by the stack of electroplaques, resulting in a several thousand volt potential difference across the entire electric organ, a voltage that is sufficient to stun prey.

Steven J. Burden and Peter Scheiffele

motor axon that terminates and arborizes over approximately 0.1% of the muscle fiber's cell surface. The neurotransmitter receptor, AChR, is highly concentrated in this small patch of the muscle fiber membrane, and its precise localization to synaptic sites during development is a hallmark of the inductive events of synapse formation. Although other proteins are likewise concentrated at synaptic sites, much of our knowledge about synaptic differentiation has come from studies designed to understand how AChRs accumulate at synaptic sites.

Nerve terminals are situated in shallow depressions of the muscle cell membrane, which is invaginated further into deep and regular folds, termed postjunctional folds (Fig. 17.1). AChRs and additional proteins (see later) are localized to the crests of these postjunctional folds, whereas other proteins, including sodium channels, are enriched in the troughs of the postjunctional folds. The nerve terminal likewise is organized spatially, and its substructural organization reflects that of the postsynaptic membrane. Synaptic vesicles are sparse in the region of the nerve terminal underlying Schwann cells, which cover nerve terminals and myelinate motor axons, and abundant in the region of the nerve terminal facing the muscle fiber. Moreover, synaptic vesicles are clustered adjacent to a poorly characterized specialization of the presynaptic membrane, termed active zones, which are the sites of synaptic vesicle fusion. Active zones are organized at regular intervals and are aligned precisely with the mouths of the postjunctional folds. This precise registration of active zones and postjunctional folds ensures that acetylcholine encounters a high concentration of AChRs within microseconds after release, thereby facilitating synaptic transmission. The alignment of structural specializations in pre- and postsynaptic membranes, separated by a 500-Å synaptic cleft, suggests that spatially restricted signaling between pre- and postsynaptic cells is important to coordinate pre- and postsynaptic differentiation. The mechanisms that align active zones and postjunctional folds are not well understood, but $\alpha 3/\beta 2$ laminin, produced by the muscle and found in the synaptic basal lamina, binds calcium channels in nerve terminals, and this interaction has a role in anchoring active zones and coordinating pre- and postsynaptic differentiation (Nishimune, Sanes, & Carlson, 2004).

The precise organization of molecules in pre- and postsynaptic membranes belies the concept that the neuromuscular synapse is a simple synapse. Rather, the substructure of pre- and postsynaptic membranes, together with the faithful registration of pre- and postsynaptic specializations, suggests that complex mechanisms are required to assemble the synapse and to coordinate pre- and postsynaptic differentiation.

Muscle-Autonomous Patterning of AChR Expression

As motor axons extend toward developing muscle, muscle cells are themselves undergoing differentiation.

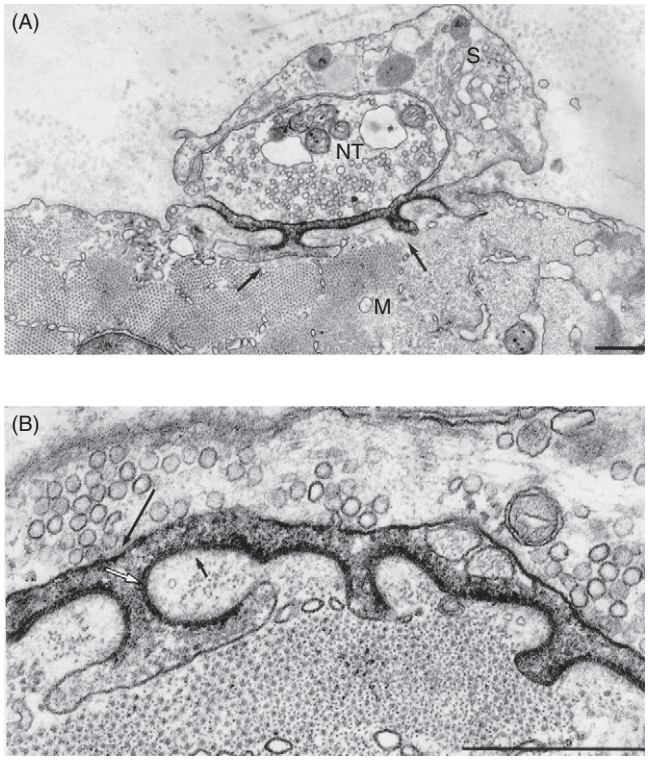

FIGURE 17.1 **Pre- and postsynaptic membranes at the neuromuscular synapse are highly specialized.** (A) An electron micrograph of a neuromuscular synapse shows that the nerve terminal is capped by a Schwann cell and is situated in a shallow depression of the muscle cell membrane, which is invaginated further into deep and regular folds, termed postjunctional folds (arrows). AChRs, labeled with α-bungarotoxin coupled to horseradish peroxidase, are concentrated at the synaptic site. (B) A higher magnification view shows that AChRs are concentrated at the crests and along the sides of the postjunctional folds (white arrow). Rapsyn, Neuregulin receptors, and MuSK are also concentrated in the postsynaptic membrane, whereas Agrin, Neuregulin-1, acetylcholinesterase, S-laminin, and certain isoforms of collagen are localized to the synaptic basal lamina. The postjunctional folds of the myofiber are spaced at regular intervals and are situated directly across from active zones and clusters of synaptic vesicles in the nerve terminal (arrows).

Myotubes, formed by fusion of precursor myoblasts, develop prior to innervation and continue to grow after innervation by further myoblast fusion. Because myoblasts fuse to developing myotubes at their growing ends, the central region of the muscle is more mature than the distal ends of the muscle. Recent studies have shown that the central region of muscle is regionally specialized prior to innervation. For example, AChRs are already clustered in the central region of the muscle prior to and independent of innervation (Flanagan-Steet, Fox, Meyer, & Sanes, 2005; Lin et al., 2001; Panzer, Song, Balice-Gordon, 2006; Yang et al., 2001; Yang, Li, Prescott, Burden, & Wang, 2000;). As such, motor axons approach muscles that are regionally specialized, or prepatterned, prior to innervation, in a manner that preconfigures the prospective zone of innervation (Fig. 17.2).

How the prospective synaptic region of the muscle becomes prepatterned is not well understood (see following), but muscle prepatterning restricts motor axon growth and promotes synapse formation in the central region of mammalian muscle (Kim & Burden, 2008).

The Synaptic Basal Lamina Contains Signals for Synaptic Differentiation

Following contact with the growth cone of a developing motor neuron, developing muscle fibers undergo a complex differentiation program in the synaptic region, which is dependent upon motor neuron–derived signals. In addition, signals from the muscle regulate differentiation of presynaptic nerve terminals. The idea that signals for regulating both presynaptic and postsynaptic differentiation are contained in the synaptic basal lamina arose from studies of regenerating neuromuscular synapses. Following damage to a motor axon, the distal portion of the motor axon degenerates, and the proximal end regenerates to muscle. The regenerated axon precisely reinnervates the original synaptic site and forms a synapse that is indistinguishable from the original synapse. Original synaptic sites are not thought to provide guidance cues to motor axons; rather, it is believed that the vacated perineural tubes, containing Schwann cells and their basal lamina, provide a favorable substrate for motor axons and have a role in directing regenerating motor axons to original synaptic sites (Son & Thompson, 1995). Although motor axons precisely reinnervate original synaptic sites, there appears to be little, if any, selectivity among motor neurons or among Schwann cells in ensuring accurate regeneration; indeed, both original and foreign motor neurons can accurately and functionally reinnervate original synaptic sites in denervated muscle.

Following damage to motor axons and muscle, nerve terminals and muscle fibers degenerate and are phagocytized, but the basal lamina of the muscle fiber remains intact. Even in the absence of nerve terminals and muscle fibers, several structures, including the terminal Schwann cells, the basal lamina of the postjunctional folds, and AChE, remain at the original synaptic site and allow for its identification.

Axons eventually regenerate into the muscle, and new myofibers regenerate within the basal lamina of the original myofiber. The regenerated motor axons form synapses with the regenerated myofibers precisely at the original synaptic sites. If axons regenerate into muscle, but muscle regeneration is prevented, axons still unerringly reinnervate the original synaptic site on the basal lamina, and active zones form in register with the basal lamina of the original postjunctional folds (Fig. 17.3) (Sanes, Marshall, & McMahan, 1978). Thus, the

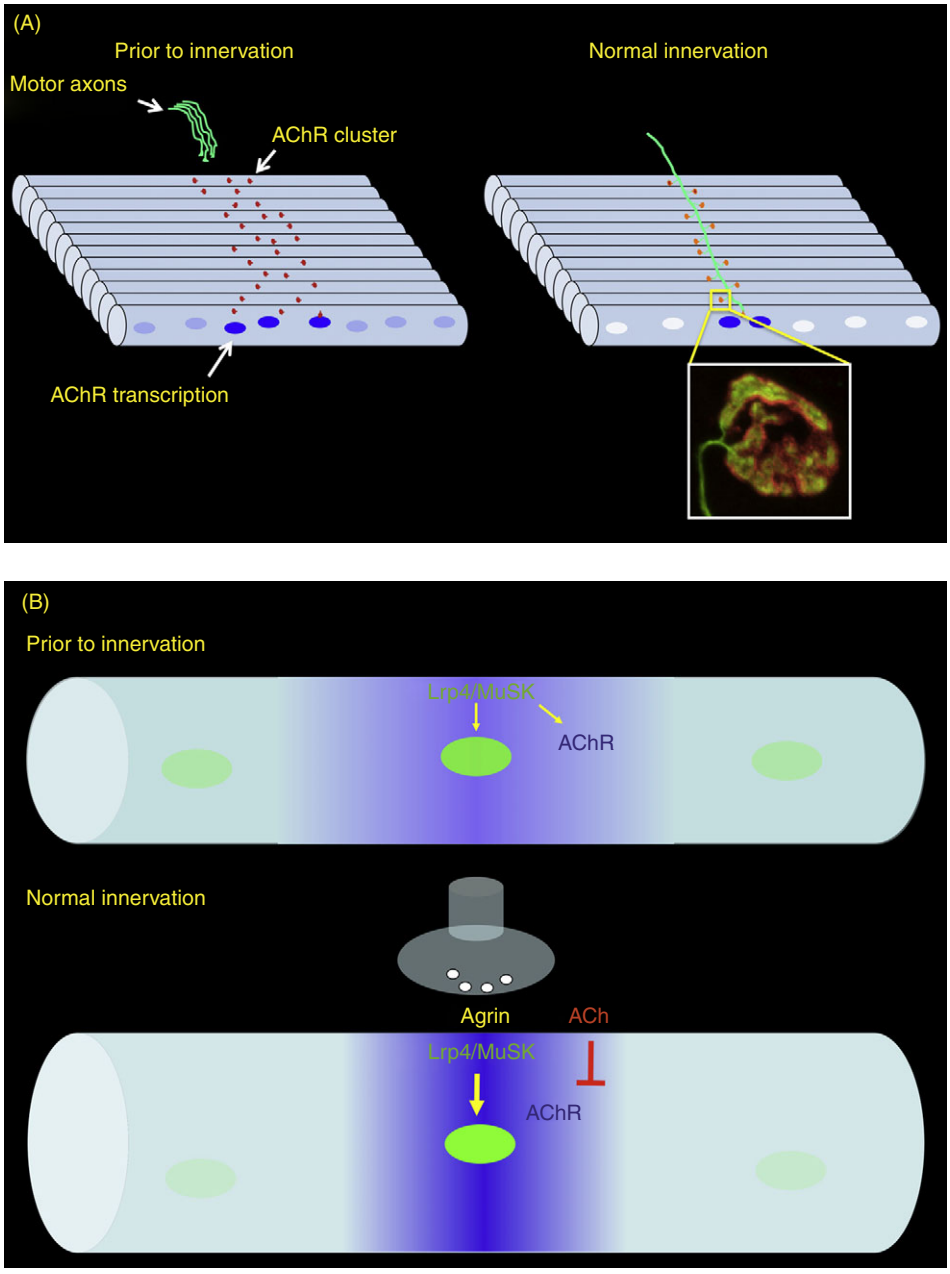

FIGURE 17.2 **Muscle prepatterning.** (A) Motor axons (green) approach muscles that are prepatterned, as *AChR* transcription (blue) and AChR clustering (red) are enhanced in the central, prospective synaptic region of muscle, prior to and independent of innervation. Motor axons terminate and form synapses (orange) in the prepatterned region. (B) Lrp4 and MuSK are required for prepatterning AChRs and are themselves expressed in the central region of muscle independent of innervation. The prepatterned zone of *AChR* expression becomes refined and sharpened following innervation, so that *AChR* expression and AChR clustering are restricted to nascent synaptic sites. Two neural signals refine AChR expression: Agrin/MuSK signaling stabilizes and stimulates AChR clustering, whereas acetylcholine (ACh) disperses AChR clusters. As a consequence of these two signals, AChR clusters are maintained only at nascent synaptic sites.

presence of the myofiber is necessary neither for precise reinnervation nor for the morphological differentiation of regenerated nerve terminals. The vacated perineurial tubes, containing Schwann cells and their basal lamina, may direct regenerating motor axons to original synaptic sites, but the induction of active zones suggests that cues in the synaptic basal lamina, possibly $\alpha 3/\beta 2$ laminin, have a role in organizing the presynaptic terminal.

If regeneration of motor axons is prevented, but myofibers are allowed to regenerate, AChRs accumulate and membrane folds form in the regenerated myofiber precisely at the original synaptic site on the basal lamina (Burden, Sargent, & McMahan, 1979). Thus, in the absence of nerve terminals, myofibers, and terminal Schwann cells, information remains at the original synaptic site and instructs both pre- and postsynaptic differentiation (Fig. 17.3). Because the synaptic basal lamina is the most prominent extracellular structure remaining at neuromuscular synapses following removal of all cells, these results indicate that the synaptic basal lamina contains signals that can induce differentiation of both nerve terminals and myofibers.

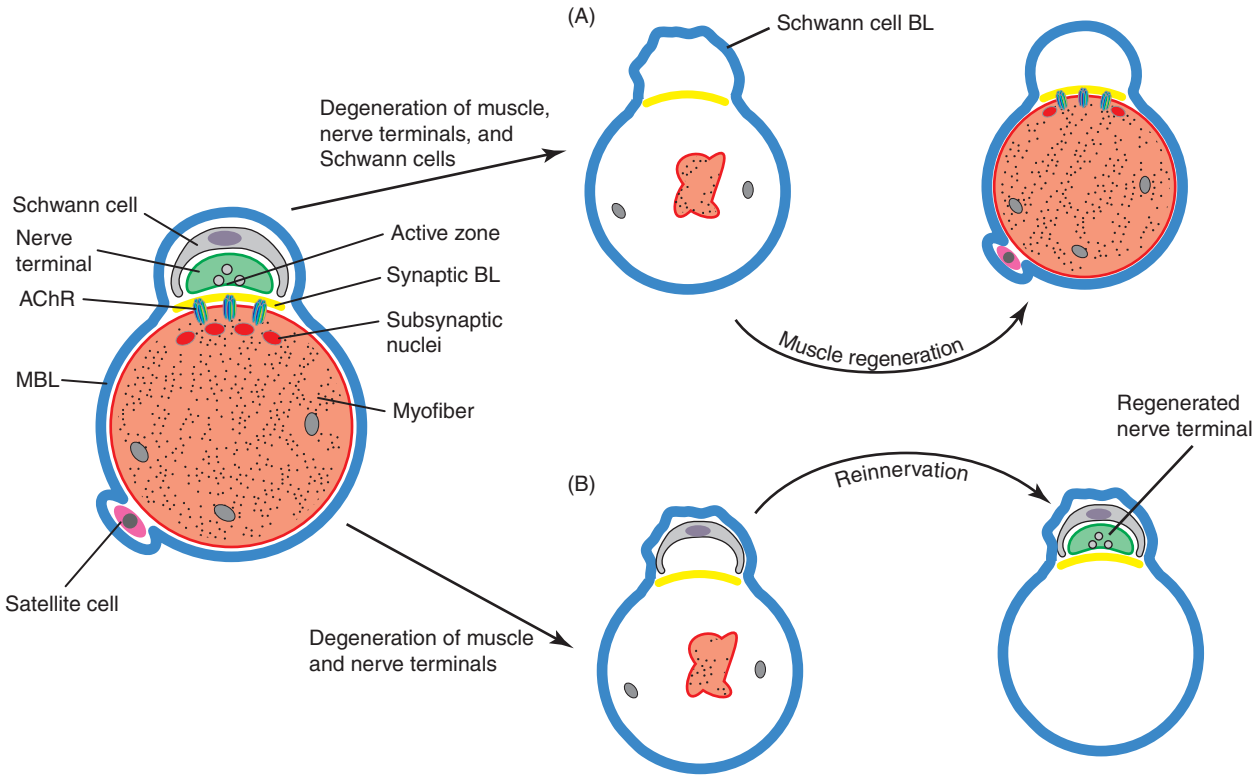

FIGURE 17.3 **The synaptic basal lamina contains signals for presynaptic and postsynaptic differentiation.** A cross section of normal muscle containing a nerve terminal, Schwann cell, and myofiber is shown at the far left. *AChR* genes are induced in synaptic nuclei (red) and AChRs (green) are concentrated at synaptic sites. Active zones and clusters of synaptic vesicles in the nerve terminal are aligned with postjunctional folds in the myofiber. Each myofiber is ensheathed by a basal lamina (MBL), which is specialized at the synaptic site (synaptic BL) and which remains intact following degeneration of the original myofiber. The MBL serves as a scaffold for regenerating myofibers, which form from the fusion of satellite cells that proliferate following damage to the original myofiber. (A) Experiments showing that the synaptic basal lamina contains signals for clustering AChRs and activating *AChR* genes in synaptic nuclei. Following damage and degeneration of axons, Schwann cells, and myofibers, new myofibers regenerate within the basal lamina of the original myofiber in the absence of the nerve. AChRs cluster and *AChR* gene expression is reinduced at original synaptic sites in myofibers that regenerate in the absence of the nerve and other original presynaptic cells. (B) Experiments showing that the synaptic basal lamina contains signals for inducing presynaptic differentiation. Following damage and degeneration of axons and myofibers, motor axons regenerate to original synaptic sites in the absence of the myofiber and accumulate synaptic vesicles precisely across from the sites of the original postjunctional folds.

Agrin is a Signal for Postsynaptic Differentiation

Because clustering of AChRs, unlike the formation of active zones, can be studied readily in cell culture, it has been far simpler to identify the basal lamina signals that induce postsynaptic rather than presynaptic differentiation. Extracellular matrix from the *Torpedo* electric organ, a tissue that is homologous to muscle but more densely innervated, contains an activity that stimulates AChR clustering in cultured myotubes (see Box 17.1). McMahan and colleagues purified the electric organ activity, which they termed Agrin, and showed that Agrin is synthesized by motor neurons, transported in motor axons to synaptic sites, and deposited in the synaptic basal lamina. Agrin also stimulates the clustering of other synaptic proteins, including AChE, Rapsyn, and Utrophin (see later), indicating that Agrin has a central role in synaptic differentiation.

Agrin is a ~200-kDa protein containing multiple epidermal growth factor (EGF)-like signaling domains, two different laminin-like domains, and multiple follistatin-like repeats. The four EGF-like domains and three laminin G domains are contained in the carboxyl-terminal region, which is sufficient for inducing AChR clusters in cultured myotubes; sequences in the amino-terminal region are responsible for the association of Agrin with the extracellular matrix.

The *agrin* gene is expressed in a variety of cell types. Alternative splicing results in multiple Agrin isoforms that differ in their AChR clustering efficiency. The isoform that is most active in clustering AChRs is expressed in neurons, including motor neurons, whereas other Agrin isoforms are expressed in additional cell types, including skeletal muscle cells. The active, neuronal-specific isoforms of Agrin contain 8, 11, or 19 amino acids at a splice site, referred to as the Z site in rat Agrin and the B site in chick Agrin. The *agrin*

gene contains multiple promoters. Although the promoter used in motor neurons leads to expression of isoforms that are associated with the extracellular matrix, the promoter used in the CNS leads to expression of membrane-bound isoforms (Burgess, Skarnes, & Sanes, 2000).

In mice lacking Agrin, AChRs are initially prepatterned, and synapses appear to form, but only transiently (Lin et al., 2001; Misgeld, Kummer, Lichtman, & Sanes, 2005). Over the course of several days, the AChR prepattern is dispersed, synapses are lost, and motor axons begin to grow throughout the muscle. Thus, Agrin is necessary to stabilize the AChR prepattern and nascent synapses. Because the AChR prepattern is stable in the absence of innervation but dispersed by motor axons lacking Agrin, neural signals, other than Agrin, extinguish the AChR prepattern (Lin et al., 2001; Yang et al., 2001). Genetic evidence indicates that acetylcholine is a key neural signal that disperses AChR clusters (Lin et al., 2005; Misgeld et al., 2005). Thus, during normal development, Agrin counteracts acetylcholine-mediated dispersion, thereby stabilizing AChR clusters selectively at nascent synapses (see following).

MuSK and Lrp4 Are Required for Agrin-Mediated Signaling and Synapse Formation

The mechanisms of Agrin-mediated AChR clustering are poorly understood, but a receptor tyrosine kinase, termed MuSK, is a critical component of an Agrin receptor complex. MuSK is expressed in *Torpedo* electric organ and in skeletal muscle, where it is concentrated in the postsynaptic membrane (Jennings, Dyer, & Burden, 1993; Valenzuela et al., 1995). Mice deficient in MuSK (DeChiara et al., 1996), like *agrin* mutant mice, lack normal neuromuscular synapses. Both *agrin* and *MuSK* mutant mice are immobile, cannot breathe, and die at birth. Muscle differentiation is normal in *agrin* and *MuSK* mutant mice, but muscle fibers in *MuSK* mutant mice lack all known features of postsynaptic differentiation. Moreover, unlike *agrin* mutant mice, the AChR prepattern is absent from *MuSK* mutant mice at all stages, indicating that MuSK is essential not only for synapse formation but also to establish muscle prepatterning. Muscle-derived proteins, including AChRs and AChE, which are concentrated at synapses in normal mice, are distributed uniformly in *MuSK* mutant myofibers (Fig. 17.4). In addition, *AChR* genes, which are transcribed selectively in synaptic nuclei of normal muscle fibers (see later), are transcribed at similar rates in synaptic and nonsynaptic nuclei of muscle fibers from *MuSK* mutant mice.

Multiple lines of evidence indicate that MuSK is required for Agrin-mediated signaling and is a component of an Agrin receptor complex (Glass et al., 1996): (1) Agrin can be chemically cross-linked to MuSK in cultured myotubes; (2) Agrin induces rapid tyrosine phosphorylation

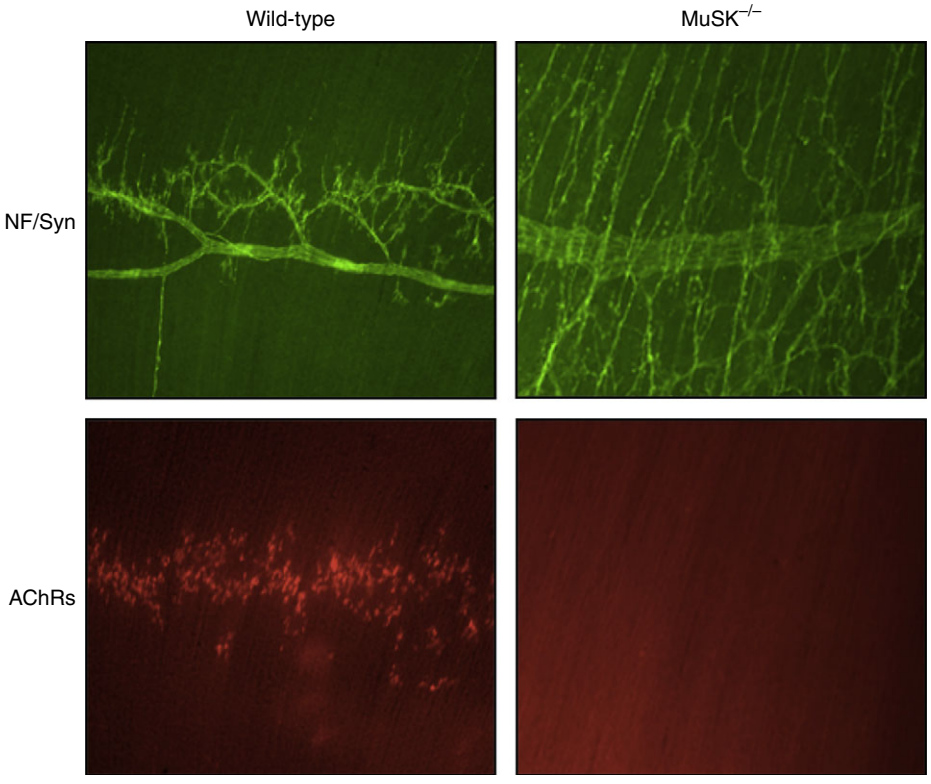

FIGURE 17.4 **Presynaptic and postsynaptic differentiation are defective in mice lacking MuSK.** Whole mounts of muscle from wild-type and *MuSK* mutant mice were stained with antibodies to neurofilament (NF) and synaptophysin (Syn) to label motor axons and nerve terminals (green), respectively, and with α-bungarotoxin to label acetylcholine receptors (AChRs) (red). In *MuSK* mutant mice, motor axons fail to stop and differentiate adjacent to the main intramuscular nerve and instead wander aimlessly over the muscle; AChRs, as well as other postsynaptic proteins, are expressed at normal levels but they fail to cluster.

of MuSK in cultured myotubes; (3) a recombinant, soluble extracellular fragment of MuSK inhibits Agrin-induced AChR clustering in cultured muscle cells; (4) cultured *MuSK* mutant muscle cells, unlike normal muscle cells, do not cluster AChRs in response to Agrin; and (5) dominant-negative forms of MuSK inhibit Agrin-induced AChR clustering in cultured myotubes. MuSK itself, however, does not bind Agrin (Glass et al., 1996).

Instead, the muscle receptor for Agrin is the low-density lipoprotein receptor-related protein 4 (Lrp4) (Kim et al., 2008; Zhang et al., 2008). Neural Agrin binds Lrp4, which stimulates association between Lrp4 and MuSK and increases MuSK kinase activity (Kim et al., 2008; Zhang et al., 2008). Only neural forms of Agrin bind Lrp4, providing an explanation for the selective activation of MuSK by neural isoforms of Agrin (Kim et al., 2008). Because Lrp4 self associates, independent of Agrin, Agrin may increase MuSK kinase activity by stimulating recruitment of MuSK to a preformed oligomer of Lrp4, thereby facilitating MuSK trans-phosphorylation. Lrp4 is essential for synapse formation, and the synaptic defects in *lrp4* mutant mice appear identical to those in *MuSK* mutant mice (Weatherbee, Anderson, & Niswander, 2006).

Interestingly, a pair of proteins with homology to MuSK and Lrp4 are required for clustering AChRs at *C. elegans* neuromuscular synapses: CAM-1, a receptor tyrosine kinase that shares homology with MuSK, and LEV-10, a transmembrane protein that contains an LDLa domain and forms a complex with two secreted proteins, LEV-9 and OIG-4, as well as AChRs (Francis et al., 2005; Gally, Eimer, Richmond, & Bessereau, 2004; Rapti, Richmond, & Bessereau, 2011). However, the kinase activity of CAM-1 is dispensable for synaptic differentiation, pointing to a different mechanism of action than MuSK at vertebrate neuromuscular synapses.

Glutamate, rather than ACh, is the neurotransmitter at *Drosophila* neuromuscular synapses. As such, perhaps it is not surprising that a different class of signals regulate differentiation of these synapses. Although little is known about the initial formation of synapses during embryogenesis in *Drosophila*, two ligands, Wingless and TGF-β, unrelated to Agrin, are involved in the growth of *Drosophila* neuromuscular synapses during larval development. Wingless is secreted by motor neurons and thought to activate Frizzled-2, a Wingless receptor expressed in muscle (Packard et al., 2002), whereas Glass bottom boat, a ligand from the TGF-β family, is synthesized by muscle and thought to activate Wishful thinking, a type II receptor, in motor neurons (Aberle et al., 2002). These signaling mechanisms participate in the regulation of bouton growth and size, which adapt to changes in synaptic activity.

Downstream of MuSK

How does MuSK activation lead to postsynaptic differentiation at vertebrate neuromuscular synapses? Agrin binds Lrp4 and stimulates the rapid phosphorylation of MuSK. The kinase activity of MuSK is essential for Agrin to stimulate clustering and tyrosine phosphorylation of AChRs. Signaling downstream from MuSK depends on phosphorylation of a tyrosine residue (Y553) in the juxtamembrane region of MuSK (Herbst, Avetisova, & Burden, 2002). Phosphorylation of this tyrosine leads to recruitment of Dok-7 (Okada et al., 2006), an adapter protein that further stimulates MuSK and becomes tyrosine phosphorylated (Bergamin, Hallock, Burden, & Hubbard, 2010). Mice lacking Dok-7 have defects identical to *MuSK* mutant mice (Okada et al., 2006), and mutations in human Dok-7 are a major cause of congenital myasthenia (Beeson et al., 2006). Tyrosine phosphorylated Dok-7 recruits Crk and Crk-L, two related adapter proteins that engage additional but unknown downstream signaling pathways essential for synapse formation (Hallock et al., 2010). Rac and Rho, small GTP-binding proteins that regulate actin organization, are activated by Agrin and required for Agrin to stimulate AChR clustering (Weston, Yee, Hod, & Prices, 2000; Weston et al., 2003). Rac acts early and is important for the formation of AChR microclusters, whereas Rho is activated more slowly and is important for the consolidation of microclusters into larger AChR clusters. Moreover, at least one kinase acts downstream from MuSK and is recruited and/or activated by Agrin-activated MuSK, as staurosporine, a protein kinase inhibitor, inhibits Agrin-induced AChR tyrosine phosphorylation and clustering without blocking tyrosine phosphorylation of MuSK. Figure 17.5 illustrates the fundamental signaling components required for forming neuromuscular synapses.

Synapses gradually mature after their initial formation and become fully mature and stable nearly one month after birth in mice. The mechanisms involved in this transition are not well understood, but may involved additional signaling molecules, such as Neuregulin and ErbB receptors, as well as Src-family kinases and cytoskeletal components, such as dystrobrevin (Grady et al., 2000; Smith, Mittaud, Prescott, Fuhrer, & Burden, 2001).

Muscle-Autonomous and Neural-Dependent Patterning of AChR Expression

The preceding sections have described the role of muscle prepatterning and motor neuron-derived signals in regulating the distribution of AChR expression. An initial, spatially restricted pattern of AChR expression is generated in muscle independent of neurally derived Agrin, or indeed of any other neural signal (Fig. 17.2). The mechanisms that are intrinsic to muscle and responsible for establishing

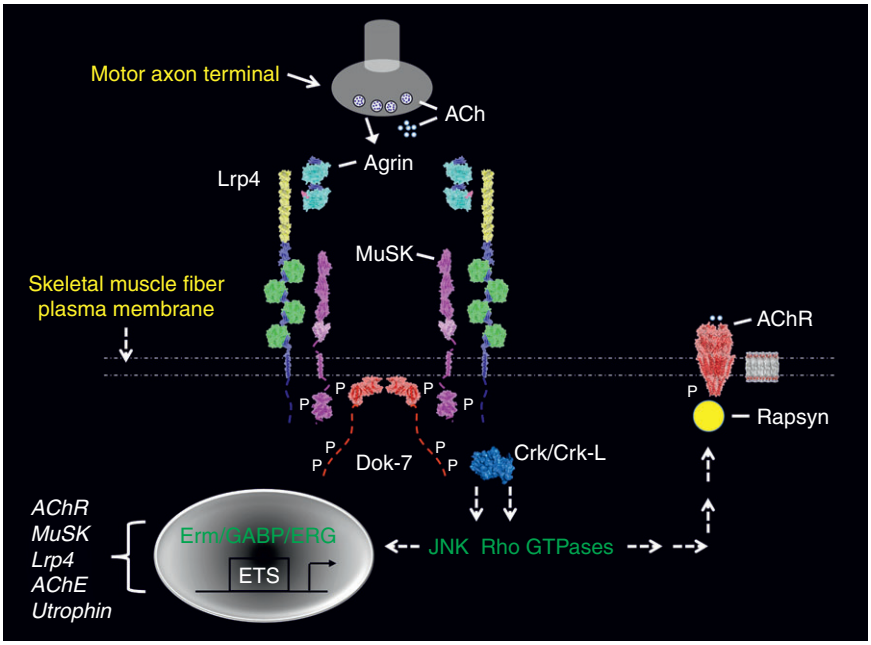

FIGURE 17.5 **Signaling mechanisms for neuromuscular synapse formation.** Agrin, released from motor axon terminals, binds Lrp4, stimulating association between Lrp4 and MuSK and increasing MuSK kinase activity. Phosphorylation of MuSK Y553, in the MuSK juxtamembrane region, causes recruitment and tyrosine phosphorylation of Dok-7, which further stimulates MuSK and recruits Crk and Crk-L adapter proteins to the MuSK/Dok-7 signaling complex. Rac and Rho GTPases function downstream of MuSK/Dok-7/Crk/Crk-L to anchor AChRs at synapses by a poorly understood process that requires Rapsyn, which binds directly to AChRs. The pathway for synapse-specific transcription is less well understood but likely involves JNK-dependent activation of Ets-family transcription factors that stimulate expression of multiple genes encoding synaptic proteins. Synaptic vesicles fuse with the plasma membrane of the nerve terminal, releasing acetylcholine (ACh), which binds to AChRs and causes a conformational change that increases the permeability of the channel to small cations and depolarizes the muscle.

regional differences in muscle in the absence of innervation are not well understood but appear to depend upon the pattern of muscle growth and positive feedback loops that sustain MuSK activation (Kim & Burden, 2008). Because this prepattern is not observed in mice lacking Lrp4, MuSK, or Dok-7, the emergence of this muscle AChR prepattern, nonetheless, coopts some of the same molecules used later during normal synaptogenesis. Additional molecules, however, may be dedicated for prepatterning; for example, zebrafish Wnt11R can function as an alternative direct ligand for MuSK and is important for prepatterning but not synapse formation in zebrafish (Jing, Lefebvre, Gordon, Granato, 2009). Whether Wnts have a role in prepatterning mammalian muscle is not known.

The prepatterned region specifies where motor axons will form synapses. Some synapses form on prepatterned AChR clusters, which become stabilized by Agrin, whereas Agrin also induces new AChR clusters (Flanagan-Steet et al., 2005; Panzer et al., 2006). Thus, the final cohort of synapses on the muscle fiber includes those recognized by motor axons and those induced by motor axons (Arber, Burden, & Harris, 2002; Kummer, Misgeld, & Sanes, 2006) (Fig. 17.2).

Arrival of the nerve, and its attendant signals, converts the AChR prepattern into the more refined pattern of AChR transcription and AChR clustering characteristic of mature synapses. This conversion appears to be dependent on two separable nerve-dependent programs: one program utilizes neurally derived Agrin to maintain AChR expression at nascent synaptic sites, and a second program, which appears to be triggered by acetylcholine, extinguishes AChR clustering at sites that are not stabilized by Agrin/MuSK signaling (Fig. 17.2). These two programs thus ensure the stable expression of AChR clusters selectively at nascent synapses.

Rapsyn is Required for Postsynaptic Differentiation Downstream of Agrin and MuSK

A 43-kDa protein, termed Rapsyn, has an important role in Agrin-mediated signaling. Rapsyn is a myristolated, peripheral membrane protein that is present at 1:1 stoichiometry with AChRs at synaptic sites and interacts directly with AChRs. In addition, Rapsyn links AChRs to components of a subsynaptic, cytoskeletal complex, including Dystroglycan and Dystrophin, Utrophin, Syntrophin, Dystrobrevin, and α-actinin.

Agrin stimulates the clustering of Rapsyn in myotubes grown in cell culture, and clustering of Rapsyn and AChRs occurs coincidentally at developing synapses. Rapsyn is critical for synapse formation, since mice

lacking Rapsyn die within hours after birth and have difficulty moving and breathing (Gautam et al., 1995). Mutations in human Rapsyn are a cause of congenital myasthenia with defects in AChR clustering that lead to muscle weakness (Engel, Ohno, & Sine, 2003). Although the mechanisms by which Rapsyn regulates the clustering of synaptic proteins are poorly understood, the clustering of most synaptic proteins, including AChRs, Utrophin, and Dystroglycan, depends upon Rapsyn. Nonetheless, MuSK is clustered at synapses in *rapsyn* mutant mice, raising the possibility that engagement with Agrin/Lrp4 is sufficient to stabilize MuSK at *rapsyn* mutant synapses. Synapse-specific gene expression (see following) is also normal in *rapsyn* mutant mice, indicating that Rapsyn acts downstream from MuSK to anchor postsynaptic proteins but not in the synapse-specific transcription pathway.

Agrin and MuSK Are Required for Retrograde Signaling and Presynaptic Differentiation

Although pathfinding of motor axons to muscle is normal in mice lacking Agrin or MuSK, *agrin* and *MuSK* mutant mice lack normal nerve terminals. In the mutant mice, branches of the main intramuscular nerve fail to arrest their growth and instead wander aimlessly across the muscle (Fig. 17.4). Because MuSK is expressed in skeletal muscle and not in motor neurons, it seems likely that the aberrant behavior of presynaptic terminals in *MuSK* mutant mice is due to indirect actions of the Agrin/MuSK signaling system. Indeed, restoring MuSK expression selectively in muscle of *MuSK* mutant mice rescues synapse formation and neonatal lethality (Herbst et al., 2002). These results indicate that Agrin, released from nerve terminals, causes the muscle cell, via MuSK activation, to reciprocally provide a recognition signal back to the nerve to indicate that a functional contact has occurred. In response to this putative muscle-derived recognition or adhesion signal, the nerve undergoes presynaptic differentiation and stops growing. Unlike our knowledge of the signals and mechanisms that control postsynaptic differentiation, unraveling the mechanisms that control the differentiation of motor nerve terminals has proved far more challenging and remains one of the glaring gaps in our understanding of neuromuscular synapses. Several muscle-derived signals regulate distinct aspects of presynaptic differentiation: FGFs of the 7/10/22 subfamily, laminin $\beta 2$, collagen IV, and SIRP-α stimulate clustering of synaptic vesicles in cultured motor neurons. Genetic studies support the idea that these signals participate in synaptic differentiation, since neuromuscular synapses do not fully mature in mice that are mutant for FGFR2, laminin $\beta 2$, or collagen IV alpha subunits (Fox et al., 2007). Nonetheless, motor axons terminate and differentiate to a considerable extent in the absence of these signaling components, indicating that additional, yet to be identified retrograde organizers regulate earlier steps in presynaptic differentiation.

Certain Genes Are Expressed Selectively in Synaptic Nuclei of Myofibers

Like AChR protein, mRNAs encoding the different AChR subunits (α, β, γ or ε and δ) are concentrated at synaptic sites. Studies with transgenic mice that harbor gene fusions between regulatory regions of *AChR* subunit genes and reporter genes have shown that *AChR* genes are transcribed selectively in myofiber nuclei near the synaptic site (Fig. 17.6). Thus, localized transcription of *AChR* genes in synaptic nuclei is responsible, at least in part, for the accumulation of *AChR* mRNA at synaptic sites. This pathway is important for ensuring that AChRs are expressed at the required density in the postsynaptic membrane, since defects in synapse-specific gene expression of the *AChR* ε subunit gene are a cause for congenital myasthenia (see later).

Like *AChR* subunit genes, the *utrophin* gene is transcribed selectively in synaptic nuclei, resulting in an accumulation of *utrophin* mRNA and protein at synaptic sites. mRNAs encoding Rapsyn, NCAM, MuSK, sodium channels, the catalytic subunit of AChE, LL5beta, and CD24 are also concentrated in the synaptic region of skeletal myofibers, raising the possibility that these genes are likewise transcribed preferentially in synaptic nuclei (Fig. 17.5).

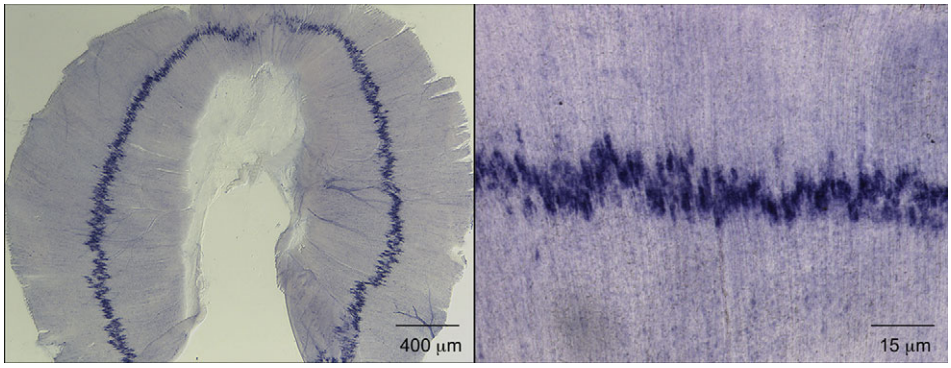

FIGURE 17.6 *Acetylcholine receptor* (*AChR*) genes are expressed selectively by myofiber synaptic nuclei, leading to enrichment of *AChR* mRNA in the central, synaptic region of the muscle. A whole mount of a mouse diaphragm muscle was processed for *in situ* hybridization to reveal the pattern of *AChR* δ mRNA expression. *AChR* δ mRNA expression is concentrated in a narrow band in the central, synaptic region of the muscle.

Thus, synapse-specific transcription may be a common and important mechanism for expressing and localizing a variety of gene products at high levels at the neuromuscular synapse.

The neural signals that regulate synapse-specific transcription remain elusive. Neuregulin-1, which stimulates tyrosine phosphorylation of ErbB2, a member of the EGF receptor family, stimulates *AChR* gene expression in cultured muscle cells, but neuromuscular synapses form normally during development in mice lacking ErbBs in skeletal muscle, as well as in mice lacking Neuregulin-1 in motor neurons and skeletal muscle (Escher et al., 2005; Jaworski & Burden, 2006). Synapse-specific transcription *in vivo*, however, requires Agrin, Lrp4, and MuSK, indicating that this signaling pathway has a critical role in regulating synaptic gene expression.

Ets Domain Transcription Factors Regulate Synapse-Specific Transcription

A binding site for Ets domain proteins in the *AChR* delta subunit gene is critical for synapse-specific gene expression in mice. Importantly, mutation of an Ets-binding site in the human *AChR* ε subunit gene leads to congenital myasthenia, due to decreased AChR expression. This Ets site can bind GABP, a complex containing GABPα, an Ets protein, and GABPβ, a protein that lacks an Ets domain but dimerizes with GABPα, suggesting that GABP may be a transcriptional regulator that stimulates transcription of *AChR* genes in synaptic nuclei (Fig. 17.5). In addition, the gene encoding another Ets domain protein, Erm, is expressed selectively by myofiber synaptic nuclei (Hippenmeyer et al., 2002), suggesting that Erm may also have a role in synapse-specific expression. Genetic analysis of *GABP* and *erm* mutant mice indicates that Erm has a critical role, whereas GABP has a more subsidiary role in synapse-specific transcription.

Electrical Activity Regulates Gene Expression

Changes in the pattern of muscle electrical activity have an important role in regulating the electrophysiological and structural properties of muscle, as well as the ability of motor axons to innervate muscle. The expression of several genes, including *AChR* genes, is repressed by electrical activity, and this repression, together with focal activation in synaptic nuclei, as described earlier, contributes to the disparate levels of *AChR* expression in synaptic and nonsynaptic regions of the muscle. A binding site for myogenic bHLH transcription factors, or E box, in the proximal promoter of *AChR* subunit genes is essential for electrical activity-dependent transcription, since transgenes containing a mutation in this E box, unlike wild-type transgenes, are not induced following denervation. These results suggest that electrical activity decreases the level and/or activity of E box binding proteins, notably Myogenin, leading to decreased *AChR* expression. The transcriptional mechanisms that control expression of *myogenin* in an activity-dependent manner are just beginning to be explored. Electrical activity induces expression of two transcriptional repressors, HDAC-9 (aka MITR) and Dach2, which act to repress *myogenin* expression (Mejat et al., 2005; Tang and Goldman 2006). A reduction in myofiber electrical activity leads to a reduction in *HDAC-9* and *Dach2* expression, causing an elevation in *myogenin* expression. Thus, the mechanisms that couple changes in electrical activity to changes in *HDAC-9* and *Dach2* expression are critical for regulating genes, such as *AChR* genes, which are dependent upon Myogenin. The mechanisms that regulate *HDAC-9* and *Dach2* expression are not understood, but the involvement of multiple protein kinases, including PKA, CAM kinase II, and PKC, has been suggested.

Summary

Signals exchanged at developing synapses ensure that differentiated presynaptic terminals are aligned precisely with a highly specialized postsynaptic membrane. Analysis of mice lacking innervation demonstrates that a coarse pattern of postsynaptic differentiation is present prior to innervation and that neuronal signals, including Agrin, both maintain and induce postsynaptic differentiation at sites of nerve–muscle contact (Fig. 17.2). We are gaining a better understanding of the pathways that act downstream from MuSK to control postsynaptic differentiation (Fig. 17.5), but we remain poorly informed about the signals and pathways that control presynaptic differentiation.

SYNAPSE FORMATION IN THE CENTRAL NERVOUS SYSTEM

Compared to synapse formation between neurons and muscle cells (at the neuromuscular synapse), we currently know relatively little about how neuron-to-neuron synapses in the central nervous system are put together. The reason for this relative lack of knowledge is the complexity of the problem. CNS synapses are much smaller (about one-hundredth the size of a neuromuscular synapse), a single neuron typically receives hundreds to thousands of synapses, and the synaptic inputs are derived from multiple different synaptic partners. Finally, these synapses employ not just one type but a variety of neurotransmitters. Some of these neurotransmitters are excitatory and depolarize the postsynaptic partner, and some are inhibitory and lead to hyperpolarization. The placement of excitatory and inhibitory synapses on the

postsynaptic cell is a critical parameter for integration of these counteracting inputs. Synaptic connectivity in the CNS is not static but undergoes extensive plastic changes. In response to experience, synaptic connections and the function of neuronal circuits are modified. All of these CNS synapse properties pose intriguing questions regarding the synthesis of synaptic components, their targeting and assembly at functionally distinct synaptic sites, and the recognition of the appropriate synaptic partners amongst an array of candidate partners.

Despite these differences between peripheral and CNS synapses, there are several common principles that apply to both systems: (1) Like neuromuscular synapses, CNS synapses are tri-partite structures. Highly specialized presynaptic release sites are closely apposed to postsynaptic specializations that concentrate neurotransmitter receptors (Fig. 17.7). This pair of synaptic partners is lined by astroglial processes that ensheath the synaptic cleft. (2) Cells contain most synaptic proteins before synapse formation and bidirectional signaling organizes these components at emerging synaptic contacts. (3) Synapses undergo extensive functional maturation. (4) During development, an exuberant number of synaptic contacts are formed, some of which later undergo elimination.

The following section focuses on the formation of CNS synapses in vertebrates. Much research has been on glutamatergic synapses—excitatory synapses using the neurotransmitter glutamate that are the most abundant in the CNS. We will also highlight important insights gained in the analysis of synapses using other neurotransmitters. We will start by discussing the time-course of *morphological rearrangements* of synapse formation and then examine emerging evidence on the mechanisms controlling *recruitment and assembly* of pre- and postsynaptic components. Finally, we will describe some candidate signals that may contribute to the *selectivity* of synaptic wiring during development.

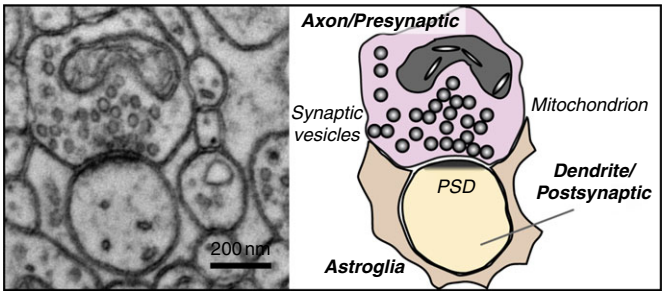

FIGURE 17.7 **Synapses are tripartite junctions.** The electron micrograph shows a parallel fiber synapse in the mouse cerebellum, an example of a glutamatergic synapse. The presynaptic terminal contains a mitochondrion and clusters of synaptic vesicles throughout the terminal. A few vesicles are morphologically docked at the active zone opposite the postsynaptic density. The postsynaptic side is a dendritic spine that in the cross section appears like a circular structure. The electron-dense material opposite the vesicle release sites is the postsynaptic density (PSD). Synaptic cleft and dendritic spine are closely ensheathed by an astroglia process (image courtesy of Stéphane Baudouin).

Initiation of Axon-Target Interaction

Prior to synapse formation, neurons already express both pre- and postsynaptic proteins. For example, growing axons and growth cones contain synaptic vesicles and release neurotransmitter. Similarly, target cells (that will later become the postsynaptic side) express functional neurotransmitter receptors on their surface. Cell–cell contact then is essential for the concentration and juxtaposition of pre- and postsynaptic components in opposing membranes and for achieving the mature complement of both pre- and postsynaptic proteins.

Many initial contacts between synaptic partners are established through filopodia, tiny actin-based extensions that rapidly protrude and retract from a cell. Importantly, filopodia extend from both axons and dendrites and increase the extracellular space sampled by a cell during development. Imaging studies, both in culture and *in vivo*, indicate that when filopodia contact potential synaptic partners, they can lose their motility and become stabilized. These contacts are then thought to transform into synaptic structures. Indeed, synaptic specializations have been seen on filopodia themselves, and neurotransmitter release from axons is likely to play an important role for the regulation of filopodial dynamics.

A further important realization from imaging studies has been that the assembly of synaptic structures occurs rapidly. The time required from initial contact to establishment of a functional synapse is only in the range of 1–2 hours, with the formation of a presynaptic terminal occurring in only 10–20 minutes and the recruitment of postsynaptic neurotransmitter receptors taking place in approximately 90 minutes after cell–cell contact (Garner, Zhai, Gundelfinger, & Ziv, 2002). How is the entire machinery for regulated vesicular release recruited within such a short time frame? This timecourse is plausible if one considers that most synaptic components are "ready-to-go" before contact and primarily need to be redistributed (rather than newly synthesized). Still, the speed of synaptic assembly is remarkable. One intriguing model poses that presynaptic components are recruited in preassembled units (Fig. 17.8). Synaptic vesicles move in axons before synapse formation in grape-like clusters. Similarly, multiple active zone components such as voltage-gated calcium channels and syntaxin can be found prepackaged in so-called "piccolo-bassoon transport vesicles" (PTVs) (Garner et al., 2002). PTVs are vesicles named after the presynaptic active zone proteins piccolo and bassoon that are closely associated with these carriers that appear as 80-nm-diameter dense core vesicles in electron microscopy. PTVs could be rapidly

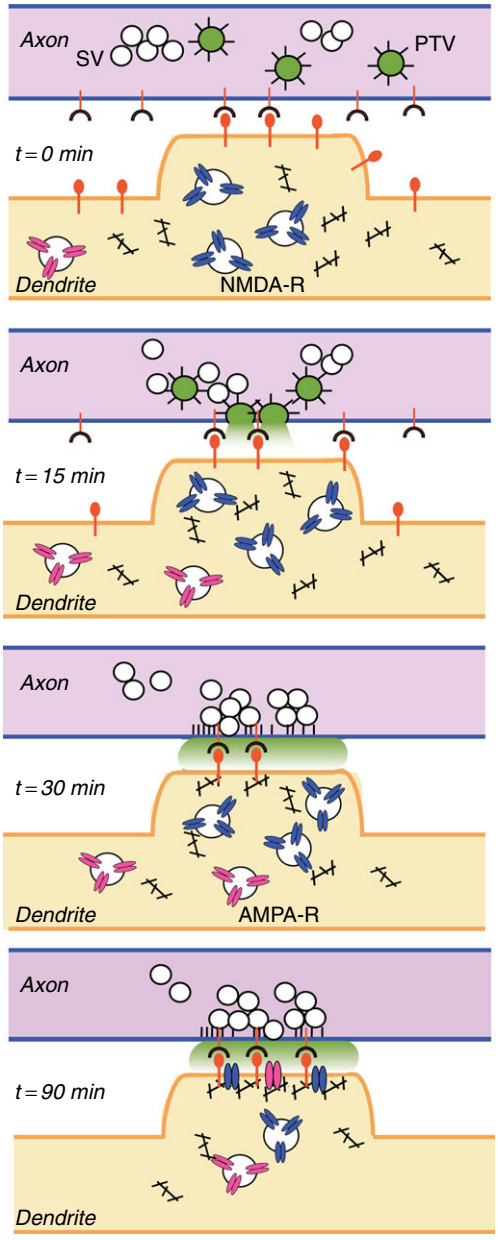

FIGURE 17.8 **Hypothetical model for the assembly of central synapses.** Before synapses formation, axons and dendrites contain synaptic vesicles (SV), active zone components, and neurotransmitter receptors, respectively. Cell–cell contact is initiated via cell surface adhesion and/or signaling molecules (red, $t = 0$ min). Contact triggers fusion of piccolo-bassoon transport vesicles (PTV, green) with the plasma membrane ($t = 15$ min), which leads to the deposition of active zone material (black spikes). Subsequently, synaptic vesicles (clear circles) are recruited to the cell–cell contact sites ($t = 30$ min), and postsynaptic scaffolding molecules (black), NMDA-type (blue), and AMPA-type neurotransmitter receptors (red) are delivered sequentially to the maturing postsynaptic membrane. *Adapted from Garner et al. (2002).*

captured and inserted in response to a target-derived signal, thereby greatly simplifying the process of presynaptic assembly (Fig. 17.8). Subsequently, neurotransmitter receptors are recruited to the postsynaptic domain. Excitatory synapses using the transmitter glutamate contain the ionotropic NMDA- and AMPA-type receptors (see Chapter 9). After cell–cell contact, NMDA- and AMPA-receptors are recruited to synapses in a stepwise manner, with an initial accumulation of NMDA receptors at postsynaptic sites and the subsequent addition of AMPA receptors (Fig. 17.8). Candidate signals for the neurotransmitter receptor accumulation at synapses and for the stabilization of filopodial contacts between pre- and postsynaptic partners are discussed next.

Molecular Signals for Synaptic Development in the CNS

What are the signals that mediate the morphological and functional differentiation of pre- and postsynaptic structures? It turns out that several transsynaptic signals "singlehandedly" induce a substantial degree of synaptic organization. Based on this ability to drive synapse assembly, these signals have been termed "synapse-organizing" or "synaptogenic" factors. Synaptogenic proteins are employed in multiple ways to drive synapse organization: First, target cells (the future postsynaptic partner) secrete growth factors that instruct presynaptic differentiation in axons. We refer to these signals as *retrograde* organizers of synapses. Second, axons (the future presynaptic partner) release signals that drive the postsynaptic accumulation of neurotransmitter receptors, much like Agrin at the neuromuscular junction. These signals are referred to as *anterograde* organizers. Third, several adhesion and signaling complexes bridge the synaptic cleft and simultaneously recruit pre- and postsynaptic components; consequently, these are considered *bidirectional* organizers of synapses. Finally, synaptic astroglia also contribute signals that promote formation and maturation of central synapses. Examples for each of these four different classes of synapse-organizing mechanisms are discussed following.

Morphogens as Retrograde Signals for Synaptic Organization

Morphogens are secreted growth factors that direct cell fate decisions during embryonic development. Components of many morphogen signaling cascades continue to be expressed in the postnatal brain, indicating that they may govern additional developmental processes after the completion of cell fate specification. For example, Wnts and fibroblast growth factors (FGFs) exhibit important, previously unanticipated signaling functions in axon guidance and synapse formation—essentially being "recycled" for morphogenetic programs in a different developmental context during postnatal development.

At CNS synapses, Wnts and FGFs both act as retrograde signals. This means they are released from synaptic target cells and promote presynaptic differentiation

in afferents. Synaptic signaling functions were first discovered in the mouse cerebellum for Wnt7a, a vertebrate homologue of the *Drosophila melanogaster* wingless gene (Fig. 17.9). Wnt7a is released from cerebellar granule cells and promotes synaptic vesicle accumulation in mossy fiber axons, a class of afferent projections derived from the brainstem and the spinal cord (Hall, Lucas, & Salinas, 2000). Presynaptic vesicle recruitment in response to Wnt7a is most likely regulated through local modification of microtubule branching and remodeling. Wnt7a signaling is mediated through the axonal receptor frizzled, a receptor that also plays a central role in Wnt signaling during early development. Frizzled acts through the signaling adapter disheveled-1 (Dvl-1) and the cytoplasmic serine/threonine kinase GSK3beta. In turn, GSK3beta regulates microtubule-associated proteins (MAP1B and adenoma polyposis complex, APC) by phosphorylation to shape a specialized microtubule network in growth cones and axonal branches.

Fibroblast growth factors comprise a large family of secreted growth factors expressed in neuronal and nonneuronal cells. The closely related isoforms FGF22, FGF7, and FGF10 are target-derived signals that contribute to presynaptic development (Umemori, Linhoff, Ornitz, & Sanes, 2004). In the absence of FGF-signaling presynaptic vesicle accumulation in axons is reduced. Notably, neither Wnts nor FGFs organize the assembly of active zones, indicating that they preferentially promote the expansion of the presynaptic vesicle pools. FGF signaling is mediated through an axonal FGF receptor complex, a receptor tyrosine kinase that couples to the PI3-kinase and Ras-MAP-kinase pathway. Similar to Wnt7a, FGFs alter cytoskeletal properties and promote axonal branching. These morphological rearrangements shape the presynaptic partner and facilitate the recruitment of appropriate organelles in response to additional transsynaptic synaptogenic signals.

Transsynaptic Adhesion Complexes as Bidirectional Synapse Organizers

Adhesion molecules are central organizers of specialized cellular junctions in all tissues. Importantly, several proteins with adhesive properties have emerged as regulators with synaptogenic activity (Fig. 17.9). One class of these factors are the neuroligins, postsynaptic adhesion molecules that can bind to neurexins, a family of receptors present on axons (Sudhof, 2008). Neuroligin-neurexin interactions mediate heterophilic adhesion across the synaptic cleft, thereby directly connecting the pre- and postsynaptic compartments. Heterologous expression of neuroligin in nonneuronal cells induces focal accumulations of neurexins and synaptic vesicle proteins in contacting axons (Scheiffele, Fan, Choih, Fetter, & Serafini, 2000). The neuroligin-induced presynaptic structures are capable of vesicle exo- and endocytosis upon depolarization, indicating that not only synaptic vesicles but the entire machinery for regulated exocytosis is recruited to these nascent presynaptic terminals. Interestingly, neurexins also serve as a synaptic receptor for another postsynaptic adhesion molecule called LRRTM2 (leucine-rich repeat protein 2). LRRTM2 drives presynaptic differentiation through direct interaction with axonal neurexins, therefore, providing an alternate neurexin ligand to neuroligins (de Wit et al., 2009). The neuroligin-neurexin and LRRTM2-neurexin transsynaptic complexes are part of a growing list of proteins with synaptogenic functions. One additional notable example is the postsynaptic receptor TrkC (Takahashi et al., 2011). TrkC is a well-known receptor for neurotrophins that regulates neuronal survival (see Chapter 19). Surprisingly, at synapses TrkC engages in adhesive interactions with presynaptic receptor protein tyrosine phosphatases (RPTPs). These interactions promote recruitment of synaptic vesicles to presynaptic sites and the maturation of the postsynaptic structures. Notably, the synaptogenic function of TrkC

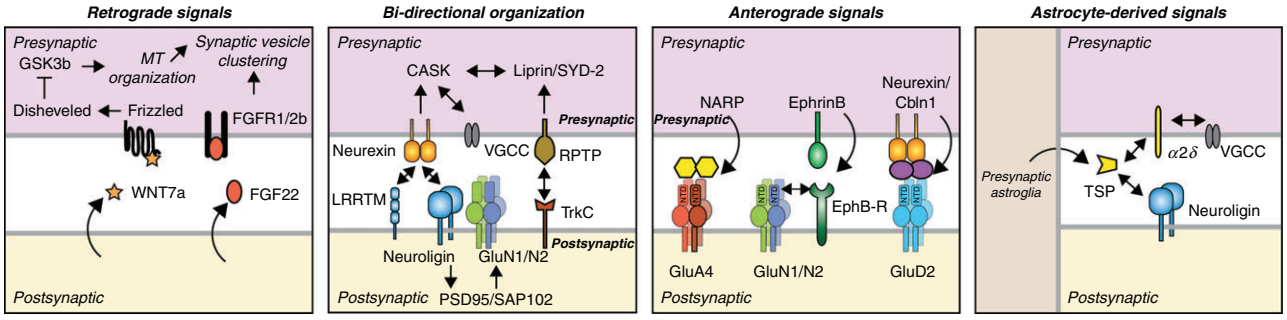

FIGURE 17.9 **Synapse-organizing signals at CNS synapses.** Different modes of synaptic organizing signals exchanged between pre- and postsynaptic partners and glial cells are illustrated. Wnt7a and FGF22 are retrograde signals derived from the postsynaptic target cell. Transsynaptic adhesion complexes link to scaffolding molecules which interact with presynaptic voltage-gated calcium channels (VGCC) or postsynaptic NMDA-receptors (GluN1/N2), respectively. Several anterograde signals from the presynaptic cell exert their synapse-organizing functions via direct interaction with the amino-terminal-domain (NTD) of glutamate receptors. Perisynaptic astroglia release synapse-organizing molecules such as thrombospondin (TSP). See text for further discussion.

does not require the presence of neurotrophins or the TrkC kinase activity. This suggests that in addition to its role in cell survival, TrkC has evolved functions that resemble an adhesion molecule.

How do transsynaptic adhesion complexes promote the assembly of synaptic junctions? The synaptogenic functions of multiple transsynaptic adhesion complexes appear to converge onto a common platform of presynaptic signal mediators. Neurexins couple via PDZ-domain interactions to a group of multidomain scaffolding molecules including Lin-2/CASK and Lin-10/Mint. RPTPs (the presynaptic receptors for TrkC) couple to liprins, which in turn interact with Lin-2/CASK. This presynaptic scaffolding complex might link synaptic adhesion molecules to voltage-gated calcium channels—the key calcium source for regulated secretion at the active zone (Missler et al., 2003). Currently, evidence for essential roles for any of these scaffolding molecules in presynaptic assembly in vertebrates is lacking. However, analysis of invertebrate model systems highlighted that these proteins are indeed key regulators of presynaptic assembly. *C. elegans* liprin has been recovered as a mutation called *synapse-defective-2* in a genetic screen for mutant nematodes with altered presynaptic differentiation (Jin, 2002). In *synapse-defective-2* mutant worms active zones are unusually lengthened and synaptic vesicles are diffusely localized along presynaptic sites. By analogy with the RPTP-liprin interactions observed in vertebrates, SYD-2 acts downstream of the receptor tyrosine phosphatase called PTP-3A. Exploring the function of liprins/Syd-2 in vertebrates is complicated by the fact that multiple independent genes encode liprin isoforms. However, expression, localization and biochemical interactions of liprins are consistent with a role in presynaptic assembly.

The concept of submembrane scaffolds organized by synaptic adhesion complexes not only applies to presynaptic organization but such scaffolds may also underlie the concentration of postsynaptic neurotransmitter receptors. In analogy to AChR clustering at the neuromuscular synapse, transsynaptic signals recruit Rapsyn-like cytoplasmic proteins that provide a scaffold lining the postsynaptic membrane. Different forms of such scaffolds selectively retain postsynaptic neurotransmitter receptors at the appropriate sites. Biochemical studies have identified a vast array of such scaffolding proteins. These proteins are characterized by combinations of protein–protein interaction domains, making them well suited to cross-link postsynaptic receptors into larger complexes (Kim & Sheng, 2004). Neuroligins bind, via PDZ-domain interactions, to SAP102 and PSD-95, major components of the glutamatergic postsynaptic scaffold. Aggregation of neuroligins results in the recruitment of the scaffolding proteins and NMDA-type glutamate receptors (Chih, Engleman, & Scheiffele 2005; Graf, Zhang, Jin, Linhoff, & Craig, 2004). Mice lacking neuroligin proteins show a subtle reduction in synapse density and a significant loss of postsynaptic neurotransmitter receptors from synapses (Varoqueaux et al., 2006). These studies highlight the coupling of neurotransmitter receptors to adhesion molecules and a potential role for scaffolding molecules in this process. The importance of these interactions is further emphasized by the association of mutations in scaffolding and adhesion molecules with autism-spectrum disorders in human patients (Box 17.2).

The concept that scaffolding molecules contribute to the clustering of postsynaptic neurotransmitter receptors applies to both excitatory and inhibitory synapses. Importantly, these synapses differ not only in their presynaptic neurotransmitters and postsynaptic neurotransmitter receptors but also in their scaffolding proteins. In fact, scaffolding molecules may ensure that the appropriate neurotransmitter receptors are selectively recruited to excitatory and inhibitory synapses, respectively. The scaffolding protein gephyrin represents one of the best-understood examples for the scaffold-mediated postsynaptic receptor clustering at inhibitory synapses. Gephyrin

BOX 17.2

SYNAPTIC TARGETS IN NEURODEVELOPMENTAL DISORDERS

Human genetic studies have uncovered genetic risk factors for autism-spectrum disorders. Autism is characterized by impairments in social interactions and communication. Patients exhibit a spectrum of restricted interests, ritualized behaviors, and stereotyped, repetitive movements. Autism is considered neurodevelopmental in origin as the defects emerge in the first years of life during the developmental time period of synapse formation and remodeling. Multiple genetic alterations (mutations or copy number variations) identified in patients encode proteins with synaptic function. For example, genes encoding the neurexin-neuroligin adhesion complex have emerged as autism candidate genes, including Nrxn1, Nlgn1, Nlgn3, Nlgn4, and the associated scaffolding molecules Shank2 and Shank3. Mutant mice recapitulating these mutations exhibit behavioral alterations that mimic core defects of autism and serve as models for developing therapeutic strategies.

Steven J. Burden and Peter Scheiffele

is a cytoplasmic protein that associates with the glycine receptor and is essential for receptor clustering at synaptic sites (Kneussel & Betz, 2000). Gephyrin is well equipped to serve as a scaffolding protein that links receptors to the cytoskeleton; it binds with high affinity to polymerized tubulin, the actin-binding protein profilin, and the lipid-binding protein collybistin. Thereby, gephyrin may link membrane lipids, neurotransmitter receptors, and cytoskeletal elements to stabilize postsynaptic specializations. Moreover, the gephyrin-collybistin complex is well positioned to recruit GABA-A-receptors in response to transsynaptic adhesion through a mechanism analogous to the scaffolding protein interactions at glutamatergic synapses. Neuroligin-2, a member of the neuroligin protein family that is concentrated at GABAergic synapses, activates collybistin, which in turn tethers gephyrin at the postsynaptic membrane. These gephyrin clusters then retain glycine and GABA-A-receptors at postsynaptic sites (Poulopoulos et al., 2009). In the hippocampus of neuroligin-2 knockout mice, the perisomatic accumulation of gephyrin and GABA-A receptors is reduced, which highlights an essential role for neuroligin-2 in nucleating a cytoplasmic protein platform of GABAergic synapses. In summary, multiple transsynaptic adhesion systems provide bidirectional signals that cooperate in the organization of pre- and postsynaptic structures.

Postsynaptic Neurotransmitter Receptors as Effectors of Anterograde Signaling

While cytoplasmic scaffolding protein interactions provide one important pathway for the clustering of postsynaptic neurotransmitter receptors, direct extracellular (scaffold-independent) interactions with neurotransmitter receptors themselves have emerged as a second mechanism (Fig. 17.9). Ionotropic glutamate receptors are tetramers, generally composed of two molecules each of two different subunits. In addition to ligand-binding and pore-forming domains, glutamate receptor subunits contain an extracellular amino-terminal domain (NTD). Proteins that directly bind to these NTDs serve as anterograde signals for the synaptic recruitment of glutamate receptors. The neuronal pentraxins were the first such anterograde signals to be identified. Pentraxins (NARP and NP1) are released from axons and interact directly with the NTD of AMPA-receptor (GluA) subunits. This interaction is sufficient to drive the synaptic aggregation of receptors at glutamatergic postsynaptic sites (O'Brien et al., 1999). Importantly, NTD-mediated interactions for postsynaptic differentiation are not unique to AMPA-type glutamate receptors but are emerging as a general principle. The NTD of the NMDA-receptor subunit GluN1 mediates direct interactions with EphB2, a member of the Eph-receptor family of receptor tyrosine kinases (Dalva et al., 2000). EphB-receptors form transsynaptic complexes with their ligands, called ephrinBs. These interactions nucleate a tripartite complex consisting of ephrinB, EphB-receptor, and NMDA-receptors, providing an anterograde signal for NMDA-receptor recruitment to synapses. Notably, EphB-receptors had been initially recognized for their critical roles in axon guidance and topographic mapping. The function of the EphrinB-EphB-receptor system at synapses highlights additional functions. In fact, other axon guidance molecules were recently identified as regulators of synapse formation. In many cases the signaling read-out downstream of these receptors varies between the different steps of neural development: some receptors that mediate repulsive signaling during axon guidance (such as EphB) have adhesive and stabilizing functions at synapses. How this functional switch is achieved is currently unknown.

Arguably, the most remarkable example for direct neurotransmitter receptor interactions in synaptic differentiation is provided by the GluD2 protein. GluD2 forms homo-tetramers and shares the same domain organization with AMPA- and NMDA-type receptors. However, owing to amino acid alterations in the receptor pore, GluD2 does not appear to mediate any currents. GluD2 is selectively expressed in cerebellar Purkinje cells where it is critical for synaptic connectivity and function. Mice lacking GluD2 suffer from cerebellar ataxia—that is, defects in motor coordination and balance. Parallel fiber synapses that form between cerebellar granule cells and Purkinje cells detach, indicating a severe weakening of transsynaptic adhesion. The GluD2 NTD stabilizes synapses through the presynaptic ligand cerebellin-1 (Cbln1), a small, secreted protein (Uemura et al., 2010). Whereas the GluD2 receptor is accumulated in Purkinje cell dendritic spines, Cbln1 is secreted from cerebellar granule cells and concentrates at parallel fiber synapses with Purkinje cells. Interestingly, Cbln1 binds to presynaptic neurexins (Fig. 17.9)—that is, the same presynaptic receptor that also transduces synaptogenic activities of postsynaptic neuroligins and LRRTM proteins (see above). In summary, Neurexin, Cbln1, and GluD2 form a tripartite complex that promotes synapse formation via the amino-terminal domain of GluD2. GluD2 is expressed exclusively in cerebellar Purkinje cells but neurexins and Cbln molecules are found more broadly in the nervous system and are likely to contribute to differentiation of other synapses as well. In fact, the cell type–specific function of the three anterograde synapse-organizing systems described in this paragraph highlight an important principle for CNS synapse formation: synapses formed between different neuronal partners have evolved a diverse range of signaling modules that control their assembly. The Agrin-Lrp4/MuSK complex is a universal signal for stabilization of all neuromuscular synapses. By contrast, signaling systems in the CNS are much more diverse and different synapses assemble by different mechanistic rules.

Glial-Derived Signals for Synapse Development

All transsynaptic signals we have discussed so far are exchanged directly between the pre- and postsynaptic partners. However, synapses are tripartite structures in which glial cells assume highly specialized morphologies and functions (Fig. 17.7). Importantly, some synaptic differentiation factors are derived from glial cells and coordinate the assembly of pre- and postsynaptic structures. Cultured astrocytes greatly enhance the number of synapses formed by cultured purified retinal ganglion cells (Eroglu & Barres, 2010). Astrocytes secrete multiple factors to control various aspects of synapse formation. One of these factors is thrombospondin (TSP), a large secreted proteoglycan molecule (Fig. 17.9). TSP induces morphologically defined synapses in cultured neurons, and mutant mice with perturbed TSP expression have fewer synapses. This suggests that this astrocyte-derived protein is required for synapse formation in the intact nervous system. The activity of TSP is mediated by interactions with both pre- as well as postsynaptic receptors. A presynaptic TSP receptor is the protein alpha-2-delta, a transmembrane protein associated with voltage-dependent calcium channels. On the postsynaptic side, TSP interacts with neuroligin-1, which in turn couples to NMDA-type glutamate receptors. This example highlights that glial cells play important roles in determining the formation and function of synapses during development. Additional glial-derived signals for synapse formation are likely to exist and remain to be discovered.

Surface Recognition Molecules in Synaptic Specificity

Understanding the molecular mechanisms of synaptic specificity is arguably the most exciting unresolved question in the field of CNS synaptogenesis. A leading model is that selective transsynaptic interactions are achieved by an adhesive code. Such a code could be generated by corresponding attractive cues in pre- and postsynaptic cells, matching appropriate partners through adhesive interactions. Such attractive cues for selective wiring are complemented by repulsive signals that limit the interaction between inappropriate partners. In the following, we will discuss examples for both mechanisms.

Cadherins are the first proteins proposed to function as adhesive synaptic specificity factors. Cadherins are a family of homophilic adhesion molecules that are major regulators of cell morphology and function in all tissues. In the CNS, cadherins are concentrated at synapses. Since there are about 20 different subtypes of classical cadherins these proteins could encode selective interactions between synaptic partners. In many brain areas specific cadherin isoforms are selectively expressed in corresponding pre- and postsynaptic partners, making them excellent candidates to impose specificity on the synapse formation process. This hypothesis has been tested in the hippocampal mossy fiber projection in mice (Fig. 17.10). In the hippocampal circuit, mossy fiber axons derived from the dentate granule cells (DG) form large glomerular synapses selectively on CA3 pyramidal cells. Interestingly, preferential synapse formation between DG and CA3 cells is maintained, even in dissociated cultures of hippocampal neurons where spatial constraints imposed by the hippocampal architecture are absent. Therefore, it is indeed cellular properties and not cell location in the neuropil that are important for selective synaptic interactions. DG and CA3 cells both express the same cadherin isoform (cadherin-9). In the absence of cadherin-9, DG-CA3 synapses are under-developed and form in lower numbers (Williams, et al., 2011). These experiments provide a first glimpse of critical roles for cadherin-mediated adhesion in selective synapse formation. Given that multiple different cadherin isoforms are found throughout different brain regions and neuronal circuits, analogous cadherin-mediated interactions may contribute to further cases of synaptic specificity.

Beside cadherins, additional homophilic adhesion molecules have been implicated in synaptic specificity. The vertebrate retina is a particularly useful system for the analysis of selective wiring due to its stereotyped organization (Fig. 17.10). Amacrine and bipolar cells elaborate neurite arborizations in the inner plexiform layer, a laminar region where synapses on retinal ganglion cell dendrites are established. The inner plexiform layer is divided into so-called sublaminae defined by the restriction of neurites from distinct amacrine and bipolar cells and their retinal ganglion cell targets. Cells elaborating neurites and synapses in specific sublaminae differ in their activation upon visual stimuli (ON and OFF cells; see Chapter 9 for details). A family of immunoglobulin domain proteins, called Sidekicks and the closely related DSCAMs, are expressed in synaptic partners (Yamagata & Sanes, 2008). Sidekicks and DSCAMs mediate homophilic adhesion and direct axo-dendritic interactions of specific pairs of amacrine and retinal ganglion cells to specific sublaminae (Fig. 17.10). Therefore, similar to the hippocampus, a substantial degree of laminar specificity can be achieved through adhesive interactions between pre- and postsynaptic partners. However, not all aspects of laminar specificity rely on attractive interactions. Repulsion from inappropriate targets has emerged as a second fundamental mechanism for achieving synaptic specificity. A compelling example for this mechanism is observed for the laminar stratification of amacrine cell neurites (Matsuoka et al., 2011). A subclass of amacrine cells (containing the neuromodulator dopamine or calbindin) elaborates neurites and synapses predominantly in the S1 and S2 sublaminae of the IPL. This restriction is achieved by

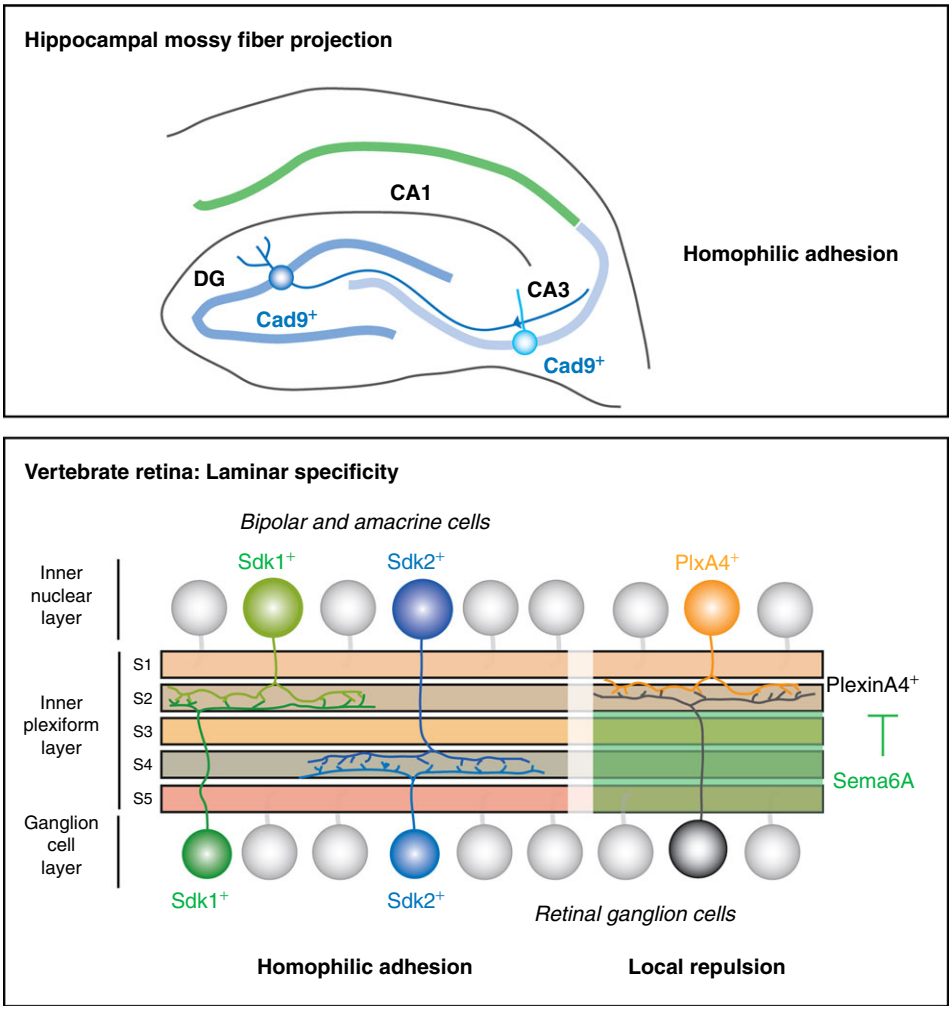

FIGURE 17.10 **Model mechanisms for synaptic specificity.** (A) In the hippocampus, dentate granule cells (DG) form synapses selectively on pyramidal cells in the CA3 region. Pre- and postsynaptic partners express the same homophilic adhesion molecule (cadherin-9) and thereby preferentially form synapses with each other. (B) In the vertebrate retina, the analysis of laminar specificity of neurite elaboration is facilitated by stereotyped layered organization of the inner plexiform layer (sub-laminae S1-S5). In this system, attractive and repulsive signals have been identified which guide synaptic specificity. Subsets of amacrine and bipolar cells in the inner nuclear layer contain different isoforms of the protein Sidekick (Sdk1 or Sdk2). Through homophilic adhesion, these cells form lamina-specific synaptic connections on the dendrites of Sdk1 or Sdk2-positive ganglion cells, respectively. In the same system, local repulsion is used as an additional specificity mechanism. The neurites elaborated by PlexinA4-positive amacrine cell ($PlxA4^+$) are repelled by semaphorin6A (Sema6A) expressed in sub-laminae S3-S5. Thereby, $PlxA4^+$ neurites are restricted to sub-laminae S1 and S2. *Figures adapted from Williams, de Wit, and Ghosh (2010) and Yamagata and Sanes (2008).*

repulsive signals transduced through the Plexin-Semaphorin receptor-ligand pair of guidance molecules. The PlexinA4 receptor is expressed in the amacrine cells, whereas the transmembrane Semaphorin 6A ligand is concentrated in sublaminae S3-S5, thereby forming a repulsive barrier for PlexinA4-positive neurites (Fig. 17.10). Removal of either molecule results in neurite mistargeting.

These two examples of attractive and repulsive mechanisms for the laminar restriction of neurites and synapses explain a small number of the many selective interactions observed in the neuronal circuits of the retina. The intricate pattern of laminar restriction of the multitude of additional cellular interactions is likely achieved by a combination of cues that target neurites to or exclude them from specific domains. It is an open question whether synaptic specificity in neuronal networks, which are not organized in anatomical laminar structures, follows similar principles or whether new, yet unanticipated mechanisms are at work.

Summary

The diversity of synapses found in the nervous system is likely to be matched by an equally diverse array of mechanisms producing the synapses. These mechanisms are only now beginning to be elucidated. Prime candidates at present for synaptogenic roles include transmembrane proteins interacting with cognate receptors on the apposing cell surface (e.g., neuroligin/neurexin; RPTPs/TrkC receptors), diffusible molecules that instruct synaptic development in target cells (e.g., FGF22) or that interact directly with synaptic components (e.g., NARP, Cbln1), and intracellular components that act locally to organize synaptic constituents (e.g., gephyrin). Advances in visualizing neuronal connectivity in the intact brain have paved the way to the identification of signals that inhibit (Plexin-Semaphorin) or promote (cadherin-9) interactions between specific synaptic partners providing the first insights into synaptic specificity.

CHAPTER

18

Programmed Cell Death and Neurotrophic Factors

Major hallmarks of embryonic development include the generation of new cells, the growth of tissues and organs, and the gradual but inexorable acquisition of new cellular and morphological properties (phenotypes). Accordingly, in the past, a major focus of developmental neurobiologists has been the study of progressive events, such as those described in several other chapters in this section. In this context, the concept of significant regressive events, such as programmed cell death (PCD), occurring during development, initially was considered counterintuitive (Oppenheim, 1981; 1991). Subsequently, however, it has been demonstrated that cell loss and other regressive events, including synapse elimination (Chapter 19), are the rule rather than the exception. In most developing tissues that have been examined in multicellular organisms, substantial cell loss occurs. As we discuss later, even a significant proportion of adult-generated neurons in the hippocampus and olfactory system also undergo normal PCD (Gage, Kempermann, & Song, 2008). Genetic programs that result in cell death have been suggested to be a default pathway for all cells. In this view neurons would escape this default fate only by receiving the appropriate receptor-mediated survival signals (e.g., neurotrophic factors, NTFs) that induce changes in the molecular and biochemical events required for cell survival and neuronal differentiation. In the absence of these ligands, the unbound receptors may activate death pathways and have been called "dependence-receptors." Neurons that express dependence receptors require—that is, are dependent upon—the presence of ligands for their anti-apoptotic role in promoting survival; however, in the absence of ligands, these neurons do not die by default, but rather the unbound receptors are *actively* pro-apoptotic and trigger cell death. Aberrations in the mechanisms regulating the balance between cell proliferation and cell elimination can lead to pathologies of tissue growth and differentiation by reduced cell death (e.g., cancer) or excessive neuronal death (e.g., neurodegenerative disease). Mechanisms that regulate the balance between cell production and death serve to determine the ultimate number and maintenance of neurons in the nervous system. Genes regulating these mechanisms provide an underlying substrate for evolutionary changes in brain size and structure and ultimately in adaptive behavior.

Both progressive and regressive events during development are regulated by intercellular signals. Somewhat surprisingly, many of the same intercellular signals (e.g., NTFs) that contribute to the regulation of progressive events during nervous system development also contribute to the control of regressive events. Neurotrophic factors are now appreciated for their role in both survival- and nonsurvival-related activities in both developing and mature nervous systems where they play important roles in the regulation of activity-dependent structural and functional plasticity of the nervous system. Accordingly, we include here a review of both survival and nonsurvival functions of NTFs.

Because neurons may die for a variety of reasons and in many different situations, it is important to describe the type of cell death observed most often in the developing nervous system. Although the loss of cells during normal development has been called by many different names (normal cell death, spontaneous cell death, naturally occurring cell death, apoptosis, and developmental cell death), we prefer the term *programmed cell death*

(PCD). PCD is defined as the spatially and temporally reproducible and species-specific loss of large numbers of individual cells both during development and, in many tissues and organs, throughout life, as adult cells die and are replaced by precursor or stem cells as a means of maintaining stable structure and function (homeostasis). Accidental, injury-induced, pathological, and disease-related forms of cell death are not included even though we recognize that the biochemical and molecular mechanisms used to kill cells in these situations may overlap with those involved in developmental PCD and in some cases, like PCD, the death may even be genetically controlled. This definition of PCD also makes no *a priori* assumptions about either the morphological or the biochemical pathways by which cells die or the stimuli that trigger cell death. The use of the word "programmed" refers to the reproducible, spatiotemporally species-specific occurrence of cell loss and is not meant to imply that the cell loss is genetically predetermined, inherited from precursor cells, or inevitable. Finally, and as we discuss in more detail later, PCD is not synonymous with the term *apoptosis*, which refers only to one specific, albeit common, mode of developmental cell death.

CELL DEATH AND THE NEUROTROPHIC HYPOTHESIS

Early embryological studies of the interactions between developing neurons and their peripheral targets laid the foundation for the discovery of cell death and the first NTF (Cowan, 2001). These studies formed the conceptual framework for the neurotrophic ("nerve feeding") hypothesis (Fig. 18.1). By 1949, Viktor Hamburger and Rita Levi-Montalcini had provided compelling evidence to support the significance of normal embryonic neuronal death and postulated that target-derived signals act to regulate the number of neurons that survive embryonic development. In subsequent studies, they and their colleagues identified a specific protein, nerve growth factor (NGF), that influenced development of the same populations of neurons (sensory and sympathetic) that their earlier studies had suggested were regulated by target-derived signals.

By 1960, the preparation of specific antibodies that block NGF activity allowed Stanley Cohen, Levi-Montalcini, and co-investigators to demonstrate the almost total degeneration of sympathetic ganglia *in vivo* following the specific deprivation of NGF activity. Only with the evidence from this "immunosympathectomy" (the deletion of the sympathetic system by antibody treatment) was NGF considered to be an endogenous survival or maintenance factor for these neurons. Three decades after the original discovery that an unknown chemical substance produced by tumor cells affects the development of sensory and sympathetic neurons, it was finally recognized that NGF was the hypothetical target-derived trophic signal first postulated by Hamburger and Levi-Montalcini in 1949 to be involved in regulating the number of surviving neurons in these populations during normal development. Historically, then, the appreciation of the role of PCD in the developing nervous system and the discovery of the first target-derived NTF (NGF) were inextricably linked; together they provided the foundation for the neurotrophic hypothesis, and both owe their origin to earlier studies of interactions between developing neurons and their synaptic targets (Oppenheim, 1991).

Despite the significance of this conceptual advance and the singular role of the neurotrophic hypothesis in guiding research in this field for over half a century, new evidence indicates that the neurotrophic hypothesis is in need of revision in order to encompass the increased appreciation that the cell–cell interactions that regulate neuronal survival and death are more complex than originally thought. It is now clear, for example, that the efferent targets of neurons are only one of several sources of survival-promoting NTFs and that NGF is only one of many diverse NTFs that regulate development and survival.

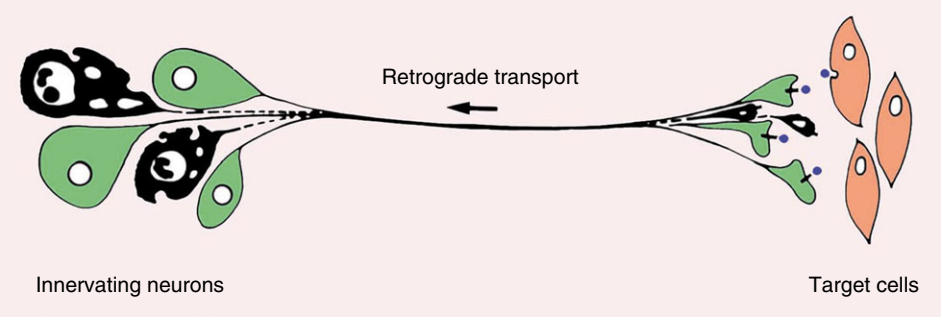

FIGURE 18.1 The neurotrophic hypothesis postulates that developing neurons survive (green neurons) only when they successfully compete for target-derived trophic molecules (blue) that are internalized at the nerve terminal and are transported retrogradely along the axon (arrow) to the cell body. Neurons that fail to obtain a sufficient flow of trophic molecules from the target die by programmed cell death (black neurons with condensed chromatin). *Modified and reproduced with permission from Barde (1989).*

THE ORIGINS OF PROGRAMMED CELL DEATH AND ITS WIDESPREAD OCCURRENCE IN THE DEVELOPING NERVOUS SYSTEM

PCD has been identified in plants, several species of unicellular eukaryotes, including yeast, as well as in prokaryotes such as bacteria, one of the oldest forms of life on earth (Ameisen, 2004). One likely explanation for the evolutionary origins of PCD in eukaryotes was the appropriation of cell death–associated genes from bacterial mitochondria by a process of endosymbiosis. Based on the principle of genetic pleiotropy, it seems likely that under the right conditions genes required for vital functions such as metabolism, proliferation, and differentiation can also serve pro- and anti-cell death functions and that this pleiotropy played a major role in their later selection in unicellular eukaryotes and metazoans. Even some of the core genetic machinery currently employed for regulating PCD in mammals, including neuronal PCD, has retained a degree of pleiotropy. Both caspases and Bcl-2 family members mediate a number of nondeath functions in both neuronal and nonneuronal cells (Jiao & Li, 2011).

After being incorporated into the eukaryotic genome, this core cell death machinery expanded in complexity over time to include the diversity found in extant multicellular organisms. Once the pro- and anti-apoptotic machinery was in place in the genome of multicellular animals, it could then be co-opted to mediate the many diverse roles now served by PCD, including different functions of PCD in developing neurons. Finally, a word of explanation is needed regarding the seemingly counterintuitive existence of PCD in unicellular organisms—that is, how can the death of individual organisms be beneficial? In fact, several adaptive roles of PCD in these organisms have been reported (Nedelcu, Driscoll, Durand, Herron, & Raskidi, 2010).

Although a systematic taxonomic survey of all representative species with a nervous system has not been done, nonetheless the available evidence is consistent with the idea that some PCD of developing neurons occurs in all such organisms. For many invertebrate and vertebrate species, the PCD of neurons involves virtually all regions and cell types in the central and peripheral nervous system. Motoneurons, sensory neurons, autonomic neurons, and both long projection and local circuit interneurons in the brain and spinal cord all undergo restricted periods of PCD. Although the magnitude of neuronal cell death varies from population to population, as many as one-half or more of all cells in a population will die during development (Fig. 18.2). In some special cases, such as the loss of transient neuronal structures during insect and amphibian metamorphosis (e.g., the Rohon-Beard sensory neurons in fish and frogs), most or all cells die. Cell death in the nervous system thus clearly occurs on a very large scale, indicating that it plays fundamental and essential roles in normal development.

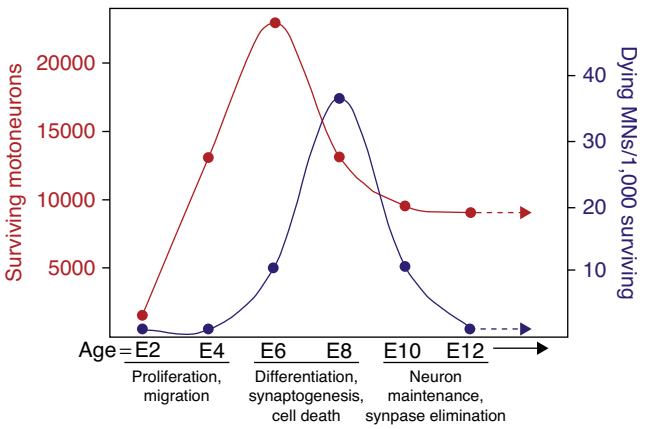

FIGURE 18.2 Changes in the number of developing lumbar spinal motoneurons in the chick embryo (in red) compared to the number of dying motoneurons (in blue) during the first half of the 21 day incubation period. Approximately 50 to 60% of these motoneurons undergo PCD between embryonic day (E)6 and E12.

Studies of cell death in the nervous system have focused on the loss of developing postmitotic neurons as they form synaptic connections with targets and afferents. However, extensive PCD also occurs during neurulation and in mitotically active neural progenitor cells, as well as in postmitotic but undifferentiated neurons in the early neural tube (Fig. 18.3). Accordingly, PCD in the nervous system is not limited to any particular stage of development. The loss of cells at different developmental stages probably serves distinct functions and may be mediated by different mechanisms. PCD also occurs in central and peripheral glial cells. For example, like neurons, myelin-forming oligodendrocytes in the optic nerve and Schwann cells in peripheral nerves are overproduced, and many die by PCD. Their loss is thought to reflect a competition for axon-derived trophic signals, the end result of which is the survival of an appropriate number of glial cells for optimal myelination of the available axons (Fig. 18.4).

Because PCD is the normal differentiated or terminal fate of many developing cells, commitment to this fate occurs in much the same way as the phenotypic fate of cells destined to survive in the embryo. Developmental biologists have identified two major ways in which the commitment of a cell to a particular differentiated phenotype occurs. The first mechanism, intrinsic or *autonomous specification*, involves the segregation of critical cytoplasmic molecules by asymmetric cell division; cell death thus is programmed into the lineages that generate somatic cells. The second mechanism of commitment involves extrinsic signals from other cells and is

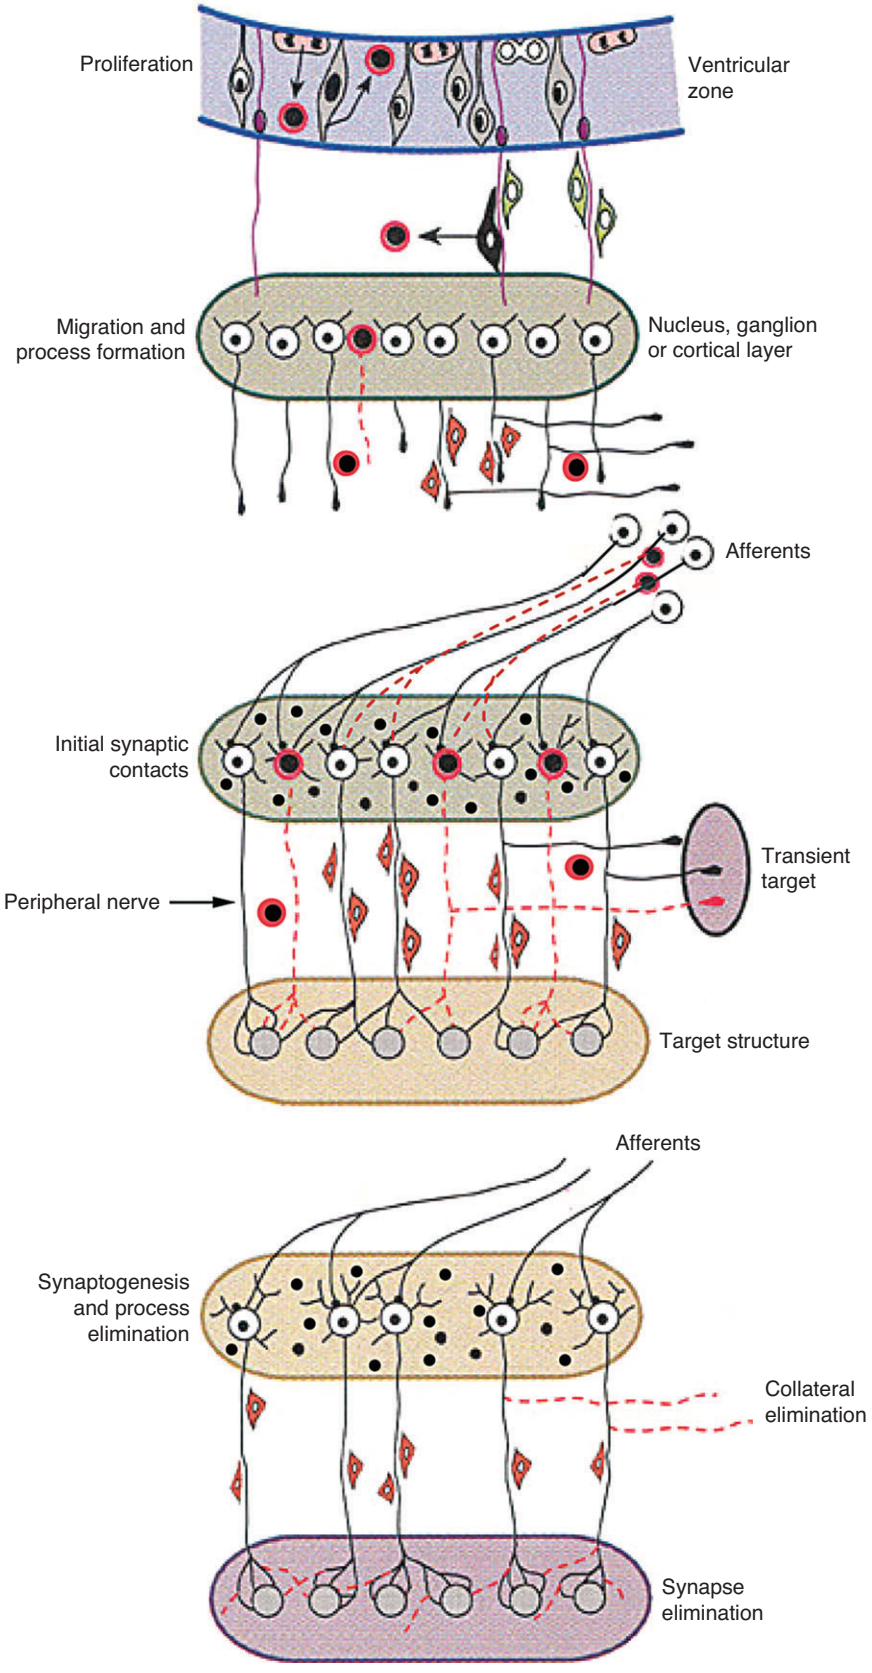

FIGURE 18.3 Schematic illustration of some key steps in neuronal development. Neurons undergoing PCD (●) are observed during neurogenesis in the ventricular zone, during migration and while establishing synaptic contacts. Schwann cells in developing nerves also undergo PCD. ◗ Represents peripheral glial (Schwann) cells; ● represents CNS glia (astrocytes, oligodendrocytes); ⊙ represents surviving, differentiating neurons (e.g., motoneurons whose targets are skeletal muscle and other neurons in the CNS, with neuronal targets).

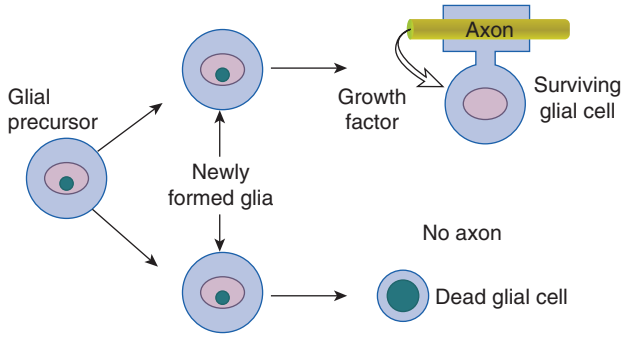

FIGURE 18.4 The PCD of glial cells is regulated by axon-derived signals. Glial cells that fail to compete successfully for these signals undergo PCD.

called *conditional specification*; initially, the cells have the potential to follow more than one path of differentiation, but as development proceeds, signals from other cells act to gradually limit and specify cell fate. Although all organisms use a combination of autonomous and conditional developmental strategies, as a general rule invertebrates are more likely to utilize autonomous specification, whereas most vertebrates exhibit conditional specification. Despite this distinction, as described later, many of the genetic and molecular pathways for PCD are remarkably similar in invertebrates and vertebrates. In addition to these two major pathways for fate determination, as we discuss below, there is increasing evidence for a third pathway involving stochasticity: random fluctuations (noise) in gene expression (fate determination by the "roll of the dice").

Summary

The PCD of developing neurons appears to occur in virtually all vertebrate and invertebrate species. More generally, PCD also occurs in many different cells and tissues of unicellular and multicellular organisms and thus may have arisen very early during evolution. With few exceptions, PCD occurs in virtually all types of developing neurons and can take place at stages of development from the time of proliferation until the establishment of synaptic connections. Developing glial cells also exhibit PCD. Cell death is the terminal phenotypic fate of subpopulations of developing neuronal and glial cells and, like other cell fate decisions, is controlled by both intrinsic and extrinsic signals.

FUNCTIONS OF NEURONAL PROGRAMMED CELL DEATH

Why does PCD occur? This is a reasonable question to ask because the loss of large numbers of developing neurons is counterintuitive. Why should embryos invest precious resources in generating cells and tissues only to later cast many of these aside? A satisfactory answer to this apparent paradox requires an evolutionary perspective that addresses two central aspects of the problem. First, how did the biochemical machinery (the cell death program) needed to actively kill cells arise? Second, why, in many developing tissues, are more cells generated than are apparently needed?

The first question was addressed in the previous section; however, understanding the evolution of the biochemical cell death program does not help answer the second question of why there is often a massive overproduction of neurons during development that are later eliminated by PCD. Two explanations have been offered (Oppenheim, 1991). First, each case of PCD may have evolved to serve a distinct biological function. For example, according to this view, in the case of spinal motoneurons, natural selection is thought to be directly responsible for both the overproduction and the subsequent death of neurons as a means for creating an optimal (adaptive) level of functional muscle innervation (e.g., systems-matching).

The second view is that the overproduction of neurons (or other cells) is an inevitable outcome of the imprecise kinetics of proliferation of precursor cells. Once too many (or too few) cells are generated and the pro- and antiapoptotic machinery is in place, natural selection then acts via regulated cell survival and death to mediate a variety of different adaptive needs. For example, following the loss or absence of essential survival signals, the death of excess cells could be accomplished easily by co-opting the cell death machinery that evolved to kill cells in early eukaryotes. In reality, both of the proposed mechanisms may occur (Table 18.1). Many of the circumstances in which the PCD of neurons occurs are thought to mediate distinct adaptive functions, as summarized in Table 18.1. In many of these examples, the production of excess neurons provides a substrate on which differential survival or PCD can then act to meet a variety of putative adaptive needs. Similarly, if fewer numbers of cells are generated, then compensation, by reducing the extent of cell death, provides a means for ensuring, for example, that a sufficient number of neurons are still available for optimal target innervation. As new genes are identified that regulate PCD, and as we gain a better understanding of how cellular and molecular signals control cell death and survival, there will be increased opportunities for preventing PCD in select neuronal populations *in vivo* and directly assessing whether its occurrence is, in fact, adaptive.

Summary

The biochemical and molecular pathways that regulate cell death and survival arose early in the evolution of animal life. Once this cellular capacity arose, however, it is likely that it was co-opted to serve a variety of biological

TABLE 18.1 Some Possible Functions of Developmental PCD in the Nervous System[a]

1. Differential removal of cells in males and females (sexually dimorphic spinal motor nucleus in many mammals).
2. Deletion of some of the progeny of a specific sublineage that are not needed (loss of specific progeny of the AB blastomere that is involved in generating ring ganglia in *C. elegans*).
3. Negative selection of cells of an inappropriate phenotype (ligand/receptor-induced cell death in the early chick embryo retina?).
4. Pattern formation and morphogenesis (neurulation/neural tube closure; differential thickness of cortical layers).
5. Deletion of cells that act as transient targets or that provide transient guidance cues for axon projections (death of pioneer neurons/glia in insects).
6. Removal of cells and tissues that serve a transient physiological or behavioral function (loss of Rohon-Beard sensory neurons during metamorphosis in frogs).
7. Systems-matching by creating optimal quantitative innervation between interconnected groups of neurons and between neurons and their targets (see text).
8. Systems-matching between neurons and their glial partners by regulated glial PCD (Schwann cells and peripheral axons; see text).
9. Error correction by the removal of ectopically positioned neurons or of neurons with misguided axons or inappropriate synaptic connections (loss of ipsilaterally projecting retinal ganglion cells).
10. Removal of damaged or harmful cells (death of cells with DNA damage).
11. Regulation of the size of mitotically active neural progenitor populations (see text).
12. The production of excess neurons may serve as an ontogenetic buffer for accommodating mutations that require changes in neuronal numbers in order to be evolutionary adaptive (evolutionary increases in limb size may require increased sensory and motoneuron survival).
13. Regulated survival of subpopulations of adult-generated neurons as a means of experience-dependent plasticity (see text).

[a]*For references, see Buss, Sun, and Oppenheim (2006).*

functions. In the nervous system, some major functions include establishing optimal levels of connectivity between neuronal populations, eliminating aberrant cells or connections, regulating the size of progenitor populations, and serving transient functional or other needs of immature animals.

MODES OF CELL DEATH IN DEVELOPING NEURONS

The specific morphological appearance exhibited by degenerating neurons can provide insight into the cellular and molecular mechanisms by which the cells are destroyed. Historically, pathologists were the first to be interested in this issue, and they focused on distinguishing different kinds of cell and tissue degeneration following disease, injury, and trauma (Clarke & Clarke, 1996). Over 125 years ago, the term *necrosis* was coined to describe what today comprises the major form of accidental or pathological degeneration. The pathological necrotic death of neurons following injury usually involves the degeneration of groups of contiguous cells in a region that initiates an inflammatory response that can be discerned easily in tissue sections (Fig. 18.5). At about the same time that necrosis was first described, however, another form of cell degeneration, called spontaneous cell death, was observed in normal adult mammals. Spontaneous cell death (now called PCD) was thought to provide a means for counterbalancing mitosis in adult tissues in which the turnover of cells normally occurs. PCD typically involves the sporadic loss of individual cells in a population that often degenerate by a different mode from necrosis, one that does not involve inflammation. Early steps in the spontaneous PCD cascade leading up to when histological signs of frank degeneration first occur may take many hours or days. Once that point is reached, however, the degenerative process is rapid, with individual cells dying and being removed in minutes or a few hours. The loss of thousands of neurons over several days is the consequence of many rapid individual cell deaths that at any moment in time represent only a small minority (~1%) of all the cells in the population. For this reason, historically, the occurrence and magnitude of even massive PCD can (and often did) go unnoticed.

Two different strategies can be used to quantify neuron death: One can determine the total number of neurons at different stages and quantify the decrease (Fig. 18.2), or one can determine an increase in the number of dying (pyknotic) cells during the period of PCD and determine the timing and (with less precision) the extent of cell death (Fig. 18.5). The counting of neurons originally was done by counting profiles in thin sections and application of correction factors to account for multiple profiles per particle; a particle is defined as an identifiable object such as a cell, nucleus, or nucleolus (Clarke & Oppenheim, 1995); such counting is now increasingly replaced by stereological methods that count particles in thicker sections, a method that is less affected by confounding differences in particle size but that still presents challenges due to other sources of potential errors if not executed properly (Schmitz & Hof, 2005).

Cell degeneration in adult and developing tissues has often been dichotomized into death by either apoptosis or necrosis, a distinction based initially on morphological differences (Fig. 18.6). *Apoptosis* is a Greek word indicating the seasonal piecemeal dropping of leaves from a tree and originally was coined to describe all forms of cell death that

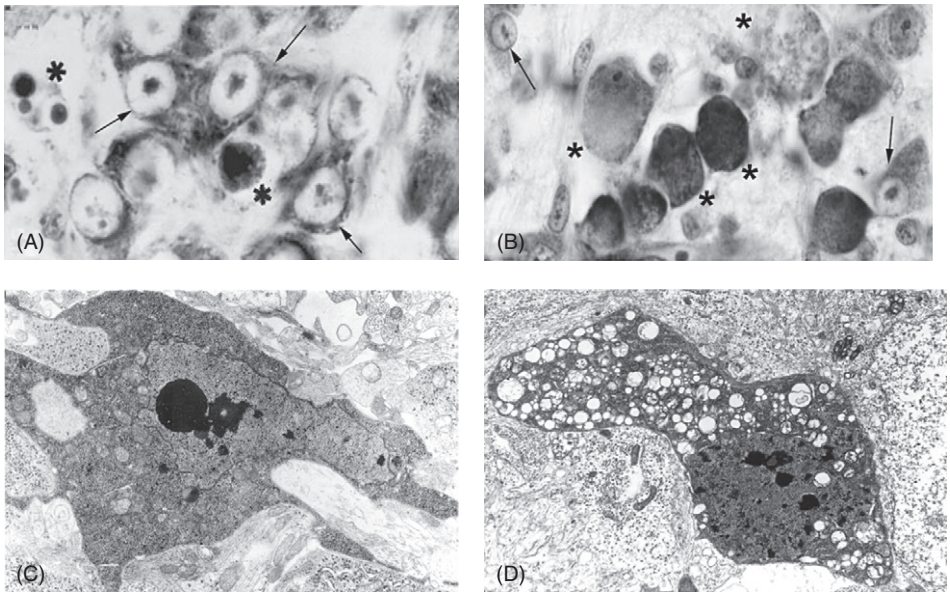

FIGURE 18.5 Spinal motoneurons in the chick embryo. (A) Ventral horn from a control embryo. Note that only two cells (asterisks) are undergoing apoptotic PCD; the others appear normal (arrows). (B) Ventral horn from an embryo following treatment with an excitotoxin. Most neurons are undergoing a necrotic type of cell death (asterisks) whereas some appear normal (arrows). Apoptotic (C) and necrotic motoneurons (D) in the chick embryo spinal cord as seen with an electron microscope.

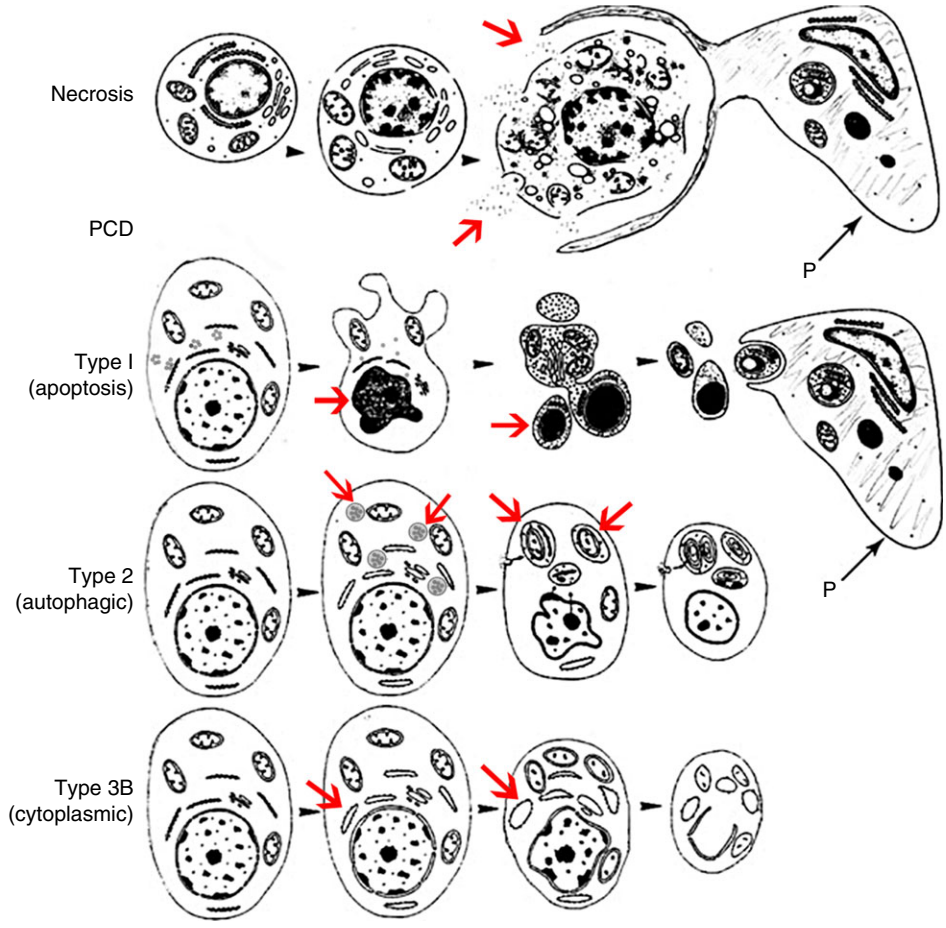

FIGURE 18.6 Schematic representation of cellular changes during necrotic cell death and during three of the most common types of PCD observed at the ultrastructural level. Key features of each type of cell death are indicated by the red arrows. Only type 1 PCD meets most of the criteria for defining apoptosis. The cells on the right marked P represent phagocytic cells engulfing necrotic cell corpses and apoptotic bodies. Phagocytosis also occurs in the other types of PCD but is not shown.

share certain morphological characteristics (Wyllie, Kerr, & Currie, 1980). Cells dying by apoptosis shrink in size, and the nuclear chromatin condenses and becomes pyknotic, whereas the cell membrane and cytoplasmic organelles tend to remain relatively intact. Eventually the cytoplasm and nucleus break up into membrane-bound apoptotic bodies that are phagocytized either by professional phagocytes (macrophages) or by healthy adjacent cells (e.g., glia

that serve as transient phagocytes). Phagocytes recognize dying cells by their expression of death-related cell surface signals. In contrast, necrosis involves an initial swelling of the cell, only modest condensation of chromatin, cytoplasmic vacuolization, breakdown of organelles, and rupture of the cell membrane allowing the release of cellular contents (causing inflammation), followed by shrinkage and loss of nuclear chromatin. Because necrotic cell death elicits an inflammatory response in adjacent tissue, macrophages derived from the immune system attack and phagocytize cellular debris. In contrast, cell death by apoptosis usually involves individual cells that are engulfed and phagocytized before they can release their cellular contents or induce an inflammatory response in adjacent tissue.

Another feature that has been used to distinguish between apoptotic and necrotic cell death is the occurrence during apoptosis of a specific form of chromosomal DNA fragmentation and degradation that is mediated by DNA-specific proteases. DNA digestion occurs at internucleosomal sites, producing small, double-stranded fragments of DNA that migrate in a ladder pattern in multiples of 180–200 bp after electrophoresis in agarose gels. This form of DNA fragmentation can also be visualized in tissue sections by a technique that labels the double-stranded DNA breaks associated with apoptosis. DNA fragmentation suggests that apoptosis is an active process undertaken by the cell, whereas necrosis is a passive process resulting from extracellular damage. However, a variety of toxic and traumatic stimuli, previously thought to induce necrosis, can also induce morphological signs of apoptosis and may be associated with changes in PCD- or apoptosis-associated genes (Bredesen, Rao, & Mehlen, 2006).

Within the context of the developing nervous system, the dichotomy of apoptosis versus necrosis is an oversimplification. Developing cells undergoing normal PCD as well as neurons dying following injury should be categorized by operational definitions that use morphological, genetic, and biochemical criteria. Studies of the developing nervous system at the ultrastructural level provided an initial characterization of neuronal death noting that there were features of dying cells that appeared to indicate that all neurons do not die by identical mechanisms (Clarke & Clarke, 1996). "Nuclear" (Type I) neuronal death featured a dissociation of polyribosomes to free ribosomes, Golgi fragmentation to numerous vesicles, swollen mitochondria, and condensation of nuclear chromatin; the cell takes on a reduced size and crenulated appearance, neurotubules and neurofilaments are grouped together, and lysosomes appear normal. This type of neuronal degeneration is consistent with apoptosis.

There are other types of neuronal death during development, however, that do not fall under the categories of apoptosis or necrosis. In "cytoplasmic" (Type III) degeneration, the cisternae of Golgi, nuclear envelope, and rough endoplasmic reticulum are swollen, together with a vacuolization of mitochondria. Polyribosomes appear normal, and while the nuclear chromatin shows some condensation, the nucleus appears relatively normal. There is another type of cell death referred to as autophagy or Type II cell death that is characterized by the presence of abundant lysosomes and autophagic vacuoles. The specific morphological events that a neuron undergoes during PCD may depend on the type of neuron, its state of differentiation, and the stimuli that induce cell death. For example, ciliary ganglion cells predominantly exhibit features of cytoplasmic cell death during PCD; however, when peripherally deprived of targets, the majority of ciliary cells exhibit features of nuclear or apoptotic cell death (Oppenheim, 1981). The PCD of developing vertebrate neurons provides a striking example of the problems encountered in attempting to rigidly classify the pathway of degeneration as being either necrotic or apoptotic. Importantly, evaluation of the morphological features of PCD can further the understanding of the biochemical pathways of PCD and the roles of the specific genes involved.

Summary

Degenerating cells are often categorized into two classes: death by apoptosis or death by necrosis. However, the occurrence of certain features of apoptosis in neurons following injury and the occurrence of several types of PCD other than apoptosis indicate that a more accurate means of identifying and defining distinct forms of cell death should now be employed.

THE MODE OF NEURONAL CELL DEATH REFLECTS THE ACTIVATION OF DISTINCT BIOCHEMICAL AND MOLECULAR MECHANISMS

As described previously, the normal death of cells in the developing nervous system has long been thought to be regulated by competition for NTFs (the Neurotrophic Hypothesis). Investigators thought that the doomed neurons, lacking sufficient amounts of an NTF to sustain normal metabolic events, passively degenerated by a process analogous to starvation. Beginning in the late 1980s, several lines of evidence forced a reappraisal of the view that cell death in the nervous system is a passive process and led to the demonstration that for many types of neurons, PCD is regulated by the interaction of specific genetic programs that either inhibit or induce degeneration.

PCD of some nonneuronal cells was known previously to be a metabolically active, ATP-dependent process. In the nervous system, inhibition of RNA or protein synthesis could also prevent the death of sympathetic ganglion cells deprived of NGF *in vitro* and motoneuron and

sensory neuron PCD *in vivo*. Additionally, in the early 1980s, genetic mutations in the nematode worm *Caenorhabditis elegans* that prevent PCD had been described, thereby providing further evidence that neuronal death is a genetically regulated, metabolically active process. Considerable progress has been made since the early 1990s in identifying cell death–associated genes and their pathways of action. Due to historical precedent, these have been classified as pro- and anti-apoptotic genes; however, it is important to point out that in many instances the genes involved may actually induce cell death with morphological features of both apoptotic and nonapoptotic degeneration (see the previous section).

Genetic studies of cell death in *C. elegans* first demonstrated that PCD is regulated by specific genes. Because the genetics, morphology, and cell lineages in *C. elegans* have been so well defined, this organism provides a particularly informative and powerful model for analyzing the molecular genetics of PCD (Horvitz, 2003). Of the approximately 1000 somatic cells generated (of which 302 are neurons and 56 are glial cells), 131 undergo embryonic PCD, and most of these are mitotically active neuron precursors. In each individual, the same cells die at specific times in development, and these corpses are then engulfed and degraded by neighboring cells. Despite the enormous evolutionary gap that separates the appearance of worms, flies, and vertebrates, significant homology exists in the structure and function of specific cell death pathways between these taxonomic groups.

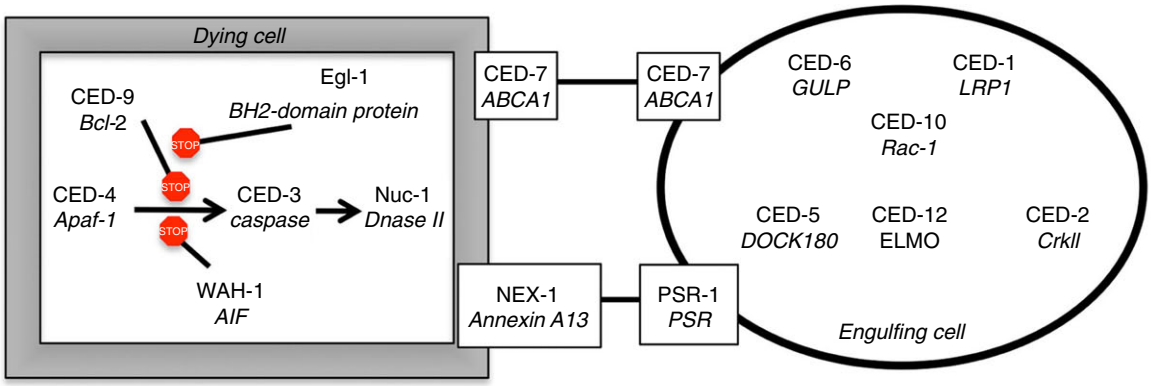
As summarized in Figure 18.7, there is a sequential cascade of genetically regulated steps involved in PCD. Upstream of the actual execution of the death process, transcription factors specify certain cell types for death, while sparing others. In *C. elegans*, manifestation of the death fate requires expression of two pro-apoptotic genes, ced–3 and ced–4 (ced, cell death), which together mediate the actual breakdown of cellular constituents. Prevention of cell death induced by ced-3 and ced-4 can occur by activation of the anti-apoptotic gene ced-9. Separate genes, such as nuclease-1 (nuc-1), are required for the degradation of DNA in dying cells, and several additional genes are involved in the recognition, engulfment, and processing of dead cellular corpses by phagocytes. Evidence for the involvement of this genetic cascade in cell death and survival in *C. elegans* comes from several different approaches, most notably from genetic studies of loss-of-function mutants. For example, in the absence of ced-9, many cells that normally survive die, whereas in the absence of ced-3 or ced-4, all PCD is prevented.

Identification of the DNA sequences of the major cell death genes ced-3, ced-4, and ced-9 in the worm in the 1980s and early 1990s resulted in the subsequent discovery of vertebrate and insect homologues that serve similar functions (Fig. 18.7). In mammals, ced-3 is represented by a large family of related proteases called caspases. Caspases are cysteine proteases that cleave after aspartate residues, and 12 distinct caspases have been cloned in human. In cell death, initiator pro-caspases are autolytically cleaved, and they then cleave effector pro-caspases. The effector caspases act on specific substrates that result in cell demise. Ced-4 is represented by a single vertebrate homologue, Apaf-1 (apoptosis protease activating factor), that is required for caspase activation. The survival-promoting function of ced-9 originally was represented by a single vertebrate homologue, bcl-2 (B-cell lymphoma-related gene), but subsequently other bcl-2 family members have been identified with similar anti-apoptotic functions (e.g., bcl-x), as well as other bcl-2 family members that are pro-apoptotic (e.g., bax, bak, bim). Loss-of-function mutations in mice by targeted gene deletion (gene knockout) of many of these vertebrate homologues have confirmed their role as important regulators of PCD.

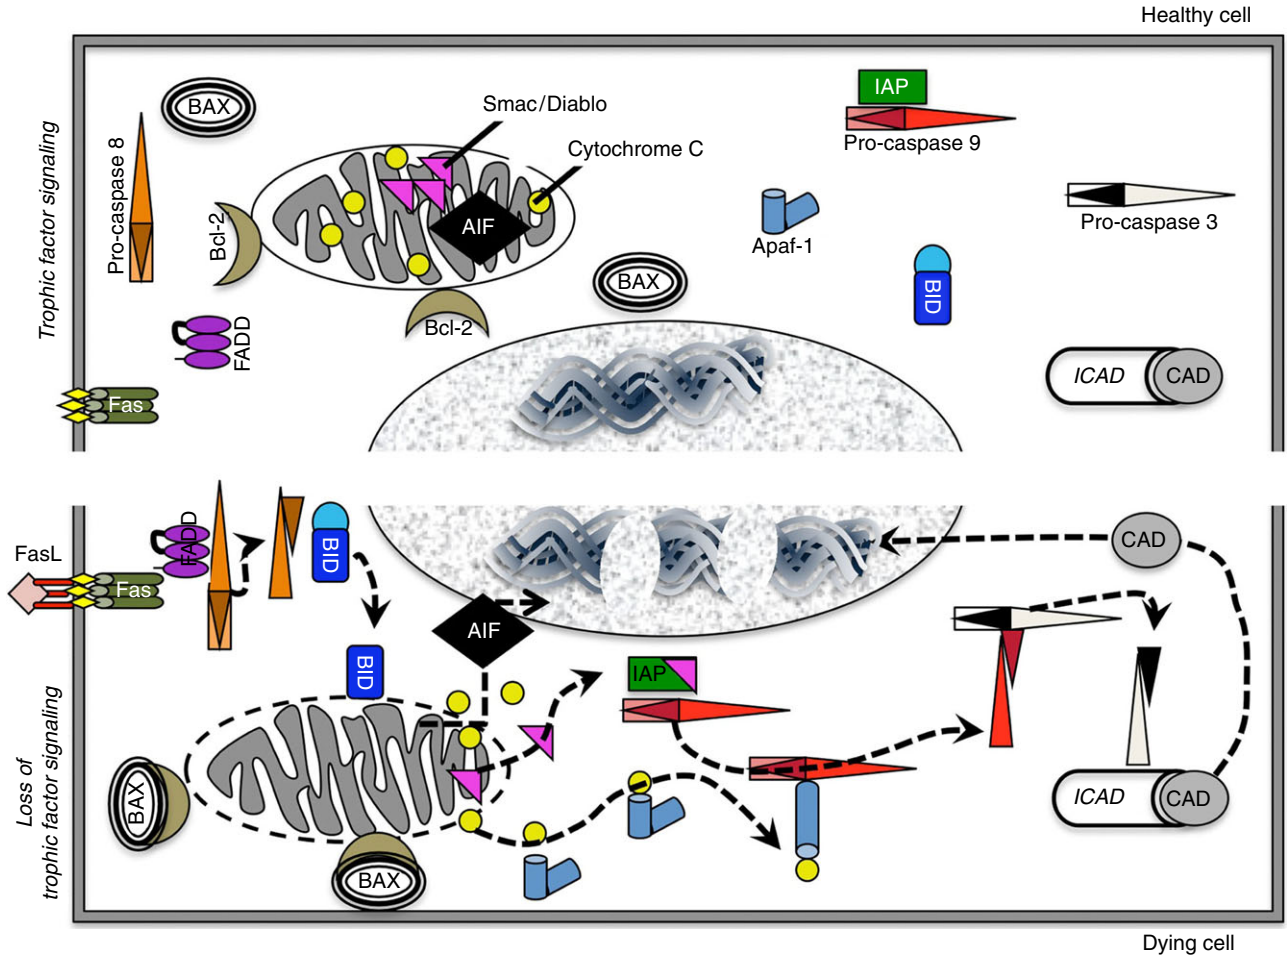
To understand cell death pathways, it is useful to consider the process of cell death in terms of signals that (i) induce death, (ii) regulate the intracellular process of cell death, and (iii) are involved in the removal of the corpse. NTFs act via membrane receptors resulting in intracellular signaling that either inhibits the expression or activity of pro-apoptotic genes or induces the expression or activity of anti-apoptotic gene products. On the other hand, as discussed below, more recent evidence indicates that pro-neurotrophins are capable of inducing cell death, suggesting that the availability of pro-survival versus pro-death signals can dictate the neuron's fate. Additionally, Fas-Fas ligand interaction has also been shown to regulate neuronal PCD.

Availability of NTFs induces or maintains activation of the PLCg, PKA, PI3-K/AKT, PKC, and ERK1/2 signal transduction pathways (see below). These pathways utilize both transcriptional and nontranscriptional mechanisms to regulate neuronal survival. For example, PI-3K/Akt has been reported to phosphorylate the pro-apoptotic molecule, Bad, promoting its association with 14-3-3 and preventing inactivation of pro-survival molecules, Bcl-2 and Bcl-x. Activation of these pathways also influences gene expression by activating transcription factors—namely cAMP responsive element binding protein (CREB)—which can result in transcription of anti-apoptotic genes like Bcl-2 and inhibitor of apoptosis proteins (IAPS). On the other hand, the JNK signal transduction pathway is activated in some neurons following NTF deprivation or Fas-Fas ligand interaction. JNK activation results in the activation of BH-3 proteins, regulation of Smac release from the mitochondria, and caspase activation.

Following inactivation of trophic receptors, and/or activation of p75NTR or Fas-Fas ligand, a series of intracellular events occurs that leads to a rapid and efficient



(A)



(B)

dismantling of the cell. A central integrator of cell death in vertebrates is the mitochondrion (Fig. 18.7). Both pro-survival and pro-apoptotic Bcl-2 proteins are critical for regulating mitochondrial membrane permeability. Permeabilization of the mitochondrial membrane results in increased reactive oxygen species, reduced ATP production, and release of the pro-apoptotic factors cytochrome c, Smac, and apoptosis inducing factor (AIF). Cytochrome c in the cytoplasm binds to Apaf-1, revealing Apaf-1's caspase recruitment domain (CARD), and in the presence of ATP forms a heptamer. Pro-caspase 9 has a high affinity for the CARD and binds at the

FIGURE 18.7 (A) Schematic representation of the major steps in the developmental PCD pathway of neurons in the nematode worm *C. elegans*. Both fly and mammalian homologues have been identified supporting the hypothesis that mechanisms of PCD are evolutionarily conserved. The mammalian homologues are listed in italics below the name of the *C. elegans* gene. (B) Some of the major events involved in mammalian PCD are illustrated. Healthy cells (top) receive signals to survive or lack signals to die (on left). Cell death mediators are present in healthy cells, but their location and/or association with regulators prevent activation of the cell death pathways. In cells that receive appropriate signals to die (bottom), cell death–specific pathways are activated. These pathways involve a permeabilization of the mitochondria membrane and release of factors that either directly or indirectly activate cell death–specific events. In neurons that fail to obtain NTF support (bottom), the pro-apoptotic gene Bax interacts with and inhibits the anti-apoptotic gene Bcl–2 in mitochondria. This results in the release from mitochondria of cytochrome-c, which forms a complex with Apaf-1 and caspase-9 that in turn activates downstream caspases such as caspase-3 that ultimately directly or indirectly degrade diverse nuclear and cytoplasmic targets. These degradative changes are what define apoptosis and result in eventual engulfment and phagocytosis of the apoptotic cell. In some situations two additional molecules released from mitochondria (along with cytochrome-c) are the pro-apoptotic proteins AIF, which can degrade the nucleus independent of caspases, and Smac/Diablo, which can inhibit IAP and promote the apoptotic pathway via caspase-9 and caspase-3. Although not shown here, in some situations developing neurons undergoing PCD activate cell cycle proteins that also serve a signaling function required for apoptosis (Copani et al., 2001). It is critical to note that all neurons do not use the identical pathways for cell death. For example, cell cycle proteins can mediate the death of sensory neurons; however, they do not play a role in motoneuron PCD (Taylor *et al.*, 2003. *Mol Cell Neurosci*. 24(2):323–39).

heptamer. This complex is referred to as the apoptosome. The increased local concentration of pro-caspase 9 results in its auto-cleavage, producing active caspase 9. Caspase 9 then cleaves pro-caspase 3 to the active form of caspase 3 that subsequently activates, inactivates, or destroys specific nuclear and cytoplasmic substrates, resulting in rapid cell degeneration. The activation of caspases as well as the availability of substrates may dictate the morphological changes associated with neuronal death (see previous section).

Many developing neurons appear to share the core cell death program described above, but there is also increasing evidence that alternative, nonapoptotic pathways may exist for mediating the normal PCD of some neurons. For example, when components of the apoptotic machinery are genetically deleted, cell death occurs by a morphologically distinct nonapoptotic death (Kroemer et al., 2009). Type II cell death or autophagy is characterized by the accumulation of double membrane–bound vesicles that fuse with lysosomes. Interestingly, Bcl-2 proteins and caspase activation appear to have regulatory roles in autophagy, suggesting that the different types of cell death utilize common mechanisms. Autophagy is also a critical nondeath event in maintaining homeostasis in many tissues, including the nervous system, and its role in normal cell death is still being debated. Another example of nonapoptotic cell death is necroptosis, a type of programmed necrosis recently characterized (Kroemer et al., 2009). Many of the stimuli that induce apoptosis instead activate necroptosis when caspases are not available. Morphological features of this type of death include organelle swelling, rapid mitochondrial dysfunction, plasma membrane permeabilization, and lack of nuclear fragmentation.

While Bcl-2 proteins and caspases are critical mediators of cell death, these factors also have important non–cell death–related roles. For example, Bcl-2 proteins are also involved in regulating mitochondrial fission and fusion independent of cell death. Caspases also have non–cell death roles, including proliferation, differentiation, and synaptic function (Fuchs & Steller, 2011). For example, caspase 3 is required for long-term depression and AMPA receptor internalization in hippocampal neurons.

The final stage of cell death is the removal of the corpse. This event is as critical as the other steps involved in the cell death process because ineffective removal of dying cells can result in apoptotic cells becoming necrotic and initiating inflammation or an autoimmune response. While nonprofessional phagocytes (e.g., ependymal or Schwann cells) can accomplish this task, professional phagocytes such as macrophages and microglia are most efficient at recognizing and removing dying cells (Mallat, Marín-Teva, & Chéret, 2005).

During early CNS development, microglia are usually not present in large numbers in the area of PCD. Some signal must be sent by the dying cells to recruit the phagocytes into the area. The phospholipid lysophosphatidylcholine, ATP, and UTP are macrophage chemotactic factors shown to be released by dying cells (Lauber et al., 2003; Elliott et al., 2009). Once the phagocytes are recruited to the area, they must be able to distinguish between healthy and dying cells. A series of evolutionarily conserved genes are involved in the expression of recognition markers on dying cells, expression of the receptors on phagocytic cells, as well as for those factors necessary for the processing of the engulfed apoptotic cells (Kinchen & Ravichandran, 2007).

Regulation of cell death is a critical issue in neurons because with only rare exceptions, postmitotic neurons are irreplaceable. One of these regulatory mechanisms is referred to as "competence to die." As neurons differentiate, they develop a dependence on NTF support. At this stage, in order to undergo PCD, developing neurons require not only the release of cytochrome c from mitochondria and caspase activation, but in addition, they require the loss of NTF support. In the presence of trophic support, the x-lined inhibitor of

apoptosis protein (XIAP) serves as a brake on caspase activation when cytochrome c is accidentally released; loss of NTF support removes this brake, thereby creating competence-to-die (Potts, Singh, Knezek, Thompson, & Deshinukh, 2003). Adult neurons also need to be protected from accidental cell death. As postmitotic neurons further mature past the period of naturally occurring cell death, they lose or reduce their dependence on NTFs such that they can now survive following NTF deprivation. This involves a block in the translocation of the pro-apoptotic Bax protein from the cytoplasm to the mitochondria, a failure of cytochrome c release and inhibition of apoptosis (Putcha, Deshmukh, & Johnson, 2000).

Summary

PCD is a metabolically active process that involves specific genetic pathways necessary for the cascade of events leading to degeneration. Several genes in the PCD pathway were first identified in *C. elegans* and homologues have been found in insects and vertebrates. The mitochondrion is a central integrator of cell death signaling. Although most developing neurons appear to share a common core PCD pathway, morphological and biochemical evidence also indicates the presence of alternatives to the core PCD machinery. One consequence of the increased evolutionary complexity in the regulation of neuronal PCD is the availability of additional checks and balances before a cell passes the irreversible point of commitment to die. Because virtually all neurons are postmitotic and neuron numbers finite, multiple, relatively fail-safe, mechanisms are required so that accidental death occurs only rarely.

NERVE GROWTH FACTOR: THE PROTOTYPE TARGET-DERIVED NEURONAL SURVIVAL FACTOR

Following the discovery of NGF by Levi-Montalcini, Cohen, and Hamburger in the 1950s and 1960s, and its possible role in the survival of developing sympathetic neurons, the characterization of the functional role of NGF became the archetypical model for the investigation of other putative NTFs. Analysis of the function(s) of a putative NTF involved several steps. Typically, the biological activities and target cell specificity of putative factors were first investigated *in vitro*. Primary cultures of neurons dissociated from peripheral ganglia were ideal for these early assays. Analysis of the developmental expression of specific NTFs and their corresponding receptors has been used to determine if both the ligand and the receptor are normally present at the appropriate time and place *in vivo* for the putative factor to serve in the regulation of a specific subpopulation of neurons.

In gain-of-function approaches, treatment of embryos with excess exogenous NTF has been used to determine if the survival or differentiation of responsive neurons is restricted by either the production or the access to a limited quantity of endogenous factor. Finally, in loss-of-function approaches, methods that inhibit or prevent the function of specific NTFs or their receptors have allowed investigators to determine whether the perturbation of endogenous NTF signaling alters normal development. These NTF/NTF receptor deprivation experiments have included treatment with activity-blocking antibodies that prevent trophic signaling, treatment with soluble receptor-derived antagonists that compete for and adsorb endogenous ligands, and the generation of transgenic mice with null mutations of either the factors or their receptors.

Sympathetic and sensory ganglia removed from developing animals have been shown to produce a dense halo of neurite outgrowth when treated with NGF. In fact, this "axonal halo" assay—not a neuronal survival assay—was the original biological activity first used to purify and characterize NGF as an NTF. NGF was shown to be required for the survival of dissociated sympathetic and some sensory neurons when they were grown in the absence of nonneuronal cells. This demonstrated that NGF could prevent cell death by the direct activation of receptors on isolated neurons. When developing embryos were treated with excess exogenous NGF, sympathetic and sensory ganglia were enlarged significantly, and neurite growth from these neurons increased markedly. In addition, ganglia in NGF-treated embryos contain many more neurons than normal because PCD had been prevented. The soma was enlarged significantly by NGF treatment, and the dendritic arbors of sympathetic neurons were more complex. These studies indicated that the supply or access to endogenous NGF in sympathetic and sensory targets was likely to be rate limiting for the survival and growth of these dependent populations.

The most convincing evidence that NGF is required for neuron survival has been gained from NGF deprivation experiments. Embryos treated with antibodies that selectively block NGF activity as well as the null mutation of either NGF or its trkA receptor in transgenic mice have both confirmed that sympathetic as well as some sensory neurons require NGF for survival (Fig. 18.8). NGF was localized to the peripheral targets of these neurons at the time of their normal innervation, consistent with its role as a target-derived survival factor. Further, the level of NGF synthesis was correlated with the density of target innervation, and the NGF receptor, trkA,

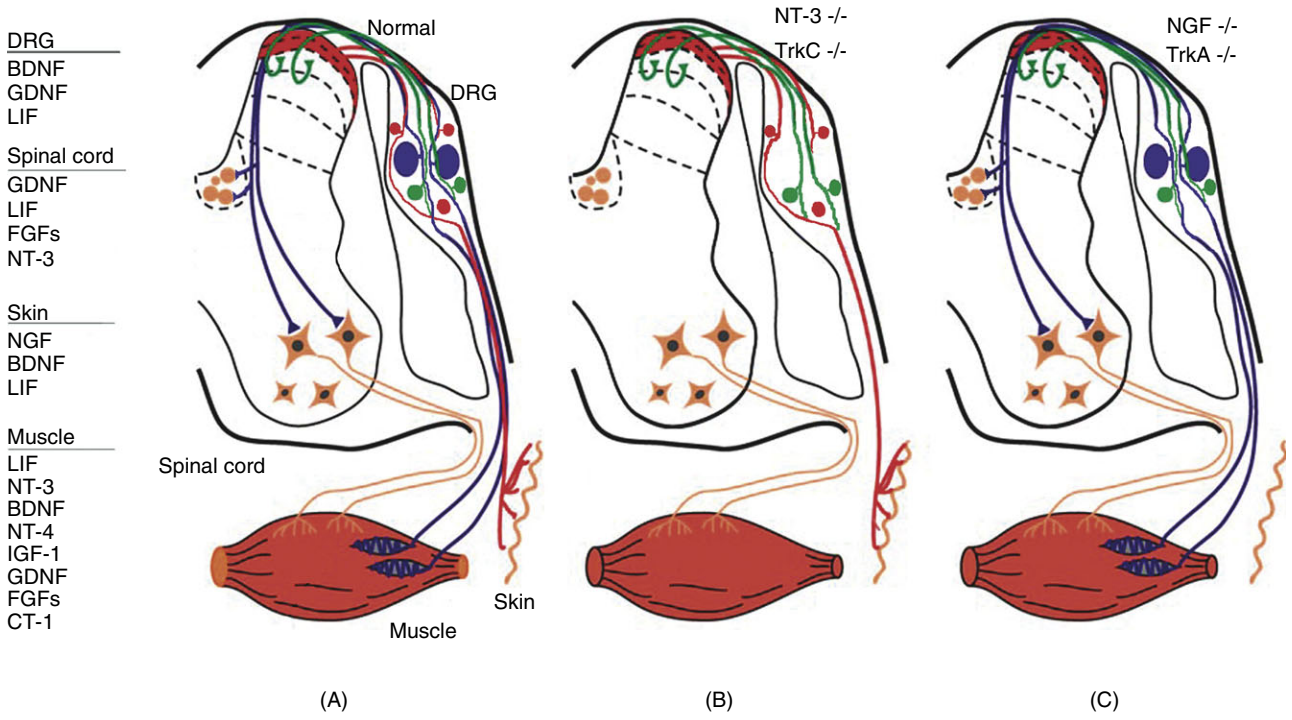


FIGURE 18.8 Phenotypic alterations in sensory/motor pathways caused by null mutations in NGF/trkA and NT-3/trkC. In the dorsal root ganglia (DRG) of normal mice (A), small-diameter (red), medium-diameter (green), and large-diameter (blue) neurons are present. Large-diameter neurons innervate muscle spindles and other proprioceptive end organs and have axon terminations in the lowest laminae of the dorsal horn and in the ventral horn. These neurons are lost when NT-3 or trkC is absent (compare A and B). Many of the small-diameter neurons innervate skin, respond to temperature and pain, and have terminations in the dorsal-most laminae of the dorsal horn. These neurons are lost when NGF or trkA is absent (compare A and C). DRG neurons indicated in green are neurotrophin-independent mechanoreceptive neurons (peripheral projections not shown). *Modified and redrawn with permission from Snider (1994).*

was localized to dependent afferent neurons at the times and places appropriate for regulating normal PCD. The localization of NGF synthesis in sympathetic targets and the loss of these afferent neurons with NGF deprivation firmly established NGF as a prototype target-derived NTF required for the survival of sympathetic neurons and a subset of sensory neurons.

One prediction of the neurotrophic hypothesis is that access to NGF in only the distant target region is adequate to support the survival of the remote cell body. This idea has been tested by Robert Campenot and colleagues *in vitro*. NGF has been applied selectively only to local axon terminals in a three-compartment tissue culture chamber to determine the long- and short-range effects of NGF treatment. NGF-dependent neuronal cell bodies in the central chamber survived when only their terminals were treated with the factor, indicating that target-derived NGF available only to neurites can generate and retrogradely transport the signal required for cell body survival. Peripheral processes were lost rapidly and selectively in outer chambers where NGF was withdrawn but were maintained and grew in the outer chambers where NGF was added. This important demonstration illustrates the capacity of target-derived NGF to have both direct long distance effects on the survival of neurons and direct local effects on the growth, maintenance, and sprouting of axonal branches. In addition, recent studies show that retrogradely transported NGF controls the assembly of afferent synapses on cell bodies and dendrites. NGF-responsive neurons possess both a "ligand-specific" receptor, trkA, and a "common" receptor, p75NTR (Fig. 18.9) that binds all neurotrophins with a similar affinity. Many of the biological activities of NGF have been attributed to the ligand-induced transduction of trkA.

Summary

The modern study of neuronal cell death began with investigations of how synaptic targets of sensory and motor neurons regulate their development. Viktor Hamburger and Rita Levi-Montalcini, beginning in the 1930s, ultimately showed that targets promote the survival and maintenance of innervating neurons. This notion, in turn, provided a conceptual framework for the discovery of the first target-derived NTF, nerve growth factor. From these beginnings, the neurotrophic hypothesis was formulated: neurons compete for limiting amounts of

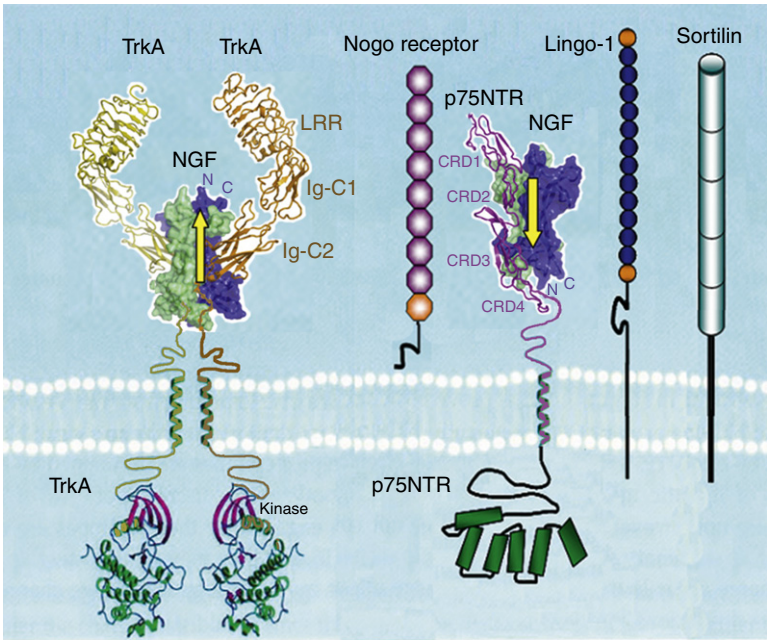

FIGURE 18.9 Models of NGF, the catalytic (full-length) TrkA receptor, and p75NTR and its binding partners (sortilin, Nogo receptor, and Lingo 1). Note the ability of one ligand (NGF dimer) to bring together two trk receptor molecules to initiate signaling. p75NTR lacks a cytosolic kinase domain, but associates with multiple partners (possibly not including direct interactions with trk receptors) to assemble signaling platforms. Note that the NGF dimer binds to a p75NTR monomer in an opposite orientation compared to TrkA (yellow arrows). C and N, C and N termini of NGF; Ig-C1, Ig-C2, C-terminal immunoglobulin ligand binding domains 1, 2; LRR, leucine-rich repeat; CRD 1–4, cysteine-rich domains 1–4. *Modified from Barker (2004) and Wehrman et al., 2007 (Neuron 53, 25-38) with permission.*

target-derived survival promoting (trophic) agents during development. NGF was established as the prototypical target-derived NTF.

THE NEUROTROPHIN FAMILY

Only a few subpopulations of peripheral neurons, including sympathetic and some sensory neurons, are exclusively dependent on NGF for survival during development. The survival of CNS neurons is largely unchanged following the null mutation of NGF. Other survival factors are now known to regulate neuron survival elsewhere in the nervous system. Extracts made from a number of tissues, as well as media containing proteins secreted by a variety of cultured neuronal and nonneuronal cells, have been shown to support the survival of many different classes of neurons that are not NGF dependent and that do not express the NGF receptor trkA, suggesting that additional NTFs exist. Because NTFs are made in extremely low quantities, the biochemical isolation of NGF-related molecules using conventional protein purification methods proved to be difficult.

A significant breakthrough occurred with the purification of a second NGF-related NTF by Yves Barde and colleagues in 1982. Unlike NGF, which was purified several hundredfold from an extraordinarily rich biological source (salivary gland) unrelated to the nervous system, endogenous brain-derived neurotrophic factor (BDNF) was purified several millionfold from adult pig brains. Each kilogram of starting material yielded only a microgram of factor that over time was eventually sequenced and cloned to produce recombinant factor. The molecular cloning and expression of BDNF opened the door for an accelerated period of research on NGF-related factors. When the protein structure of BDNF was compared with NGF, they were both found to encode homodimers of small, very basic secreted peptide ligands with an amino acid homology of approximately 50%. Using polymerase chain reaction primers prepared from homologous domains to search for other related proteins, investigators rapidly identified additional neurotrophin family members in multiple species (Lewin & Barde, 1996). Described as neurotrophins or nerve feeding factors (i.e., NT-3 and NT-4/5, NT-6), these additional proteins were cloned and sequenced without the requirement of exhaustive protein purification.

Each neurotrophin family member is synthesized as an approximately 250 amino acid precursor (proneurotrophin) that is processed into a roughly 120 amino acid protomer. The precursor was initially thought to be functionally irrelevant, but it turned out to have important death-signaling capabilities, as described below. Homologous regions of the several different family members are concentrated in six hydrophobic domains containing cysteine residues. The linkage formed by each homodimer ligand utilizes these regions to form a "cysteine knot" that maintains the twin protomers in juxtaposition. The secreted dimer appears as a symmetrical twin with variable regions containing basic amino acid residues exposed on the surface (Fig. 18.9). Because all family members share this core structure, they are remarkably similar, with three-dimensional symmetry around two axes. The symmetry of this twin structure allows the neurotrophin ligand to activate trk receptors by binding separate

receptor molecules together in the membrane, permitting docking of additional intracellular signaling molecules, and initiation of signal transduction cascades (Fig. 18.9). The exposed outer regions that vary among neurotrophin family members are responsible for receptor-binding specificity.

Summary

The purification, molecular cloning, and expression of BDNF opened a floodgate of research on an NGF-related family of NTFs called neurotrophins or nerve feeding factors. Each neurotrophin family member is synthesized as a pro-neurotrophin that is processed into a homodimer with a conserved region containing a cysteine knot in the core of the molecule. The secreted factor is a symmetrical twin with duplicate sites used for bivalent receptor binding and formation of signaling platforms.

NEUROTROPHIN RECEPTORS

NGF binds to a relatively small number of very high-affinity binding sites and a second set of about 10-fold more abundant, but lower affinity, binding sites at higher concentrations (Roux & Barker, 2002). A 75-kDa protein (p75) was purified and cloned first. This transmembrane glycoprotein with extracellular cysteine repeat motifs shares structural homology with the tumor necrosis factor receptor family. The cytoplasmic domain of p75 lacks the kinase domain present in most growth factor receptors for intracellular signal transduction, but it can associate with several other signaling proteins (discussed later) (Fig. 18.9). When expressed in fibroblasts, this receptor has low-affinity NGF-binding properties (ligand binding is rapidly on and off) and therefore also has been called the low-affinity NGF receptor. This name has proven to be a misnomer, since other neurotrophin family members also bind p75 with a similar affinity. It is therefore more appropriately named the "common" neurotrophin receptor (p75NTR).

A major breakthrough in the characterization of the NGF receptors came with the fortuitous discovery and cloning of an oncogene identified in a human colon cancer. The sequence of this 140-kDa transmembrane protein contained a cytoplasmic kinase common to many growth factor receptors. The corresponding proto-oncogene was named trk (pronounced "track"—for tropomyosin-related kinase). It rapidly was appreciated as a member of the tyrosine kinase-containing receptor superfamily with trk mRNA expression localized to NGF-responsive neurons.

Low-stringency screening of cDNA libraries with the original trk proto-oncogene probes led to the discovery of other related neurotrophin receptors. The NGF binding receptor was called trkA, whereas two additional 145-kDa members of this protein family were named trkB and trkC (Fig. 18.10). Expression of trkA conferred specific high-affinity NGF binding and NGF-induced receptor phosphorylation. NGF-signaling properties have been examined extensively in the NGF-responsive pheochromocytoma (PC12) cell line, derived from adrenal medullary cells. Mutant PC12 cell lines that have lost their capacity to respond to NGF contain many p75NTR receptors but lack trkA. Transfection of these mutant cells with trkA restores their biological responses to NGF treatment. The most convincing evidence for the necessity of trkA comes from the analysis of transgenic mice lacking functional trkA receptors. As expected, these mice have a phenotype that is similar to that of transgenic animals that have a null mutation for NGF (Table 18.2).

The trkB receptor is activated specifically by low concentrations of BDNF or NT-4/5 and, to a lesser extent, by higher concentrations of NT-3. NT-3 activates the trkC receptor most effectively. All trk receptors contain three leucine-rich motifs, two cysteine clusters, and two immunoglobulin-like motifs in the extracellular region, a transmembrane domain, and a tyrosine kinase domain in the cytosolic region (Fig. 18.9). The unusual combination of extracellular motifs makes up the ligand-binding region and places this family in a novel class of tyrosine kinase receptors. The region of highest sequence homology among family members and other growth factor receptors is in the kinase domain.

Receptor isoforms resulting from splice variants of trk mRNA transcripts exist for each family member. A variety of both full-length and kinase-deleted or truncated receptors are widely expressed on neurons throughout

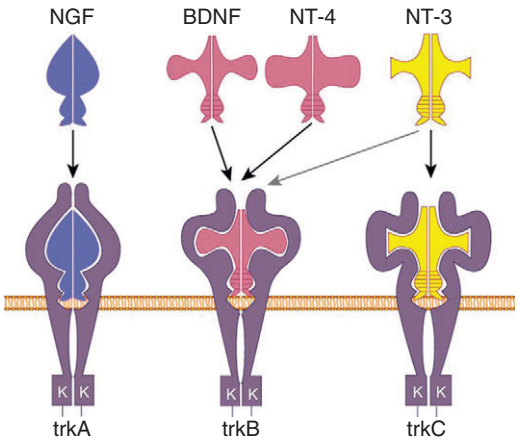

FIGURE 18.10 Ligand binding preferences of neurotrophins for each member of the trk receptor family. Not shown are the truncated (kinase deleted) isoforms of trkB and trkC. Other isoforms containing inserts and deletions also exist, providing a wide variety of receptors. NT-4 is also named NT-4/5. K = tyrosine kinase.

the nervous system. Truncated receptors, which also are expressed on glial cells, can bind and internalize their cognate ligand and are capable of limited signaling, but they cannot initiate the phosphorylation events required for mainstream receptor signal transduction (see below). As a result, the distribution and membrane concentration of truncated receptors could potentially modulate neurotrophin activity.

Although trk receptors account for many of the biological responses of neurons to neurotrophins, p75NTR can modify trk ligand binding and neurotrophin specificity, it associates with additional signaling partners, and can initiate pathways for intracellular signaling independent of trk receptors (Fig. 18.9). Several mechanisms have been proposed to account for an accessory role of p75NTR. The fast on and fast off kinetics of p75NTR could maintain and increase the local concentration of neurotrophins at the membrane surface and thereby increase the access of trk receptors to ligands. The p75NTR does not appear to form a transient heterodimer with trk receptors, and NGF's binding sites overlap in a way that prevents them from binding simultaneously to p75NTR and trkA in a 2:2:2 complex (Fig. 18.9). Despite lack of evidence for a direct p75NTR/trk interaction, p75NTR may still "hand off" the factor for trk binding (Roux & Barker, 2002).

In addition to enhancing NGF binding to and activation of trkA, p75NTR initiates NGF responses in cells that lack trkA. NGF binding to p75NTR can cause activation and nuclear translocation of a transcription factor, nuclear factor kappa B (NFkB), that promotes cell survival. However, p75NTR is related structurally to members of the tumor necrosis factor receptor (TNFR) family, many of which regulate the onset of cell death programs in the immune system and, for that reason, are termed death receptors. The cytoplasmic domain of p75NTR contains a "death domain" sequence similar to active sequences found in the TNFR family, and the p75NTR mechanisms of inducing PCD appear to be shared with other death receptors.

In neurons that express p75NTR but not trkA, NGF or proNGF induce cell death via p75NTR binding (Roux & Barker, 2002). Once bound, p75NTR may activate a PCD signaling pathway via the Jun kinase cascade. The Jun kinase cascade activates the transcription factor p53 with gene targets that include the pro-apoptotic gene BAX. It should be noted that NGF and other trophic factors can be utilized in different cells or in different epochs of time to induce many diverse biological activities. It is noteworthy that under specific circumstances (such as the absence of trk activity), a factor originally identified for the capacity to prevent PCD instead is utilized to execute programs promoting neuronal death.

Neurotrophin receptors were generally considered to be inactive ("neutral" in terms of neuronal survival) unless bound by their ligand. However, as noted above, recent work has shown that several receptors, including trkA and trkC, actively transduce a negative (apoptotic) signal in the absence of the ligand, and thus behave as "dependence receptors" (Mehlen, 2010; Nikoletopoulou et al., 2010).

Summary

Many neurons have both specific and common binding sites for neurotrophins. Biological responses primarily are associated with high-affinity binding and rapid phosphorylation signaling events. All neurotrophins bind p75NTR, the common neurotrophin receptor. p75NTR lacks a cytoplasmic kinase domain but can independently initiate signaling, can associate with additional signaling partners, and can enhance signaling through trkA. There are three tyrosine receptor kinase (trk) family members: trkA, trkB, and trkC. Each receptor binds one or more members of the neurotrophin family. Splice variants of trks result in isoforms that include truncated receptors with reduced signaling capabilities. p75NTR is related to the TNFR family of death receptors and contains a cytosolic "death domain." Activation of p75NTR, especially by pro-neurotrophins, may serve to kill neurons or other cell types through well-established signaling pathways used to promote PCD.

SECRETION AND AXONAL TRANSPORT OF NEUROTROPHINS AND PRO-NEUROTROPHINS

Processing and Secretion of Neurotrophins

Neurotrophins are expressed as larger precursors that are cleaved by furins and prohormone convertases. The extent and location (intra- or extracellular) of cleavage differs between cell types. The precursor forms were believed for a long time to be of little functional significance, and it was thought that the mature neurotrophins were the only important moiety that was secreted. Research by Barbara Hempstead and her colleagues in the early 2000s demonstrated that many cells secrete pro-neurotrophins and that the release of both pro-neurotrophins and mature neurotrophins contributes to the spectrum of physiological functions. Pro-neurotrophins bind with higher affinity to p75NTR than mature neurotrophins and appear to be the "preferred" ligand for p75NTR. Whether endogenous pro-neurotrophins bind with lower affinity to trk receptors is still controversial. To activate different signaling pathways, the neurotrophin-bound p75NTR can associate with several signaling partners, including

Nogo receptor (a GPI-linked protein), sortilin (a member of the VPS10 family), and LINGO-1 (involved in myelin-based growth inhibition; Fig. 18.9). This complex is involved in regulating neurite outgrowth in response to myelin-derived proteins such as Nogo, MAG, and OMgp. Formation of these different platforms may explain the multiple effects of p75NTR in different cell types and contexts. Sortilin also facilitates anterograde axonal transport of trk receptors to the axon terminus, which is required for subsequent retrograde neurotrophin signaling.

The proteolytic cleavage of pro-neurotrophins, and thus the local balance and concentrations of pro- and mature neurotrophins, provides a mechanism to regulate the direction of action of neurotrophins in a wide range of cellular processes (Lu, Pang, & Woo, 2005). Recent work has shown that pro-neurotrophins can be released from neurons, apparently leading to elimination of either competing p75NTR-expressing neurons or neurites, in what may be considered a molecular correlate of neuronal competition (Deppmann et al., 2008; Singh et al., 2008).

Neurotrophic Factors and Synaptic Plasticity

The classic neurotrophic hypothesis postulates that NTFs, including neurotrophins, are released by postsynaptic target cells and bind to presynaptic receptors for internalization, retrograde axonal transport, and activation of signal transduction cascades after arrival at the neuronal soma (Fig. 18.1). Yet, NTF receptors are present on both post- and presynaptic sites of the synaptic cleft. *In vitro* studies have shown that NTFs, and in particular BDNF, have rapid effects on synaptic transmission (McAllister, Katz, & Lo, 1999; Poo, 2001). Numerous studies have confirmed that NTFs have important functions in synaptic plasticity, meaning that these "synaptotrophins" regulate the functional strength of synaptic transmission including long-term potentiation (LTP), an experience-dependent, long-lasting increase in chemical strength of neurotransmission that is a crucial mechanism in learning and memory (Table 18.3).

The regulation of secretion of neurotrophins is particularly important for mechanisms of synaptic plasticity (Lessmann, Gottmann, & Malcangio, 2003). Neurotrophins can be released by constitutive modes (from cell bodies and processes) and by activity-dependent modes of secretion (from dendrites and axons). The pattern of activity, such as high-frequency stimulation, is crucial for the release. LTP is relatively synapse-specific; only active and successfully transmitting synapses are strengthened, so the regulated release of neurotrophins and subsequent signaling should be restricted to active synapses. Depolarization and cAMP-dependent pathways are thought to regulate the locally restricted release of neurotrophins such as BDNF. This may contribute to the local "tagging" or marking of the active synapses destined for strengthening. Trafficking of BDNF mRNA within the neuron might also contribute to synapse-specific plasticity, if the mRNA is "captured" for local translation at active synapses. Interestingly, a naturally occurring polymorphism of the BDNF gene (a Val-Met substitution in the 5'pro-region of BDNF) gives rise to a reduced capacity for activity-dependent (but not constitutive) secretion of BDNF, causing abnormal hippocampal function and some learning and memory deficits in humans (Egan et al., 2003).

TABLE 18.3 Nonsurvival Functions of Neurotrophic Factors[a]

Function	Examples of Relevant Trophic Factors and Cytokines
Cell fate decisions (stem cell/neuronal precursor derivatives)	BDNF, NGF, EGF, NT-3, CNTF, LIF, oncostatin M, CT-1
Axon guidance	NGF, BDNF, HGF, GDNF, neurturin
Neurite growth, branching	BDNF, NT-3, NT-4, CNTF, CT-1, HGF, GDNF, LIF, IGF-I
Myelination	IGF-1, BMPs, NT-3, BDNF, GDNF, CNTF
Dendrite development	BDNF, NT-3, NGF, GDNF
Synapse development	BDNF, NT-3, GDNF, neurturin, NT-4, CNTF
Synapse stabilization and plasticity	BDNF, NT-3, GDNF, FGFs, HGF, VEGF, CNTF, LIF, NGF, IGF-I
Long-term potentiation, learning, and memory	BDNF, NT-3, NGF, NT-4, IGF-I, interleukins
Pain physiology and pathophysiology	NGF, BDNF, GDNF, artemin, NT-3
Neurotransmitter phenotype	NGF, LIF, FGFs, GDNF, CNTF, BDNF, NT-3, IGF-I
Ion channel regulation/function	BDNF, interleukins
Neurological disease and neurodegeneration	
Seizure, epilepsy	BDNF, NGF, NT-3, VEGF, GDNF, LIF, CT-1, oncostatin M, CNTF
Stress, ischemia	NGF, NT-3, BDNF, IGF-I, VEGF, GDNF, HGF, BMPs
Traumatic injury, axonal regeneration, inflammation, stress	GDNF, IGF-I, LIF, CNTF, oncostatin M, CT-1, NGF
Psychiatric disease: depression	BDNF, NGF, FGFs, IGF-I, GDNF

[a]*For references, see Snider (1994), McAllister et al. (1999), Huang and Reichardt (2001), Poo (2001), Chao (2003), Zweifel et al. (2005).*

Endogenous neurotrophins may be derived from either pre- or postsynaptic sites, and they may act on either side of the synaptic cleft in paracrine or autocrine modes to implement functional and structural changes in synaptic plasticity. Trophic responses can also be modified by the recruitment of receptors to surface membranes from internal storage sites. Furthermore, after release and binding of newly synthesized neurotrophins, they can be recycled, and the internalized neurotrophin is not necessarily degraded immediately after the initial binding and internalization steps. Recycled neurotrophins have been shown to play functionally significant roles in LTP.

The Endosome Signaling Hypothesis of Retrograde Axonal Signaling

The neurotrophic hypothesis postulates retrograde axonal movement of trophic signals. Although evidence for retrograde transport of exogenous neurotrophins (NGF) was established in the 1970s, the precise mechanisms of axonal transport of trophic signals from the nerve terminal to the neuronal soma remained largely elusive. The prevailing hypothesis is that neurotrophins bind presynaptic surface membrane receptors on nerve terminals, are internalized, and form a ligand-receptor complex with the neurotrophin inside transport vesicles, leaving the trk receptor with its kinase domain on the outside of the vesicle or endosome (Fig. 18.11). The trk receptors may remain "active" (phosphorylated) during axonal transport along microtubules, because the ligand remains bound to the receptor within the vesicle. When the endosome, with the ligand-receptor complex attached, arrives at the neuronal soma, the phosphorylated trk receptor initiates a signal transduction cascade that results in changes of gene expression. Signaling endosomes can be isolated from axons; trk receptors and other signaling proteins interact at the level of the axon; trks bind to the dynein light chain subunit (part of the dynein motor complex) directly, and thus partake in the axonal transport machinery (Fig. 18.11). Furthermore, axon-derived endosomes that reach the soma may generate a different signal (activate a different ERK) than those generated by binding to cell surface receptors on the soma.

However, not all trophic signals from the nerve terminal that arrive at the soma may require the neurotrophin to be physically transported in a ligand-receptor complex. In addition to retrograde axonal transport from nerve terminals to the soma, trophic signals also are transported anterogradely along axons (possibly even a quantitatively more important route) from soma to nerve terminals, mediated by kinesin motors, followed by activity-dependent release of neurotrophins from axon terminals.

Summary

Expression and secretion of pro-neurotrophins has significant physiological functions in the regulation of cell death. Pro-neurotrophins bind preferentially to the p75NTR. The p75NTR associates with several different signaling partners to form multiple signaling platforms that include sortilin and Nogo receptors. Secretion of neurotrophins requires activity-dependent stimulation patterns that may specifically strengthen active synapses. Neurotrophins are transported retrogradely along axons in signaling endosomes, but they can also be transported anterogradely for release from axon terminals. Trk receptors are expressed both pre- and postsynaptically, forming paracrine as well as autocrine loops of synaptic signaling.

SIGNAL TRANSDUCTION THROUGH TRK RECEPTORS

Neurotrophin binding to trk receptors at the cell surface causes the formation of receptor dimers and coactivation of their tyrosine kinase activity. The homodimeric structure of the factors allows each bivalent ligand to bring two separate receptor molecules into close proximity. Aggregated receptors phosphorylate each other on specific tyrosine substrates within intracellular domains. The generation of phosphotyrosine residues in turn activates the receptor kinase and further catalyzes the formation of large signaling complexes through the recruitment of adaptor proteins. These proteins link the activated receptor kinase with intracellular signaling pathways shared by other growth factors (Ip & Yancopoulos, 1996). Once activated, the receptor initiates intracellular signals both locally in the cytoplasm and by a series of enzymatic cascades that eventually produce changes in gene transcription within the nucleus (Segal & Greenberg, 1996).

Receptor signal transduction involves multiple signaling pathways that can differ between individual neurons or even in the same neurons depending on recent events. Thus, the response of neurons to trophic factor stimuli is dependent on the current intracellular status of the cell in a dynamic fashion. The molecular components of these pathways are so well conserved that many of the signaling proteins are interchangeable among invertebrate and vertebrate species.

Three major pathways have been identified to implement trk signal transduction events that mediate survival as well as many other cellular responses to neurotrophins (Fig. 18.12). They are (1) the *phospholipase C (PLC-g) pathway*, (2) *Ras-MAP kinase pathway*, and (3) *phosphatidylinositol-3 kinase (PI3K) pathway*. The latter two pathways begin with adaptor proteins that contain a structural motif, the src

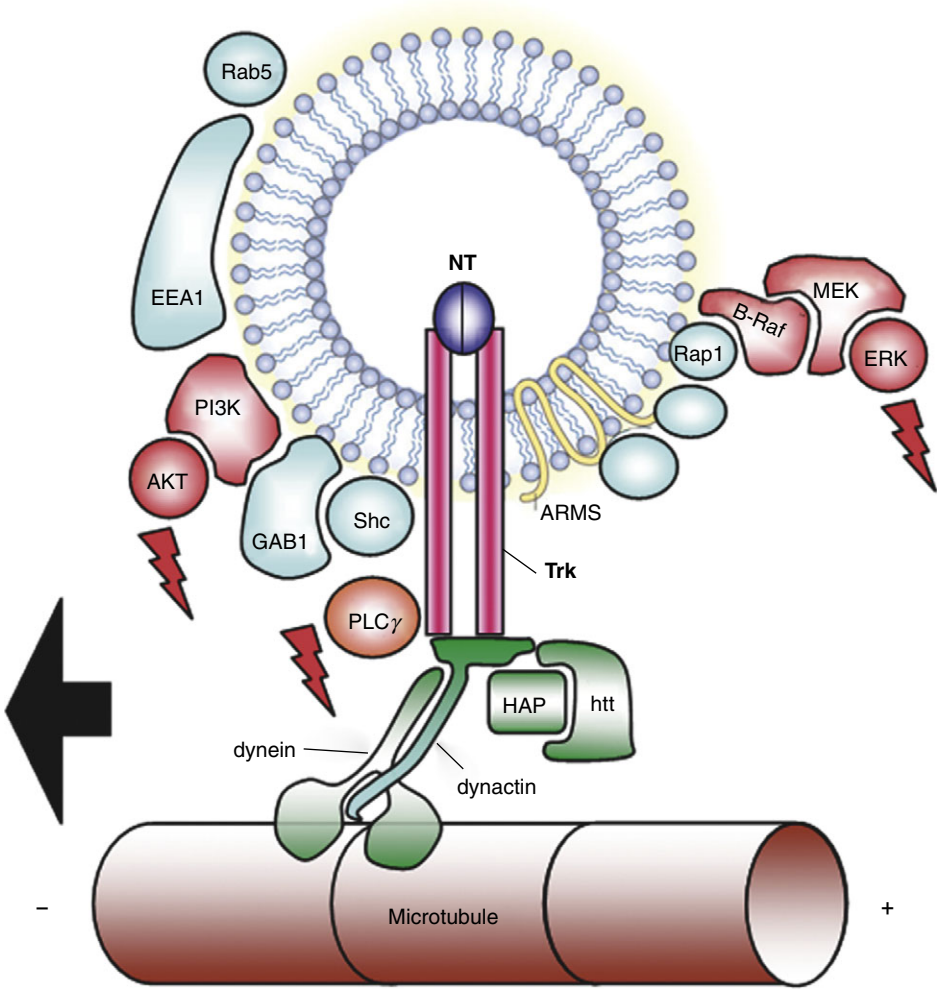

FIGURE 18.11 The signaling endosome. The internalized neurotrophin (NT)–receptor (Trk) complex is transported retrogradely from the nerve terminal to the cell body. The internalized vesicle serves as a platform for docking of adaptor proteins (light blue) that elicit signal transduction cascades via kinases (red); molecular motors and regulators (green) attach for transport along microtubules (brown). The arrow indicates the direction of transport toward the minus end of microtubules. The main signal transduction cascades are via the phospholipase C-γ (PLCγ), Raf-MAPK-ERK, and PI3K signaling pathways (red lightning symbol). For details of signal transduction, see legend to Figure 18.12. Rap1 and Rab5 are small G-proteins. Other abbreviations: Akt, v-akt murine thymoma viral oncogene homologue (protein kinase B); ARMS, ankyrin-rch membrane spanning protein; B-Raf, v-raf murine sarcoma viral oncogene homologue B1; EEA1, early endosome antigen 1; ERK, extracellular signal-regulated kinase; GAB1, GRB2 (growth factor receptor bound protein 2)-associated binding protein1; HAP, huntingtin-associated protein 1; htt, huntingtin; MEK, MAPK (mitogen-activated protein kinase); NT, neurotrophin; PI3K, phosphatidylinositol 3-kinase; Shc, Src homology 2 domain-containing transforming protein C; Trk, trk tyrosine kinase receptor. For details and references, see Zweifel, Kuruvilla, and Ginty (2005) and Gauthier et al. (2004).

homology domain 2 (SH2), which specifically recognizes the phosphotyrosine residue and flanking sequences. PLC-g activity generates two distinct second messenger signals: inositol triphosphate (IP_3) and diacylglycerol (DAG). IP_3 rapidly releases intracellular Ca^2 sequestered in local membrane compartments. This signal initiates the activity of local Ca^2 dependent enzymes (protein kinases and phosphatases). Similarly, DAG regulates the activity of DAG-dependent enzymes. Both Ras and PI-3 kinase pathways are engaged via adaptor and associated linker or extender proteins.

One of the best known Ras-dependent signaling pathways involves the ERK family of MAP kinases. This cascade is composed of serine/threonine kinases that are serially phosphorylated and activated. The initial member of this cascade is Raf, which phosphorylates and activates MEK, which phosphorylates the MAP kinases (ERK1 and ERK2). Once activated, these MAP kinases in turn phosphorylate a number of cytoplasmic and nuclear effectors. Importantly, activation of MAP kinases and their substrate, the protein kinase RSK, results in the phosphorylation of a number of transcription factors, including CREB (cAMP responsive element-binding protein), which controls expression of immediate-early genes (i.e., *c-fos* and *c-jun*) and delayed response genes. Once activated, transcription factors cause rapid and long-lasting changes in gene expression regulating cell survival, axonal and dendritic growth, neuronal differentiation, synaptic potentiation, and plasticity. In addition, the requirement on Ras-dependent pathways for biological responses varies among neuron types.

Neurotrophic factor receptor activation of the PI-3 kinase pathway is essential for the normal survival of many neurons. The phosphatidyl inositides made by PI-3 kinase regulate in part the activity of AKT (protein kinase B). This important protein kinase plays a critical role in controlling the biological activity of several regulatory proteins that govern normal PCD (see Fig. 18.12 and previous sections). Trk receptor activation of both the PI-3 kinase and the Ras-ERK pathways suppresses the capacity of activated p75NTR to induce cell death programs via Jun kinase. p75NTR may therefore induce neuronal death when appropriate neurotrophin binding to trk receptors is absent. Interactions between the multiple trk receptor signaling pathways in different cell

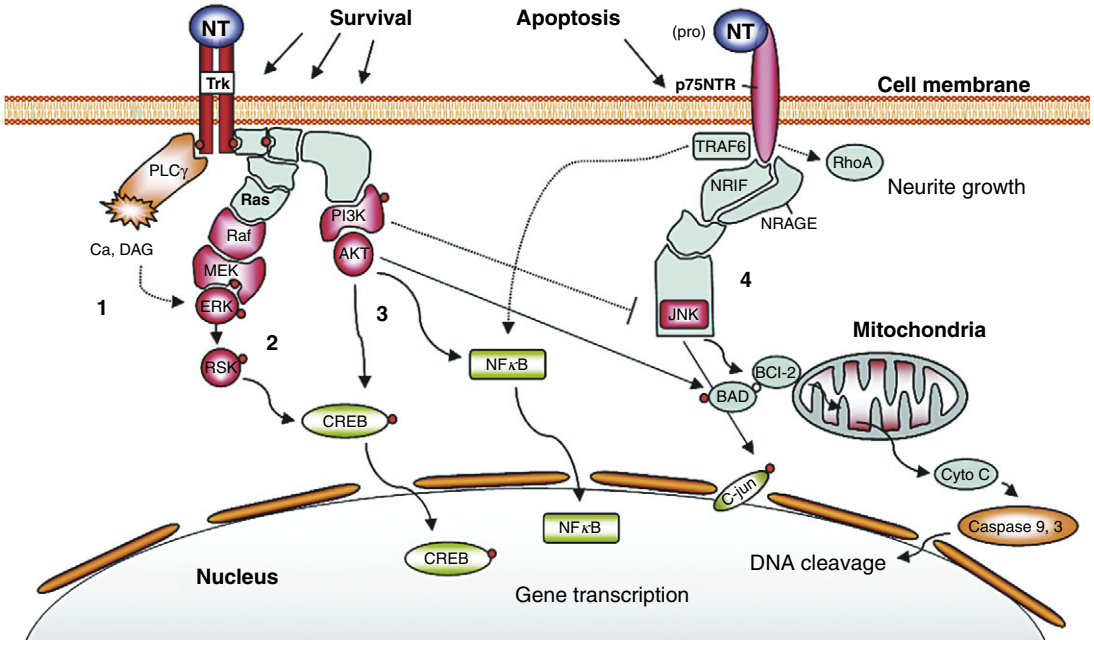

FIGURE 18.12 Trk and p75NTR signaling pathways. Neurotrophin (NT) dimers bind two trk receptor monomers or one p75NTR to activate survival (1–3) or apoptotic (4) signaling pathways. Ligand binding initiates trk receptor transduction by the phosphorylation (indicated by small red dot) in the cytoplasmic domains. The activated Trk kinase docks adaptor and linker proteins (light blue), which engage signaling cascades often containing multiple kinases (red). The three principal signaling pathways illustrated are the (1) phospholipase C pathway, (2) Ras-MAP kinase pathway; and (3) PI-3 kinase pathway. These pathways lead to nuclear translocation of transcription factors (green), such as CREB and NFκB, and ultimately regulation of gene expression. The binding of neurotrophins or proneurotrophins to p75NTR can activate BAD via the JNK cascade and eventually engages, via release of effectors from mitochondria, caspases involved in apoptosis (see also Fig. 18.7). There are several venues for crosstalk between the survival- and pro-apoptotic signaling cascades as indicated. Abbreviations not already explained in Legend 18.11: BAD, bcl2-antagonist of cell death; Bcl2, B-cell lymphoma 2; Ca, calcium; CREB, cyclic AMP response element binding protein; Cyto C, cytochrome C; DAG, diacylglycerol; JNK, C-Jun N-terminal kinases; NFκB, nuclear factor-kappa B; NRAGE, neurotrophin receptor interacting MAGE (melanoma antigen gene expression) homolog; NRIF, neurotrophin receptor interacting factor; p75NTR, p75 neurotrophin receptor; (pro)NT, pro-neurotrophin; Raf, Ras, and RhoA, small GTPases; RSK, ribosomal S6 kinase. For details, see text, and Huang and Reichardt (2001), Chao (2003), and Barker (2004).

phenotypes and under a variety of dynamic receptor signaling conditions provide a rich assortment of interrelated mechanisms to govern the PCD machinery.

Summary

Three tyrosine receptor kinases and trk family members—trkA, trkB, and trkC—transduce neurotrophin signals. Signaling pathways used by the trk family members are shared with those activated by many other growth factor receptors. Neurotrophin binding to trk causes receptor dimerization and phosphorylation of cytoplasmic tyrosine residues. Phosphotyrosines recruit cytosolic adaptor proteins that couple the activated receptor with intracellular signaling pathways. The biological response of the cell to a neurotrophic factor is dependent on the dynamic status of the pathway that can vary with recent cell history. Three of the well-known signaling pathways are PLC-g, Ras-ERK kinase, and PI-3K. Normal PCD is governed in many neurons by PI-3 kinase activation of the protein kinase Akt. Trophic factor deprivation of dependence receptors can activate pro-apoptotic mechanisms that promote cell death.

MULTIPLE CYTOKINES AND GROWTH FACTORS IMPLEMENT NEUROTROPHIC ACTIVITIES

Several Cytokines Mediate Cell Interactions within the Nervous System

We have emphasized neurotrophins as an example of the activities of NTFs in the developing and mature nervous system. Yet there are several other important families of NTFs. Often NTF families utilize receptors with co-receptor complexes (e.g., neurotrophins—trk, p75NTR; and GDNF family ligands—ret and GFRs). In many tissues, intercellular induction factors are important for governing the proliferation and differentiation of both embryonic and adult stem cells. In addition, these factors also play an important role in the response of tissues to trauma, inflammation,

infection, or tumor growth. In 1974, Stanley Cohen proposed that both lymphocyte-derived and nonlymphocyte-derived chemotactic and migration inhibitory factors be grouped into families of cytokines ("cell movement factors"). More recently, this term has been adopted as a general umbrella for many families of secreted proteins that mediate diverse biological responses, including changes in the immune system (interleukins), tumor cytotoxicity (tumor necrosis factors), and inhibition of viral replication or cell growth (interferons) (Table 18.4).

Many cytokines originally were named according to the particular biological activity that was utilized for their isolation, only to be later rediscovered or identified as important mediators of other physiological processes. For example, some factors were isolated on the basis of their ability to enhance the survival of specific populations of neurons isolated *in vitro*. These include ciliary neurotrophic factor (CNTF); glial cell line–derived neurotrophic factor (GDNF); and the other GDNF family members, neurturin, persephin, and artemin. CNTF is a member of a broader family of neuropoietic cytokines, including leukemia inhibitory factor (LIF), oncostatin M, cardiotrophin-like cytokine/cytokine-like factor (CLC/CLF) and cardiotrophin-1 (CT-1), that share a common three-dimensional structure and receptor subunits. CNTF originally was isolated and named because it supports the survival of neurons cultured from the parasympathetic ciliary ganglion.

The GDNF family primarily supports enteric neurons, dopaminergic neurons, and some motoneurons. Other proteins that originally were identified as mitogens or chemotactic factors in nonneuronal tissues also have been shown to affect either the survival or the differentiation of neurons, including the fibroblast growth factors (FGFs), insulin-like growth factors (IGFs), and hepatocyte growth factor (HGF). More recent additions to this list include cerebral dopamine neurotrophic factor (CDNF) and mesencephalic astrocyte-derived neurotrophic factor (MANF) (Lindholm & Saarma, 2010). The first neuronal function identified for LIF was the induction of cholinergic properties in cultured sympathetic neurons, but it also supports the survival of several classes of neurons and induces neural precursors to become astrocytes.

LIF, which has a number of actions in the immune system and other nonneuronal tissues, shares receptor subunits with the CNTF family and therefore can mimic both the survival and the cholinergic differentiation activities of CNTF observed in culture. Many cytokines important for the development or maintenance of other organs and tissues are also widely expressed within the nervous system. Their roles in the nervous system, however, remain to be defined. Likewise, factors first recognized as neuronal survival factors have mitogenic properties for either nonneuronal cells or neuronal precursors. As a result, these pleiotropic factors are grouped into families based on their protein sequences and receptor usage rather than on their biological properties. Table 18.4 summarizes major known ligands, receptors, and biological functions for cytokines and growth factor families.

Neurotrophic Factors Have Multiple Activities

Neurotrophic factors that prevent neuronal death during development appear to have many other important biological activities, including effects on cell

TABLE 18.4 Cytokine and Growth Factor Families

Family	Representative Members	Original Biological Activities
Neurotrophins	NGF, BDNF, NT-3, NT-4/5, NT-6	Neuronal survival and differentiation
Neuropoietic cytokines	CNTF, LIF, CT-1, CLC/CLF, oncostatin M	Survival of ciliary neurons and motoneurons, leukemia inhibitory activity, increased cholinergic properties
Tissue growth factors	TGF-α, TGF-β, FGFs, IGF-Iα,	Cell proliferation and differentiation in diverse tissues and organs
GDNF family	IGF-Ib, IGF-II, EGF, PDGF GDNF, neurturin, artemin, persephin	Neuronal survival and dopaminergic cell differentiation, and morphogens in kidney and sperm development
Interleukins	IL-1α, IL-1β, IL-2 through IL-15	Immunoregulation, diverse activities in the immune system
Tumor necrosis factors	TNF-α, TNF-β	Tumor cytotoxicity
Chemokines	MCAF, MGSA, RANTES, NAP-1, NAP-2, MIP-1	Leukocyte chemotaxis and cell activation
Colony-stimulating factors	G-CSF, M-CSF, GM-CSF	Hematopoietic cell proliferation and differentiation
Interferons	IFN-α, IFN-β, IFN-γ	Inhibition of viral replication, cell growth, or immunoregulation
CDNF/MANF family	CDNF, MANF	Survival of dopaminergic neurons

proliferation, migration, differentiation, axonal growth and sprouting, alterations in dendritic arbors, and synaptic plasticity of the nervous system (Table 18.3). Frequently, different populations of neurons respond to the same factor in distinct ways, and the same neuron may respond differently to the same factor at different developmental stages. Variations in neuronal responses to the same factor appear to depend not only on modifications of trophic receptors and their binding partners, but also on potential differences in the intracellular context of downstream signaling pathways. The distinctive activities of an NTF on different cells or during different epochs of development reflect the intrinsic properties of differentiating neurons or a dynamic change in a trophic response due to alterations in neural activity or other signaling events.

As described earlier, neurotrophins have been shown repeatedly to play fundamental roles in the survival of many peripheral neuronal populations (Table 18.2; Fig. 18.8). However, relatively few changes in the number of neurons have been observed in the CNS of neurotrophin or trk receptor null mutant mice. This observation was surprising because significant cell death occurs in the CNS, and NTFs and their receptors are widely expressed in the CNS during this period. The complexity and number of synaptic relationships established by CNS neurons compared to those established by PNS neurons may partially explain why CNS neurons are not as sensitive to the loss of a single neurotrophin or neurotrophin receptor (Fig. 18.13). The trophic support to CNS neurons is likely to arise from multiple families of NTFs with possible synergistic and/or compensatory effects.

The traditional view of the neurotrophic hypothesis has been that trophic support is derived from target tissues, but other sources of trophic support are now recognized (Figs. 18.13 and 18.14). Interpretation of mRNA localization studies is complicated by the fact that NTFs may not simply be released locally in the region of the cell body, but may also (or instead) be delivered to distant regions of the nervous system by anterograde or retrograde axonal transport. Thus, although the original neurotrophic hypothesis that neurons depend on target-derived trophic factors still holds true for many neurons during critical periods of development (including sympathetic neuron dependence for target-derived NGF), other sources of trophic support appear to play an important functional role in development, as briefly described

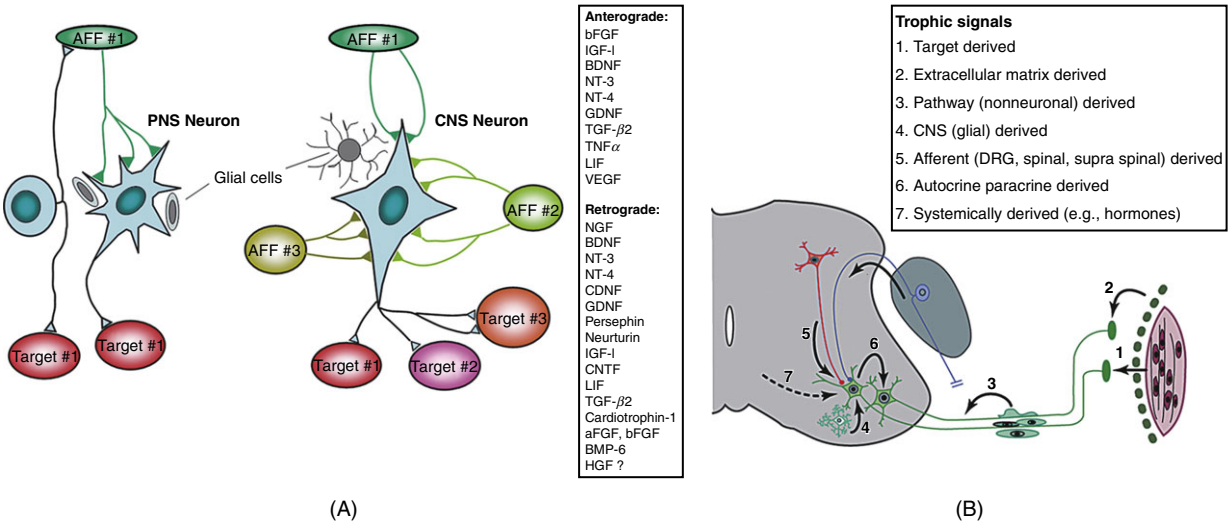

FIGURE 18.13 Possible sources of trophic support for peripheral (PNS) and central (CNS) neurons. (A) Many peripheral neurons such as sympathetic and bipolar sensory neurons (left side) have only two sources of support: one in the periphery (Target #1) for retrograde support and one from afferents (AFF #1) or the central target (for bipolar sensory neurons). Glial cells (gray) may also provide trophic factors. In contrast, central neurons (right side) receive synaptic input from many different types of neurons (AFF #1, 2, and 3), which may serve as a source of anterograde trophic support. Central neurons may also project to several different targets (Targets #1, 2, and 3), which each may provide retrograde trophic support. We list trophic factors that have been demonstrated to be either anterogradely or retrogradely transported along axons, with question marks when transport is suspected, but not proven. *Adapted, with permission, from Snider (1994) and von Bartheld, Wang, and Butowt (2001).* (B) Schematic illustration of different sources of potential trophic signals acting on one specific cell population (motor neurons in the spinal cord). Motor neurons (green cell bodies) can receive trophic support from a number of different sources. Axon terminals of the motor neurons have access to diffusible muscle-derived (1) or extracellular matrix-associated (2) trophic factors. Schwann cells (3) in the peripheral nerve or ventral root are another source of trophic support. Glial cells (4) in the spinal cord (astrocytes and/or oligodendrocytes) may also influence motor neuron survival. Motor neurons receive afferent input from several sources, including descending fibers from the brain, spinal interneurons, and axons from dorsal root ganglion (DRG) neurons (5), which can supply trophic support. Finally, motor neurons may influence their own growth and survival via autocrine or paracrine trophic support (6), as well as respond to trophic support provided by circulating hormones (7).

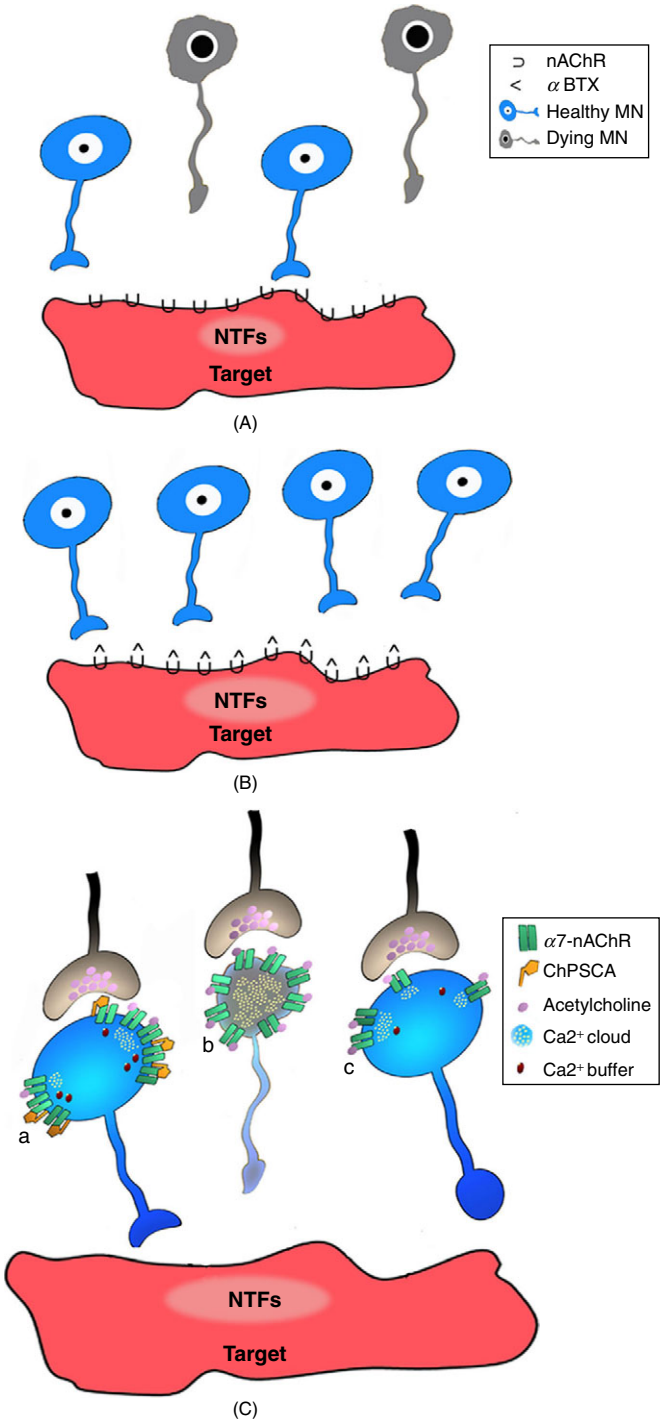

FIGURE 18.14 During embryonic/fetal development motoneurons establish functional synaptic connections with skeletal muscles via the neuromuscular junction (NMJ). This normal synaptic transmission activates skeletal muscles resulting in embryonic movements. If left unperturbed, this muscle activity reduces the production of (or access to) muscle-derived NTFs resulting in the PCD of a subset of motoneurons (MNs) (A). By contrast, if muscle activity is blocked, either genetically or pharmacologically, causing paralysis, the PCD of MNs is prevented (B). In addition to the role of synaptic activity at neuronal targets (e.g., the NMJ) in regulating PCD, afferent synapses also play a role in regulating PCD. A model is illustrated that integrates afferent- and target-derived influences on the choice of neuronal death or survival (C). In the developing chick embryo ciliary ganglion (CG, blue cells), young CG neurons are very heterogeneous with respect to the number of α7nAChRs that regulate calcium influx (e.g., b vs c) and they are already innervated by afferent cholinergic axons from the accessory oculomotor nucleus (gray terminals). There is also very little of the endogenous chicken prostate stem cell antigen (chPSCA), a prototoxin that blocks α7nACHR activation (b). Thus, young neurons with excessive α7nAChRs have a higher probability of PCD. As the developing neurons grow out axons that reach their targets in the eye, they become exposed to target-derived NTFs such as CNTF, GDNF, activin as well as other as yet unidentified factors. The influence of these factors facilitates maturation of the neurons, enhancing calcium buffering as well as inducing the expression of chPSCA. The end results are mature neurons (a), stable synapses, a population of silenced nAChRs together with active nAChRs at the stabilized synapses (*Part **C** courtesy of Rae Nishi; see Hruska and Nishi, 2007 (J. Neurosci.* **27**, *11501-11509)*).

earlier. Additionally, as described below, neuronal survival not only depends on competing successfully for trophic support but also on avoiding those cell–cell interactions that can actively kill cells, another example of how the traditional view of the neurotrophic hypothesis has had to be modified.

Finally, although beyond the scope of the present chapter, neurotrophins and other NTFs and their receptors also are distributed throughout the mature brain, and NTFs can alter neural activity by rapid and long-term changes in synaptic transmission. Neurotrophins and other NTFs also play a role in modulating long-term changes in functional and anatomical plasticity in the developing and mature brain by altering long-term potentiation, synaptic connectivity, development of adult-generated neurons, and responses to stress, inflammation, and trauma (Table 18.3).

Summary

There are multiple families of NTFs. CNTF and LIF belong to a neuropoietic cytokine family. The expression and biological properties of these cytokines distinguish them from neurotrophins. They possess widespread neurotrophic activity for many different neuronal and nonneuronal populations *in vitro* and facilitate the cholinergic differentiation of sympathetic and motor neurons. The GDNF family (GDNF, neurturin, artemin, and persephin) is related to the TGF-β gene family and has effects on enteric, dopaminergic, and motor neurons. FGFs may play important roles during development or after injury. NTFs have different functions

during different developmental stages: After early effects on proliferation and phenotype determination (stem cells), NTFs influence neuronal migration, survival, differentiation, and dendritic, as well as axonal growth. At later stages, NTFs regulate synaptic competition and plasticity, LTP, responses to injury, regeneration, and adult neurogenesis. The activity of multiple trophic factors from multiple sources is integrated to achieve a functional circuitry.

PROGRAMMED CELL DEATH IS REGULATED BY INTERACTIONS WITH TARGETS, AFFERENTS, AND NONNEURONAL CELLS

The PCD of vertebrate neurons and their precursors can occur at any stage of neuronal development from neurogenesis and neurulation to the time of establishment of synaptic connections with targets and afferents, and can involve mitotically active cells and migrating neurons, as well as undifferentiated and immature postmitotic cells (Fig. 18.3). However, the most common and historically the best studied type of PCD of neurons involves postmitotic, differentiating cells that die while establishing synaptic connections with other neurons and target cells (Oppenheim, 1991).

Because massive neuronal death and its regulation were first clearly recognized in early studies of neuron-target interactions (Oppenheim, 1981; Cowan, 2001), the role of targets in controlling PCD historically has received the most attention. However, as discussed in the previous section, signals derived from afferent inputs, as well as from nonneuronal cells such as central and peripheral glia and endocrine glands (e.g., steroid hormones), have now been shown to be possible sources of trophic regulation of cell death and survival (Fig. 18.13).

Studies of the regulation of vertebrate neuronal PCD have shown that targets are critically involved in regulating how many postmitotic cells in the innervating population survive or die; in this way the final number of surviving neurons can be maintained at an optimal level despite individual differences in target size. Complete or partial deletion of targets reduces survival, whereas increasing the size or number of available targets results in increased survival (Oppenheim, 1991).

As noted in a previous section, if too few neurons are generated by proliferation in individual animals, the extent of PCD in that population may be curtailed so as to preserve an optimal quantitative relationship between neurons and their synaptic targets (DeMarco Garcia & Jessell, 2008). Although it is thought that the relationship between neuronal survival and the availability of synaptic targets is proportional and linear (this has been called numerical-, quantitative-, size-, or systems-matching), there may also be other ways in which the number of neurons that innervate a target can be regulated. For example, signals from glial cells along axon pathways may modulate neuron numbers prior to target innervation. Spinal motoneurons provide one of the best examples of how systems-matching is regulated by a competition for target-derived signals (NTFs) that promote survival (the Neurotrophic Hypothesis).

However, before discussing the example of motoneurons, it is first necessary to discuss the principle of competition. Competition at the cellular level is a key principle in the conceptualization of neuronal death and survival. It occurs when individual cells with different properties interact with each other, directly or indirectly, and results in the survival of the "stronger" cell and the death of the "weaker" cell. However, despite its long history, neither the origins of nor the characteristics themselves that define weak versus strong neurons are well understood (Oppenheim, 1991).

Cells commonly adopt different phenotypes by virtue of either their lineage (autonomous specification) or cell–cell interactions (conditional specification). In some cases, however, cells may initially differ stochastically, independent of either lineage or cell–cell interactions, by the random generation of genetic noise and a means to amplify and stabilize the noise-generated differences between cells (Losick & Desplan, 2008). Although speculative, it seems plausible that the generation, amplification, and stabilization of genetic noise could provide a separate mechanism whereby neurons become "stronger" (winners) by virtue of, for example, their expression of NTF receptors or of other features that confer a competitive edge over "weaker" cells (the losers).

In the case of avian spinal motoneurons that innervate limb skeletal muscle, the number of neurons that survive the period of PCD bears a 1 : 1 relationship with the number of primary myotubes present in individual muscle precursors during the period of cell death, rather than being correlated with the final number of myotubes or myofibers (i.e., muscle size) present after the cessation of cell death. Accordingly, in this situation, motoneuron numbers are controlled, in part, by signals that are limited by the number of primary myotubes available. Although for many populations of neurons the essential factors provided by targets that mediate neuronal survival are not known, extrapolation from what is known for sensory, sympathetic, and motor neurons suggests that specific target-derived NTFs are involved. The PCD of CNS neurons in the avian isthmo-optic nucleus and neurons in the mammalian

thalamus and substantia nigra are controlled by many of the same mechanisms involved in the PCD of peripheral neurons, including a need for target- and afferent-derived signals. As discussed previously, the survival of myelin-forming glial cells also involves competition, in this case, competition for trophic signals derived from axons. In both neurons and glia, the final outcome of this competitive process (Figs. 18.3 and 18.4) is the survival of optimal numbers of cells for innervation (neurons) or myelination (glia).

Motoneurons (and some other neuronal populations as well, including retinal ganglion cells, isthmo-optic neurons, and ciliary ganglion neurons) have another interesting property in that their target dependency appears to be regulated by physiological synaptic interactions with their targets (Oppenheim, 1991). For example, following the formation of initial synaptic contacts between motoneurons and target muscles, the initiation of synaptic transmission activates the muscle and results in overt embryonic movements. Chronic blockade of this activity during the cell death period with specific drugs or toxins that cause paralysis, or in genetic mutants lacking synaptic transmission, prevents the death of all motoneurons (Fig. 18.14).

Because PCD is enhanced after the pharmacological blockade of afferent synaptic activity, the functional input provided by afferents also appears to be of fundamental importance in this situation. Functional afferent input may act to regulate the survival of both developing and adult-generated postsynaptic neurons by several different mechanisms:

1. Neurotransmitter release results in depolarization by afferent signals that can alter intracellular calcium levels in postsynaptic cells, which in turn can independently modulate survival.
2. Afferent activity can regulate the expression of NTFs and their receptors in postsynaptic cells.
3. The activity-dependent release of NTFs from terminals of afferent axons or from adjacent glial cells may also provide survival signals to postsynaptic cells.

In addition to the survival-promoting role of afferent-derived signaling, in some neuronal populations afferents may also have the counterintuitive role of promoting either death or survival depending, in part, on the extent to which receptor-mediated afferent signals change calcium influx: high influx promotes death, and low or moderate influx promotes survival. Because these neurons may also depend upon target-derived NTF signaling for survival, when taken together this kind of evidence indicates that the original version of the neurotrophic hypothesis is no longer sufficient for understanding the complexity of the cell–cell interactions involved in regulating the survival and death of developing neurons (Fig. 18.14). Competitive differences between neurons in a population may involve success in competing for survival-promoting signals as well as competitive success in avoiding death-promoting signals (Fig. 18.15) and these signals may include activity-independent signals derived from targets, afferents, and nonneuronal cells. In the final analysis, the various target- and afferent-derived extrinsic signals influence survival (or death) by modulating intracellular signaling pathways that regulate the expression of pro- and anti-apoptotic gene products (Figs. 18.7 and 18.12).

Although the cellular mechanisms are not yet well established, the survival and death of newly generated neurons in the adult hippocampus (Fig. 18.16) and olfactory system provide another example of how afferent activity can regulate these events. For example, learning, stress, motor activity, sensory stimuli, and other environmental influences appear to control granule cell numbers in the dentate gyrus of the hippocampus by activity-dependent modulation of neuronal survival, and odor experience modulates the survival of adult-generated olfactory neurons. Similar to developing neurons during embryonic and postnatal stages, the default state of developing adult-generated neurons is PCD and their survival, differentiation, and incorporation into functional circuits requires synaptic input and NTF signaling (Gage et al., 2008). Although there is still debate and controversy over whether and if so how adult-generated neurons contribute to brain functions that mediate learning, memory, and neural plasticity, increasing evidence supports the role of adult neurogenesis in specific behavioral adaptations.

Summary

During development, the fate of a cell, including the decision to live or die, can be determined by intrinsic cell-autonomous mechanisms or by extrinsic signals derived from cell–cell interactions. The survival of most developing neurons is likely to be dependent on a variety of signals, including multiple NTFs derived from diverse sources, that serve to maintain survival and regulate differentiation in complex ways that reflect the specific requirements of neurons at each step in their development. Targets and afferents provide critical survival-promoting signals that prevent PCD. One major class of such signals are NTFs. Neurons are thought to compete for limiting amounts of these NTFs. For many populations of neurons, synaptic transmission and physiological activity also plays an important role in regulating survival. Accordingly, both NTFs and electrical activity/synaptic transmission are important for the regulation of PCD and are closely linked functionally.

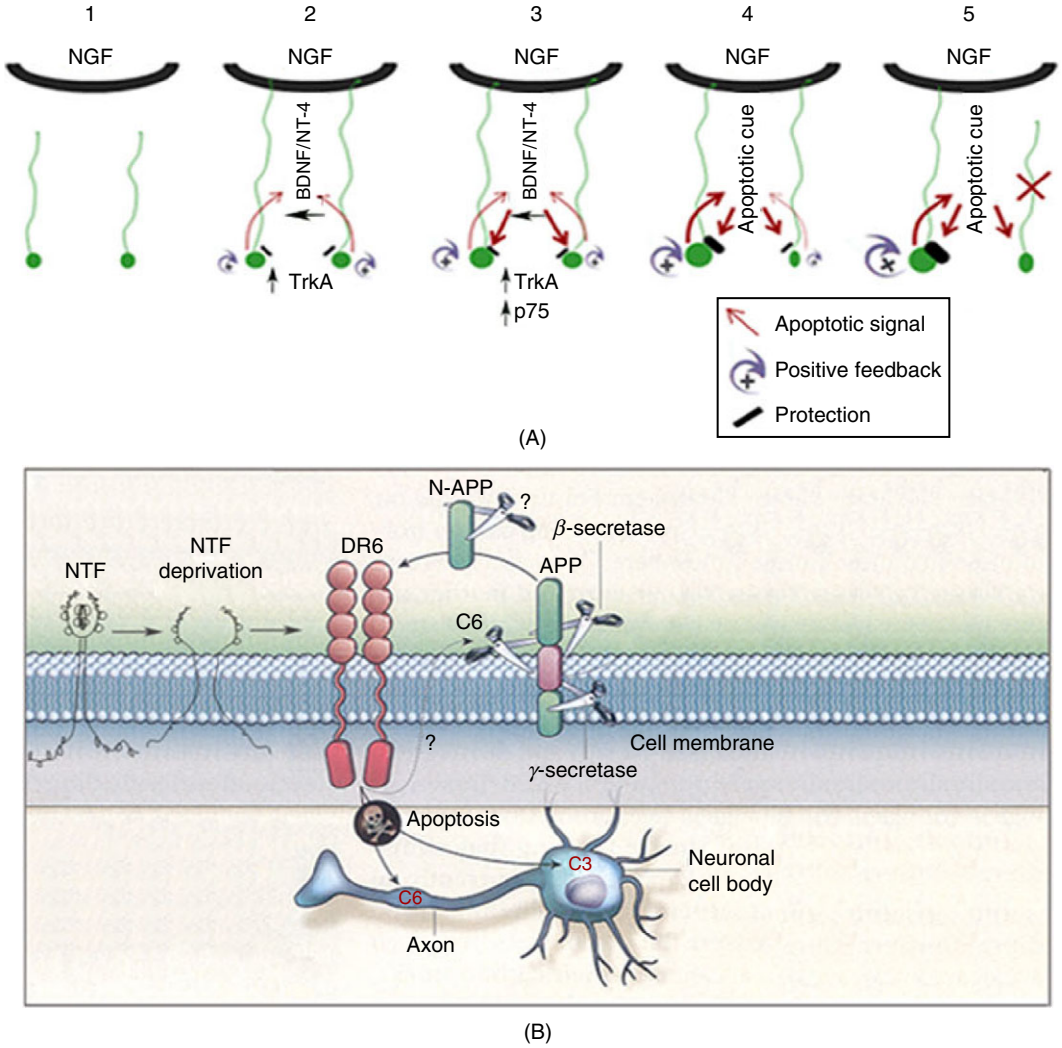

FIGURE 18.15 In (A) a model for developmental competition based on studies of developing sympathetic neurons is illustrated: (1) Before target innervation neurons (green) are modestly responsive to NGF; (2) upon target innervation and exposure to NGF, levels of TrkA, then BDNF and NT-4 (not shown) are increased; (3) induction of p75NTR expression, as well as differential sensitization of neurons, by modulation of NGF-TrkA signal strength and duration. (4) BDNF and NT-4 (apoptotic cues) kill neurons with low NGF-TrkA signaling; neurons with high NGF-TrkA signaling are resistant; (5) selection and neuronal death (*Adapted from Deppmann et al., 2008, Science* ***320****, 369-373*). In (B) a model of neurodegeneration involving the selective loss of developing neurons and their axons is illustrated. Following NTF deprivation the transmembrane amyloid-ß precursor protein (APP) is routinely cleaved by ß- and γ-secretase enzymes to generate both amyloid-ß peptide (Aß) and the amino-terminal portion of APP (N-APP). The soluble N-APP may then undergo further processing before binding to the death receptor DR6. DR6 responds to interaction with N-APP by engaging and activating key mediators of apoptotic cell death: caspase-3 (C3) in the neuronal cell body and caspase-6 (C6) in axons. Caspase-6 can also cleave APP near the ß-secretase target site, potentially contributing to the formation and/or amplification of this apoptotic circuit (*adapted from Nicholson, 2009, Nature* **457**, *970-971*).

THE ROLE OF TROPHIC FACTORS AND PROGRAMMED CELL DEATH IN NEUROPATHOLOGY

The role of trophic factors and the widespread occurrence of PCD during normal development indicate that cell loss, together with cell production (proliferation), is a fundamental mechanism for controlling final cell numbers in many tissues. During development trophic factors promote neuronal development, survival, and function. Therefore, it is not surprising that much research has been devoted to exploring their use as therapeutic agents to protect neurons in neuropathology (Lanni, Stanga, & Govoni, 2010). Trophic factor administration has been explored in animal models of many disorders of the nervous system, including the neurodegenerative diseases such as Parkinson's Disease (PD) and Amyotrophic Lateral Sclerosis (ALS) (Rangasamy, Soderstrom, Barkay, & Kordower, 2010; Gould & Oppenheim, 2011).

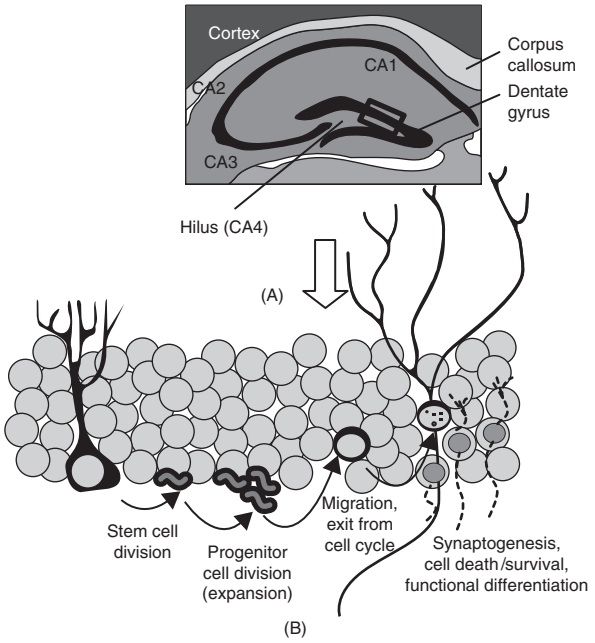

FIGURE 18.16 Schematic illustration of the hippocampus (A) including the dentate gyrus, a portion of which is shown enlarged in B. (B) The dentate gyrus is comprised of several layers of differentiated granule cells (light gray circles and dark cell with dendrites on left). Stem cells in lower subgranule layer of dentate gyrus undergo cell division and a subset of these migrate into the granule layer and differentiate (cell with dendrites on right) whereas others migrate and begin differentiation but then undergo PCD (small dark cells with dashed axons and dendrites). *Modified and redrawn from Kempermann (2006).*

In ALS, motoneurons become dysfunctional and die. Many trophic factors such as IGF-1, BDNF, GDNF, and CNTF that promote motoneuron survival during development have been administered to the ALS mouse model with positive results. These encouraging results of preclinical studies where administration of trophic factors promoted neuronal survival and delayed disease progression led to numerous clinical trials in ALS patients. Unfortunately, the results from the animal model studies did not translate into positive results in clinical trials. The failure of the clinical trials, however, does not warrant dismissal of the therapeutic potential of trophic factors, but rather brings to light the complexity of developing effective therapeutics for neurodegenerative diseases, including trial design, delivery mechanisms, dose and cellular targets.

The dysregulation of normal PCD can be maladaptive and pathological. Developmental, genetic, or congenital neurological defects may be caused by perturbations of PCD. For example, one proposed mechanism underlying autism is that there is a delay or absence of PCD (Courchesne et al., 2011). In the mature CNS, cell death exhibiting morphological characteristics and mechanistic components of PCD is a hallmark of many neuropathological conditions (Table 18.5). Neuropathology is a key example of why morphological characteristics of dying cells must be interpreted with caution. While DNA fragmentation and damage are observed in dying cells in pathological conditions, rarely are cells with morphological features of apoptosis observed; rather, dying cells appear to exhibit a combination of features characteristic of PCD types II, III, and necrotic cell death discussed above.

Autophagy is thought to be an adaptive response that can promote survival; however, dysregulation of autophagy is also proposed to contribute to neurodegenerative disorders (Banerjee, Beal, & Thomas, 2010). Although the morphological features may be different, many pathways of developmental cell death (see Fig. 18.7) can be re-activated in mature cells following insult or injury. As with developmental PCD, the mitochondria appear to have a central role in initiating cell death in epilepsy, Alzheimer's disease (AD), PD, ALS, and stroke (Martin, 2010). The Bcl-2 proteins that have key roles in mediating release of pro-death factors from the mitochondria have altered expression or interactions in neuropathologies. Caspase activation has also been observed in postmortem tissue from AD, PD, ALS, and stroke patients.

In some of these diseases, specific gene mutations have been identified, and the identification of these mutations has facilitated the development of transgenic or cellular models of these diseases. Studies of these model systems indicate that the mutated proteins may directly or indirectly perturb inter- and intracellular mechanisms involved in the maintenance and survival of specific populations of neurons. For example, mutations in PTEN-inducing putative kinase 1 (PINK1) and Parkin are associated with some familial forms of PD, and these mutated proteins may function to modulate mitochondrial degradation. Mutations in copper, zinc superoxide dismutase 1 (SOD1) are associated with some forms of familial ALS. Misfolded mutant SOD1 has been shown to associate specifically with Bcl-2 in mitochondria, and this SOD1-Bcl-2 interaction appears to be toxic. In familial AD, mutations in the amyloid precursor protein (APP) genes have been identified. APP, amyloid-β, and the cytoskeletal protein tau are major contributors to the plaques and tangles observed in AD brains. Although the secretases appear to be the major proteases that modulate cleavage of APP, APP has also been shown to be a substrate for caspases, and inhibition of caspase activity resulted in decreased production of Aβ, a molecule thought to mediate neurotoxicity in AD. Tau is also a substrate for caspases, and the caspase-cleaved tau fragment is a component of the neurofibrillary tangles.

The examples above illustrate potential roles for mutated proteins in pathological cell death; however, other mutations may affect how damaged or dying cells are cleared. For example, mutations in progranulin resulting in decreased expression of the protein are associated with frontotemporal dementia. Interestingly, in

[a]*Enhanced or reduced cell death has been associated with many developmental and neuropathological conditions listed in the table. Also provided are review articles or reports describing the aspects of cell death identified in each disorder.*

C. elegans mutants lacking progranulin, there are fewer apoptotic corpses observed, consistent with the suggestion that the clearance of dying cells may contribute to disease processes (Kao et al., 2011).

The idea that aberrant cell death in the developing and adult nervous system may reflect a loss of normal control mechanisms for survival is appealing in that the increased understanding of the genetic regulation of PCD provides a potentially powerful and rational approach for the development of therapeutic treatment strategies. However, recent evidence questions the validity of the widely held assumption that it is the death of neurons that is the primary cause rather than the result of the pathophysiology in these diseases. There is growing evidence that neuronal and synaptic dysfunction that precedes any significant neuronal loss may be a major factor in the functional and behavioral pathology that characterizes many neurodegenerative diseases (Gould & Oppenheim, 2007; Saxena & Caroni, 2011). Therefore, identification of the initiating factors leading to cell dysfunction and death will be critical for the development of effective therapeutics.

Summary

Because PCD is primarily a developmental phenomenon, historically the major focus of investigation has been the normal biology of cell death in the embryo, fetus, and newborn. However, with the growing recognition that pathological neuronal cell death may share certain biochemical and molecular features with PCD, there is growing hope that a better understanding of PCD may reveal potential therapeutic strategies for the treatment of developmental neuropathologies, neurodegenerative disease, and neuronal loss following CNS trauma and disease.

CHAPTER

19

Synapse Elimination

OVERVIEW

In the development of both central and peripheral nervous systems, synapse formation generates some connections that exist only transiently. Proof that synapses are eliminated comes from both anatomical and physiological studies showing that in many parts of the mammalian nervous system, presynaptic axons are connected to postsynaptic partners during development that they are not connected to at later stages. One unambiguous example of such loss is the change in innervation of mammalian neuromuscular junctions in early postnatal life. At birth, each neuromuscular junction receives convergent innervation from multiple motor axons (Fig. 19.1A and 19.1C). In adult muscles, however, only a single motor axon innervates each neuromuscular junction (Fig. 19.1B). Also in the sympathetic and parasympathetic autonomic ganglia of the peripheral nervous system, axons transiently supply extra inputs to each ganglion cell (Fig. 19.2). In the developing mammalian central nervous system (CNS), there are also several cases of documented synapse elimination (Table 19.1). For example, multiple climbing fibers innervate each cerebellar Purkinje cell at birth, whereas all but one is removed in early postnatal life. In the auditory system, developing neurons in the magnocellularis nucleus receive innervation from several inputs but in later life only one axonal input per neuron remains. Perhaps the best-known examples of synapse elimination occur in the visual system where some neurons that are initially activated by input from both eyes become monocularly driven later on.

In all these cases, synapse elimination reduces the number of axons that innervate target cells, making the term *input elimination* perhaps a better descriptor. Input elimination, however, is only easy to measure in relatively unusual situations, such as when neurons end up with one axon or innervation from one eye. It remains unclear how common synapse elimination is in the more typical situation where neurons receive hundreds or even thousands of different axonal inputs from a diverse set of presynaptic cells. Thus in most parts of the developing nervous system, it remains unknown whether synapse elimination is occurring at all. The uncertainty is further confounded by contemporaneous synapse formation in the developing nervous system. As described following, some of the additional synapses are originating from axons that are already connected to a postsynaptic cell. Thus the *total* number of synapses impinging on a postsynaptic cell may even be increasing at the stage when there is a net reduction in the number of axonal inputs innervating the target cell. Thus assaying for synapse elimination requires quantifying a change in the number of innervating axons rather than counting the number of synapses, which in turn requires a means of counting axons, or at least having a situation where distinct but overlapping pathways can be separately labeled or stimulated (such as the two eyes). It seems likely that there is far more synapse elimination during development than presently documented. For example, stimulation of the optic nerve with progressively larger voltages to estimate the number of different retinal ganglion cells innervating individual lateral geniculate neurons has revealed a dramatic change from more than 20 innervating axons to only several during the first postnatal month (Chen & Regehr, 2000), a much larger change than had been previously suspected in that system.

Importantly, synapse elimination, despite causing a reduction in the number of sources of innervation to a target cell, does not lead to a net weakening of synaptic drive on target cells. In the example just mentioned, the retinogeniculate axons that persist undergo a greater than 50-fold increase in synaptic efficacy, which more than compensates for the loss of other axonal inputs to the same target cells. Analogous increases in synaptic efficacy of inputs that

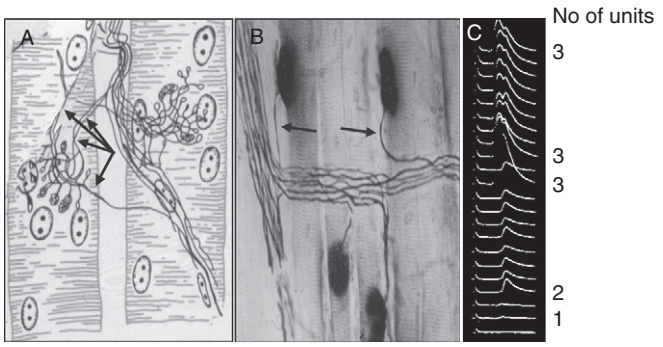

FIGURE 19.1 **Evidence of synapse elimination at the neuromuscular junction.** (A) Drawing of a silver stain made by J. Boeke in 1932 of the motor nerve terminals converging on two adjacent muscle fibers from the tongue muscle of a 4-day-old mouse. Each fiber is innervated by endings from several different axons (see arrows). (B) Photomicrograph of several adult muscle fibers from the rat extensor digitorum longus muscle. Each adult fiber receives innervation from a single axon (arrows). Axons are impregnated with silver and stained for cholinesterase (dark oval smudge on each muscle fiber). (C) Intracellular recordings from a muscle fiber in the neonatal rat diaphragm showing multiple innervation of a skeletal muscle fiber. Gradually increasing the strength of motor nerve stimulation elicits three different postsynaptic responses in this fiber. Similar assays in adult animals give only a single postsynaptic response that cannot be fractionated by graded stimulation. The preparation was partially curarized to prevent the endplate potentials from reaching threshold. *Figures adapted from (A) Boeke (1932); (B) Gorio, Marini, and Zanoni (1983); (C) Redfern (1970).*

persist have been described for the excitatory drive to neurons of the magnocellularis nucleus (Lu & Trussell, 2007) and for the climbing fiber inputs to Purkinje cells in the cerebellum (Hashimoto & Kano, 2003). In each case, the inputs that remain increase their efficacy by 10-fold or more as other axons are eliminated. The same trend was seen many years ago in the parasympathetic submandibular ganglion, where the remaining single input was always far more powerful than any of the inputs at the earlier stage when five to six multiple axons converged to the same single target cell (Lichtman, 1977). Similarly, at the neuromuscular junction, the remaining motor axon increases its quantal content as other inputs are eliminated (Colman, Nabekura, & Lichtman, 1997). It thus appears that although some inputs are being removed, the survivors are potentiated. Such results raise the outstanding question of the degree to which the compensation is explained by changes in the efficacy of the maintained synapses or rather the elaboration of new synapses.

A partial answer to this question comes from studies in the peripheral submandibular ganglion. Here, the simplicity of the neuropil (most synapses are axosomatic) allows for direct counts of synapse number during the period of synapse elimination. In this ganglion, input elimination was accompanied by concurrent synapse addition by the

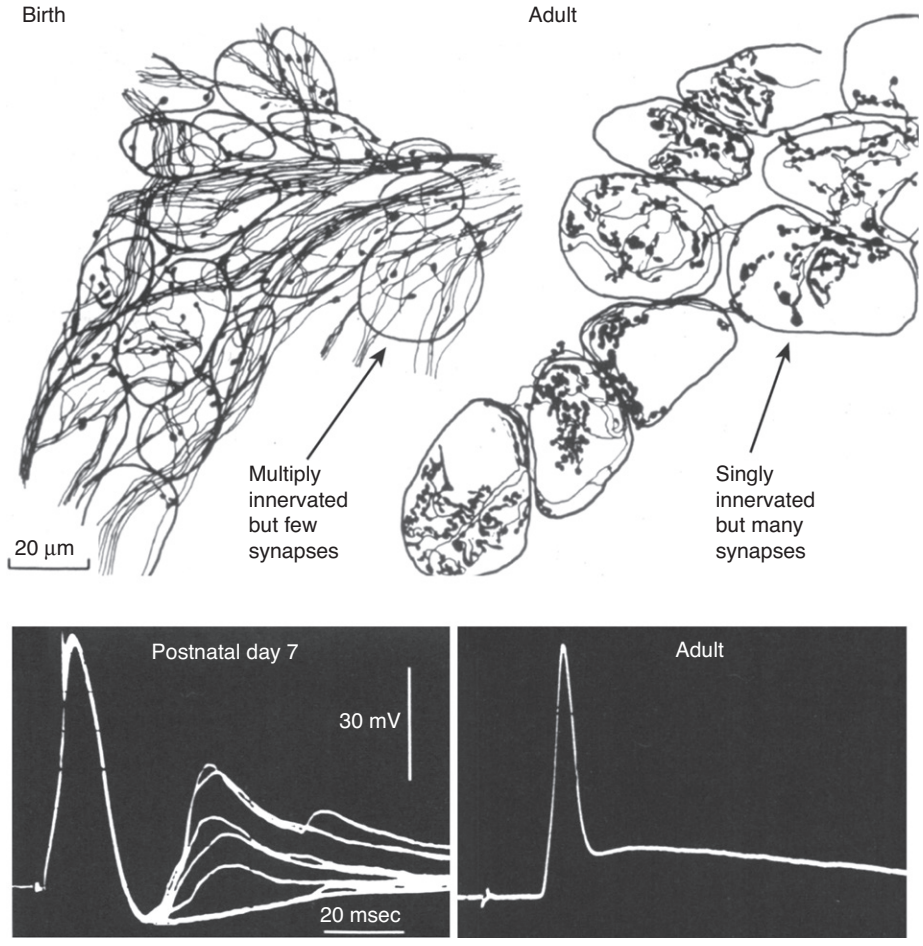

FIGURE 19.2 **In the developing nervous system synapse number is increasing while axonal convergence is falling.** The total number of preganglionic synapses on ganglion neurons in the rat submandibular ganglion increases in early postnatal life during the period of synapse elimination. Camera lucida drawings of clusters of ganglion neurons at birth and in adult animals that were treated with zinc iodide osmium. This reagent selectively fills terminal axons and synaptic boutons with a dense black precipitate. The number of synaptic boutons increases (compare the amount of synaptic boutons (arrows) at birth and on adult ganglion cells), and the number of preganglionic axons innervating each ganglion cell, identified by electrophysiological measurements, decreases (see the number of electrophysiological steps (arrow), each representing an input, at early postnatal life and in adult ganglion neurons, see lower panels). Thus axons that are not removed create new synapses to more than compensate for the loss of synapses from other axons. *From Lichtman (1977).*

TABLE 19.1 Synapse Elimination in the Mammalian Nervous System

Visual cortex: Layer IV	Binocular to monocular	Postnatal monkey, cat, ferret	(Hubel et al., 1977; Hubel & Wiesel, 1963; Wiesel, 1982)
Thalamus: Lateral geniculate nucleus	Binocular to monocular >20 to ~1–2 retinal axons	Postnatal cat and rat	(Chen & Regehr, 2000; Shatz, 1990)

remaining input. In particular, over the first postnatal month, there was approximately a twofold increase in the total number of synapses per ganglion cell, whereas the number of innervating axons was reduced fivefold (Fig. 19.2). This compensation indicates that the remaining axon on each ganglion cell must be increasing the number of synaptic contacts by approximately a factor of 10 as other axons lose all their connections to the same neuron. Such compensatory synaptogenesis means that assays of the total *number* of synapses at various developmental stages or following learning paradigms may belie a rather dramatic change in the *source* of the synapses.

It is also clear that in many situations the alterations occurring during this developmental reorganization are better described as a *redistribution of synapses* than as loss *per se*. The view is based on the fact that counts of the total number of neurons that innervate the entire target are not changing during the stage when the number of axons innervating each postsynaptic cell is decreasing (see, for example, Brown, Jansen, & Van Essen, 1976). Moreover, in several regions of the nervous system, it is known that synapse elimination occurs after the period of *naturally occurring cell death* is complete (see Chapter 18). Thus, as the elimination process reduces the number of axons converging on postsynaptic cells, it does not entirely remove axons from the postsynaptic target region but rather reduces the number of target cells innervated by each axon—that is, it reduces the axonal divergence (sometimes called fan-out) as individual axons restrict their synapses to a smaller number of postsynaptic target cells (Fig. 19.3). In muscle, axonal branch trimming during development has been long appreciated by an electrophysiological assay: the proportion of the total twitch tension an individual axon exerts decreases gradually over early postnatal life (Brown et al., 1976). This assay suggests that motor units (the term given to the number of muscle fibers innervated by a single motor axon) reduce their sizes by about threefold after birth.

Newer techniques of visualizing all the branches of single axons by transgenic expression of GFP (Feng et al., 2000) have, however, suggested that the changes are far more dramatic. Transgenic animals, in which only one axon is labeled, show that axonal arbors are about ten times larger at birth than in adults (Fig. 19.4A). These very large motor units imply that individual muscle fibers are innervated by ten or so axons because the total number of muscle fibers and neuromuscular junctions is fixed from birth onward. Direct evidence of this massive convergence on neuromuscular junctions was obtained by serial electron microscopy (Fig. 19.4B). Thus in muscle there is simultaneously extensive fan-in on neuromuscular junctions and fan-out of motor units in early life that is dramatically removed in early postnatal life.

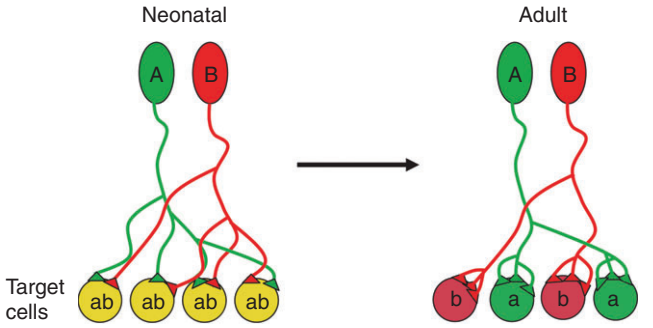

FIGURE 19.3 **Changes in fan-in and fan-out at developing circuits.** In neonatal vertebrates, neurons (A, green and B, red) project their axons to fan out to many target cells (each labeled ab). These nascent connections are typically weak and mediated only by a small number of synaptic contacts (triangles from the green and red axons). Axons undergo several structural rearrangements before reaching adulthood. First, axons disconnect from many target cells reducing their fan-out or divergence. Second, this rearrangement leads to less fan-in or convergence. Third, at the same time as axons disconnect from some target cells they are strengthening their connection with other target cells by increasing the number of synapses at their remaining targets.

The transgenic expression of fluorescent proteins has allowed study of how this removal occurs. Direct observation of axonal *branch retraction* in living animals by time-lapse imaging shows that axons that are removed first become thin (axonal "atrophy"); they then disconnect from the postsynaptic site and temporarily possess

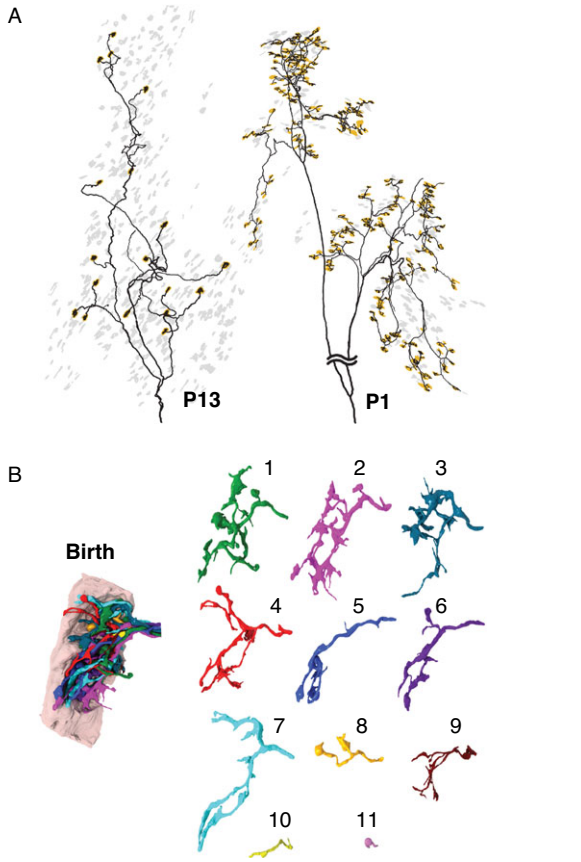

FIGURE 19.4 **Profound changes in axonal arbors and synapses at birth.** (A) Left, The axonal arbor of a motor axon's motor unit from a postnatal day 13 mouse. The neuromuscular junctions innervated by this axon are highlighted (yellow), and the rest of the neuromuscular junctions are shown in gray. Right, The branching arbor of a motor unit in the same muscle at postnatal day 1. At this young age the axon arbor is dramatically more complicated, and it innervates manyfold more neuromuscular junctions (yellow). B, The image on the left shows a serial electron microscopy 3D reconstruction of a single neuromuscular junction at birth that was then traced to show that 11 different axons converged on the site. On the right, each of the 11 axons that innervate this neuromuscular junction at birth are separately displayed, showing that they are quite intermingled and none occupies a majority of the neuromuscular junction.

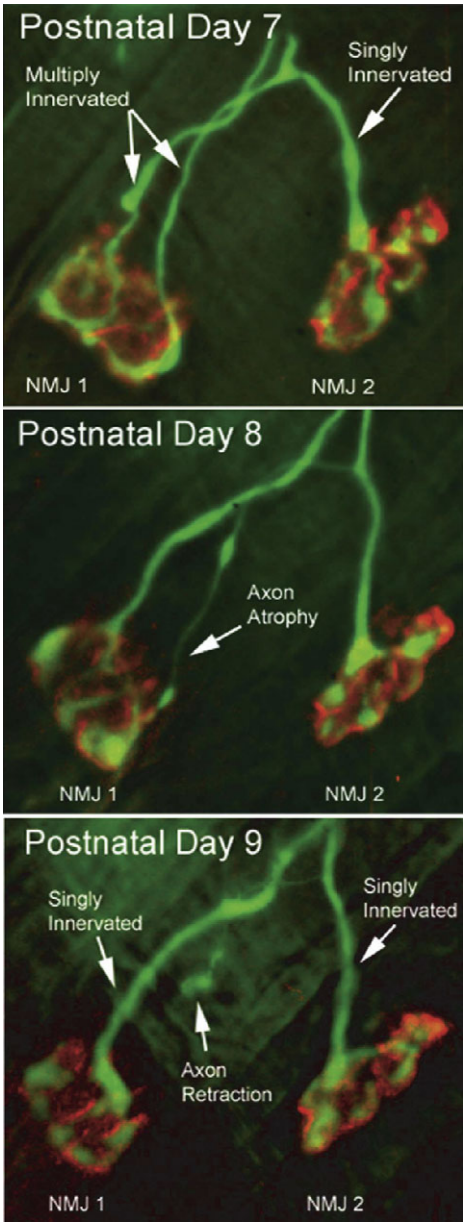

FIGURE 19.5 **Time-lapse imaging shows how axonal branches are lost during synapse elimination at the neuromuscular junction.** Two neuromuscular junctions (NMJ1 and NMJ2) were viewed *in vivo* on postnatal days 7, 8, and 9 in a transgenic mouse that expresses YFP in its motor axons (green). The acetylcholine receptors at the muscle fiber membrane are labeled with rhodamine-tagged α-bungarotoxin (red). On day 7, NMJ1 is multiply innervated, whereas NMJ2 is singly innervated by a branch of one of the axons that innervates NMJ1. One day later (postnatal day 8), one of the motor axons innervating NMJ1 becomes thinner all the way back to its branch point. When viewed on postnatal day 9, this thin branch is no longer connected to NMJ1 and now ends in a bulb-shaped swelling that is called a retraction bulb. *Modified from Keller-Peck et al. (2001).*

a bulb-tipped free axonal ending called a *retraction bulb* (Fig. 19.5). The withdrawing axon sheds small spherical membrane-enclosed axonal fragments filled with synaptic organelles (axosomes) to be engulfed by surrounding Schwann cells (Fig. 19.6). The sites formerly occupied by the withdrawing axon are mostly taken over by the axon that remains at the junction (described in detail following).

Summary

In the developing nervous system, both the number of axons that converge on postsynaptic cells and the number of postsynaptic cells an axon contacts decrease. The removal of inputs is due to a process of branch trimming. Concurrently, the remaining inputs appear to compensate by adding synaptic strength at least in part by the

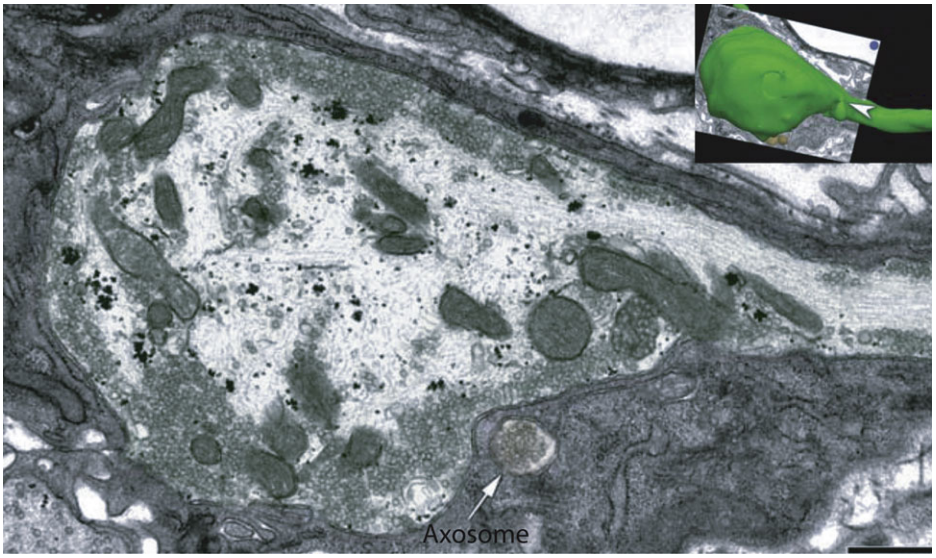

FIGURE 19.6 **Retracting axons shed material as they disappear.** The inset shows a surface rendering of a serial electron microscopy reconstruction of a retraction bulb (green, arrowhead) during synapse elimination at a developing neuromuscular junction. The electron micrograph shows that the retracting axon contains clusters of vesicles and mitochondria. In the vicinity of the bulb but not connected are small spherical axonal fragments (axosomes, arrow) that are engulfed by glial cells (i.e., Schwann cells (SC), darker cytoplasm). Scale bars, 1 mm. *From Bishop, Misgeld, Walsh, Gan, and Lichtman (2004).*

formation of new synapses. This redistribution refines synaptic circuitry by allowing an axon to strongly focus its innervation on a subset of the cells it initially contacted while each postsynaptic cell is restricted to responding to a subset of the axons that initially innervated it.

THE PURPOSE OF SYNAPSE ELIMINATION

At first sight, it might seem reasonable that synapse elimination is some form of error correction to rid the developing nervous system of outright connectivity mistakes. Indeed, there are clear examples of classes of nerve cell connections that disappear during development. For example, there are connections between mossy fiber axons and Purkinje cells in the developing cerebellum but not in the adult (Kalinovsky et al., 2011). In other situations, synapse elimination may *sharpen specificity* of the connections in a slightly more subtle way. For example, in some muscles there is a topographic map that matches the position of an axonal arbor to the location of the cell body within the motor neuron pool in the spinal cord. In these muscles synapse elimination makes these maps more precise (see, for example, Laskowski, Colman, Nelson, & Lichtman, 1998).

However, synapse elimination also occurs robustly in muscles and autonomic ganglia in which there is no evidence for intrinsic positional or other qualitative differences between axons that are maintained and those that are lost from any particular postsynaptic cell. Thus, while synapse elimination may be employed to refine the specificity of synaptic circuits, it seems to occur even in situations where it is not obvious that the synaptic connections that are maintained are from a different class of neuron than the ones that are eliminated.

An alternative hypothesis to the idea of error correction is that the loss of connections is a natural consequence of the extreme degree to which mammalian (and other vertebrate) nervous systems are composed of *duplicated neurons* (Lichtman & Colman, 2000). For example, pools of motor neurons that may number in the hundreds innervate individual skeletal muscles that contain thousands of muscle fibers. This reduplicated arrangement differs from the cellular plan in most parts of invertebrate nervous systems. For example, in the fly neuromuscular system, sometimes a single identified motor neuron innervates a muscle consisting of only one muscle fiber (Fig. 19.7A). Thus in mammals a cadre of nearly identical motor neurons that seem to have approximately equivalent roles project to a target consisting of a large population of roughly equivalent postsynaptic cells that constitute a muscle (Fig. 19.7B).

There are two potential circuit consequences of such redundancy in pre- and postsynaptic populations. First, many postsynaptic neurons are appropriate matches for each presynaptic axon, causing substantial axonal divergence or *fan-out* (Fig. 19.7C). Second, many presynaptic neurons could be appropriate matches for each postsynaptic cell, causing substantial axonal convergence or *fan-in* (Fig. 19.7D). Therefore, given the redundancy in both pre- and postsynaptic populations, one might expect overlapping *converging and diverging pathways* (Fig. 19.7E). Indeed this *is* the pattern of innervation in the neuromuscular systems in mammals and many other vertebrates, but only during development.

Therefore, what is surprising is that this overlap is short-lived and circuits undergo a radical transformation in postnatal life. As already mentioned, during neuromuscular development, axonal branches are pruned in a highly selective way, causing the projection

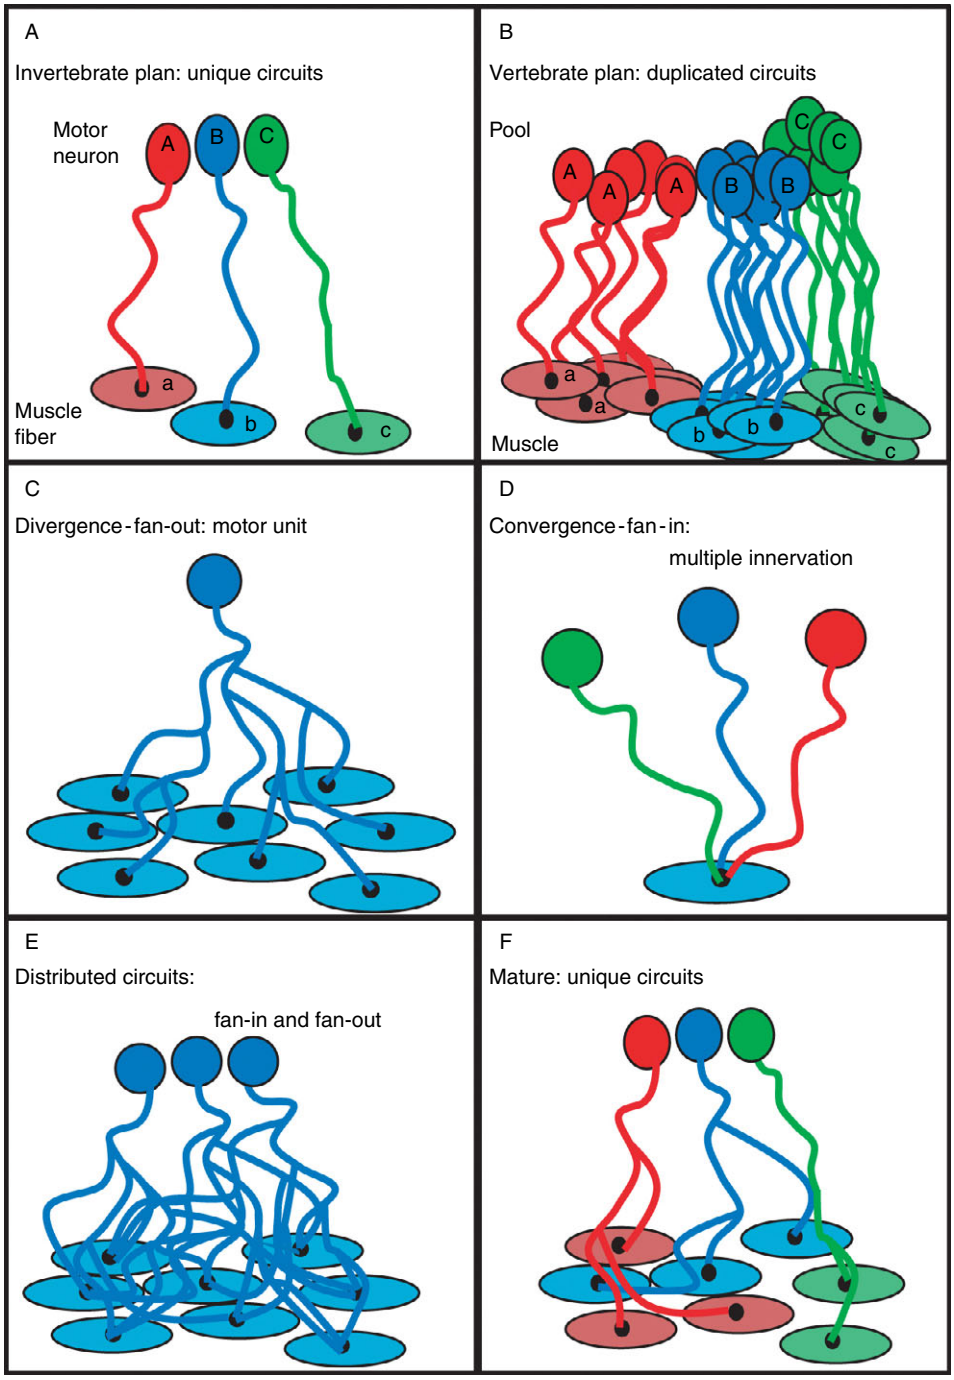

FIGURE 19.7 A diagram showing differences between the vertebrate and invertebrate synaptic circuits. (A) Invertebrates have small numbers (for example, sometimes just one motor neuron) of identifiable neurons innervating small numbers of identifiable target cells (e.g., sometimes just one muscle fiber), whereas in vertebrates, pools of similar neurons innervating targets contain hundreds or thousands of similar postsynaptic cells (B). The redundancy in the vertebrate nervous system allows a neuron to diverge (fan out) and innervate many equally appropriate target cells (in the neuromuscular system, this is called a motor unit) (C). The homogeneity of innervating neurons allows multiple axons to converge (fan in) on each target cell (D). As a result, vertebrate circuits contain a substantial amount of fan-in and fan-out (E), at least initially. Synapse elimination's purpose may be to transform such a set of redundant circuits into multiple unique ones by trimming away the multiple innervation of target cells (F). The result of the widespread loss of synapses is the generation of thousands of nonredundant circuits from an initially much less specific innervation pattern. *From Lichtman and Colman (2000).*

of each motor axon to become completely nonoverlapping and thus completely distinct from other axons' projections (Fig. 19.7F). From a functional standpoint, once synapse elimination is complete, the recruitment of each motor axon gives rise to activation of a different set of muscle fibers and consequently a substantive increase in tension of the muscle. This stepwise tension increase is a necessary aspect of the *size principle* (see Chapter 18). Therefore, the circuit rearrangement has an important consequence on neuromuscular output—that is, behavior.

By parsing highly redundant circuitry into multiple, unique, functionally distinct circuits, synapse elimination may be an essential maturation step for synaptic circuits that begin with considerable redundancy, such as those in our own nervous systems and those of other terrestrial vertebrates. It is possible that this paring down strategy is less relevant in other kinds

of animals. Indeed, in most invertebrates, identified neurons are the rule, and there is scant evidence for the type of neuronal redundancy seen throughout the mammalian nervous system. This difference suggests that a distinct neurodevelopmental strategy is at play in mammals and perhaps other vertebrate classes compared to the strategy used in the vast number of species in all the other subphyla. It is perhaps not a coincidence that another difference that partitions humans and other mammals from most invertebrates is that they seem highly dependent on experience for the acquisition of their behavioral repertoire. Invertebrate behavior is, to a greater degree, intrinsic and stereotyped. Compare, for example, the ease with which a newly hatched dragonfly takes wing versus the protracted period necessary for a human child to learn to walk. It is possible that the neuronal redundancy found in higher vertebrates that gives rise to overlapping convergent and divergent pathways is used in the acquisition of skills by the experience-mediated *selection* of connections.

This difference between mammals and invertebrates does not mean that synapses cannot be eliminated in invertebrates. Indeed, many studies have made the point that synaptic remodeling through addition and removal occurs in insect nervous systems (see, for example, Ding, Chao, Wang, & Shen, 2007; Eaton & Davis, 2003). The molecular mechanisms involved in invertebrate synaptic remodeling may provide insights into the mechanisms of synaptic loss and maintenance in higher vertebrate nervous systems. In worms, for example, the ubiquitin proteosome complex has been shown to regulate the elimination of motor neuron synapses onto vulval muscles (Ding et al., 2007). Similar degradation mechanisms may also be involved in synaptic remodeling of vertebrate neurons (Bingol et al., 2010; Li et al., 2010). The important point here, however, is that these mechanisms are used in mammals to alter the connectivity of the nervous system (i.e., to alter the number and identity of an axon's postsynaptic targets). In most invertebrate systems, and perhaps lower vertebrates such as fish, these same mechanisms may play more of a role in modifying the strength of existing connections without altering the circuit's wiring diagram.

Summary

In contrast to invertebrates, the nervous systems of terrestrial vertebrates contain reduplicated populations of neurons that serve each function. Elimination of synaptic connections during development may be an adaptation that converts highly overlapping connections of redundant neurons into unique circuits. Because this conversion may be based on experiences that affect the development of the nervous system, this process may tune the nervous systems of higher animals to the particular environment of each individual animal.

A STRUCTURAL ANALYSIS OF SYNAPSE ELIMINATION AT THE NEUROMUSCULAR JUNCTION

Thanks in large part to the power of fluorescence microscopy and the accessibility of the neuromuscular junction, it has been possible to describe the physical changes in axons and synapses that take place during synapse elimination. Interestingly, this purely descriptive analysis has yielded important clues and some mechanistic insights into the process of synapse elimination. As Yogi Berra said, "You can observe a lot by just watching." Imaging neuromuscular junctions at various ages in early postnatal life makes clear the fact that the process of synapse elimination is not a sudden calamitous event but rather a protracted process. At birth, multiple axons converging at a neuromuscular junction are highly intermingled, and the extent of the receptor areas occupied by each is similar (Balice-Gordon, Chua, Nelson, & Lichtman 1993). These highly intermingled connections eventually become progressively segregated over several days (Figs. 19.4B and 19.8). The partitioning of synaptic areas associated with different axons suggests that there is a spatial component to the mechanism. One scenario, for example, is that each axon *locally destabilizes* other inputs in their immediate vicinity but cannot as efficiently affect slightly more distant branches of the same axons. If the destabilization of an input was followed in turn by the takeover of its synaptic sites by the remaining axon, then an axon with a larger consolidated area might begin to destabilize more distant inputs. The idea of progressive consolidation was put to the test by the use of transgenic mice expressing different-color fluorescent proteins in individual axons. With these animals it is possible to obtain a precise map of the territories occupied by two axons at the same neuromuscular junction. *In vivo* time-lapse imaging of a multiple innervated neuromuscular junction over several days showed both gradual withdrawal of one axon from postsynaptic sites and a corresponding expansion of another axon to take over those synaptic sites (Fig. 19.9). This result may mean that axons are vying to occupy the same sites. Interestingly, it was not inevitable that the withdrawal of one axon was followed by the takeover of its sites by another input. In some cases, an axon that was already somewhat segregated from the other input would vacate its postsynaptic territory, but rather than being replaced by the remaining axon, its acetylcholine receptor-rich postsynaptic site would disappear. Synaptic loss without reoccupation by another input suggested that the takeover process *per se* was not causing withdrawal of the other axon. These observations suggest rather that synaptic takeover might be a response to the recent synaptic vacancy.

These time-lapse studies also demonstrated that the shift in favor of one axon was not irreversible. In some

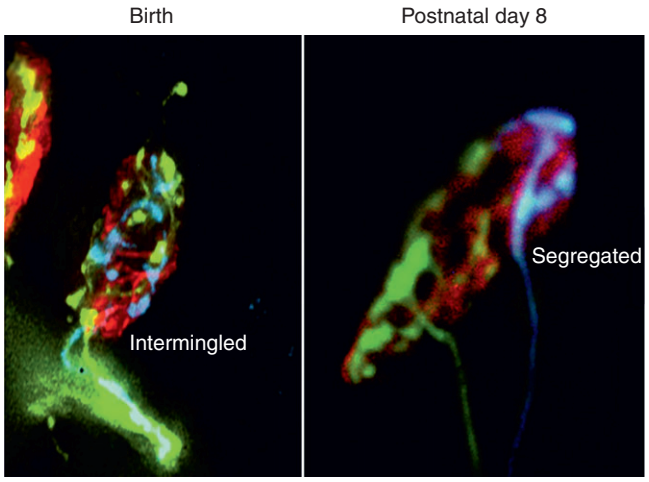

FIGURE 19.8 **Segregation of synaptic territory as axons compete during synapse elimination.** Double transgenic mice expressing YFP and CFP in different motor axons were used to observe axons' nerve terminal interactions. At birth is shown two competing nerve terminals, one expressing CFP (blue) and the other YFP (green) at this neuromuscular junction, which are intermingled. By the second postnatal week, however, YFP and CFP axon terminals are generally completely segregated from each other in multiply innervated junctions. Red is fluorescently tagged α-bungarotoxin that binds to AChRs. *Modified from Gan and Lichtman (1998).*

junctions, for example, it was hard to predict which axon might ultimately be maintained because the input with the majority of the territory shifted back and forth. Such flips in which axon seemed to be dominant suggest that the outcome is not preordained. Instead, axons at multiply innervated neuromuscular junctions appear to be in the midst of a highly dynamic interaction to determine which axon is most likely to stay.

Insights into the regulation of this dynamism come from analyses of each of the branches of individual motor axons. In lines of transgenic mice in which fluorescent proteins are expressed in a very small subset of motor neurons, it has been possible to examine all the branches of one axon during the developmental period when branches are being pruned. These studies show that axonal branch loss is occurring asynchronously among all the branches of one axon (Fig. 19.10). Thus, while some branches are recently eliminated (i.e., retraction bulbs), other branches are still connected to neuromuscular junctions that are multiply innervated. This range suggests that the fate of each branch is controlled independently. If axonal branches of one neuron are interacting with different axons at each of its neuromuscular junctions, then perhaps the rate of synapse

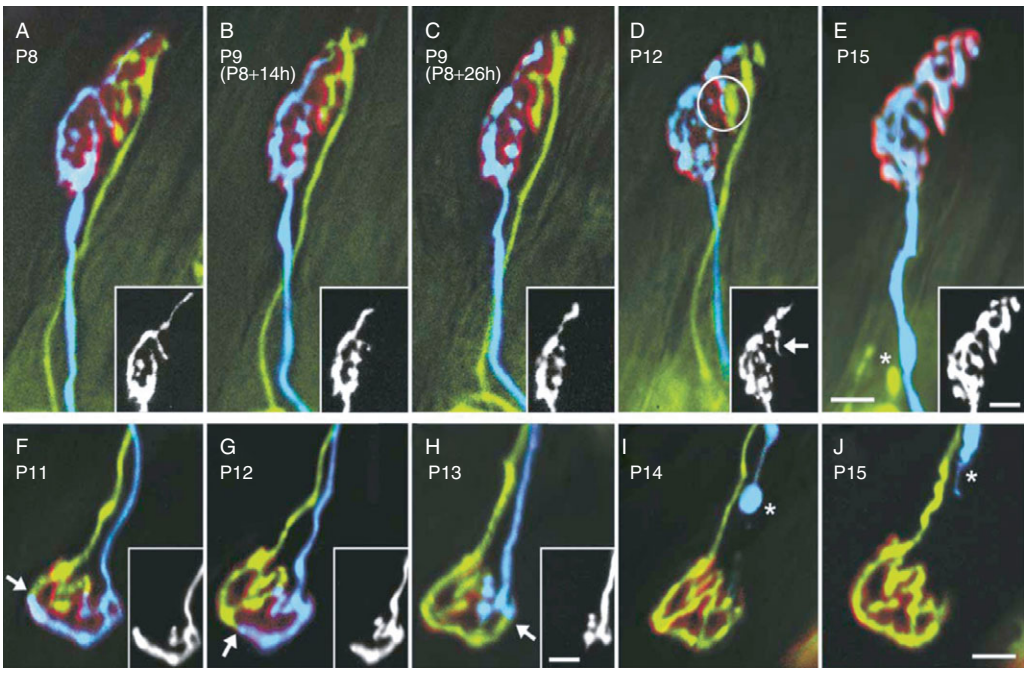

FIGURE 19.9 ***In vivo* imaging shows takeover of synaptic territory by the remaining axon during the period of synapse elimination.** Neuromuscular junctions in transgenic mice that express YFP (yellow) and CFP (blue) were imaged multiple times during early postnatal life. (A–E) views of one neuromuscular junction between P8 and P15. The CFP axon takes over occupancy of the postsynaptic sites (labeled red) in the upper parts of the junction that were formerly innervated by the YFP axon. The YFP labeled axon withdrew until only a retraction bulb remained (E, asterisk). At P12, a process of the CFP axon had begun to invade the territory of the YFP axon (D, circle and arrow in inset). (F–J) Although the CFP axon (blue and insets) has greater terminal area (~70%) at the first view, it progressively withdraws from the junction (arrows). Its retraction bulb can be seen in (I) and (J) (asterisks). Scale bars = 10 μm. Insets show the blue axons. *From Walsh and Lichtman (2003).*

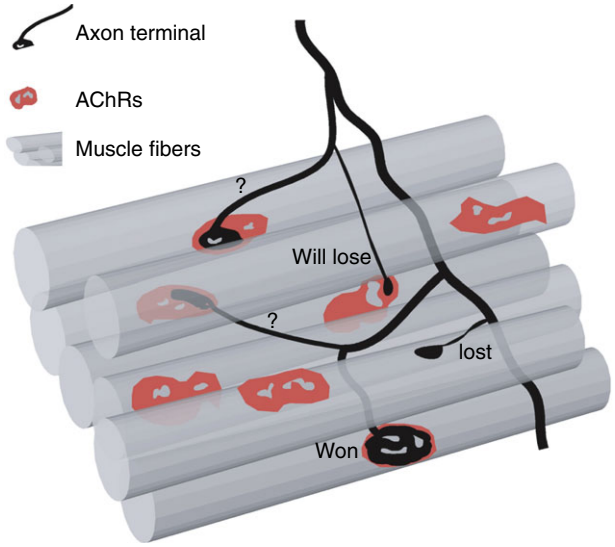

FIGURE 19.10 **Asynchronous synapse elimination among the branches of one axon.** Using transgenic animals that express YFP in a small subset of motor axons, it was possible to monitor the behavior of multiple branches of the same axon. This diagram shows the typical result for an axon in the midst of the synapse elimination process. Represented in red are the AChRs on each muscle fiber (represented as gray tubes). This motor axon (black) has won the competition on the bottom muscle fiber and occupies the entire receptor plaque. The same axon has lost the competition for the adjacent muscle fiber, where only a retraction bulb remains. The three other neuromuscular junctions that this axon innervates are still undergoing competition. In one case a small portion of AChRs is being innervated by this axon. It is likely that this synapse will be eliminated. On the other two muscle fibers, each axon terminal occupies 50% of the AChRs. This indicates that its fate is not yet determined in these junctions. *Adapted from Lichtman and Colman (2000).*

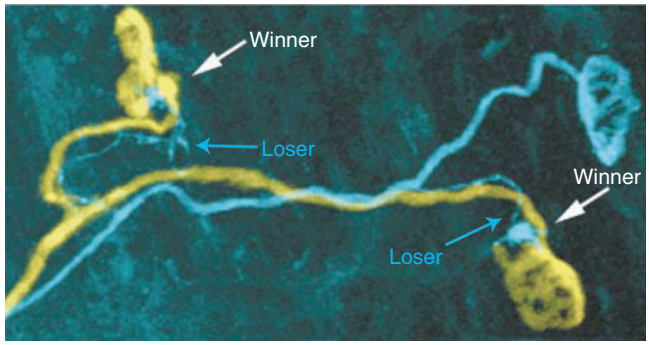

FIGURE 19.11 **Axonal fate at individual neuromuscular junctions is related to the identity of the competing axons.** Using transgenic animals that express YFP (yellow) and CFP (blue) in a small subset of motor axons, it was possible to reconstruct two motor units in which several neuromuscular junctions are innervated by the exact same two axons, one expressing YFP and the other CFP. At these coinnervated junctions, it appears that the same outcome is occurring at each. In this case, the YFP axon always occupied more territory than the CFP axon. Note also that the axon calibers of the YFP axon branches are thicker than CFP branches to the same junctions. Thus synapse elimination seems to be biased such that when the same two axons compete, the fate is the same at each coinnervated neuromuscular junction. *Image from Kasthuri and Lichtman (2003).*

elimination is regulated by which particular axons are co-innervating each of these junctions. These interactions might not only determine the rate but also the fates of the terminals—that is, which neuron's branches are maintained and which are eliminated. For example, an axon might be eliminated quickly at neuromuscular junctions innervated by some other neurons but fare better at junctions innervated by other axons.

To explore this possibility, transgenic mice with only two labeled axons (one yellow and one cyan) were generated to examine each of the neuromuscular junctions co-occupied by the same two axons within a developing muscle. The result was dramatic: at each of the shared neuromuscular junctions, the two axons often seemed to be in the same relative state (Fig. 19.11). Thus if the cyan axon was occupying only a small amount of territory at one junction that it shared with the yellow axon, then it occupied a small amount of territory at all or nearly all the other junctions it shared with the same yellow axon. However, where the cyan axon was interacting with other axons, its fate could be quite different. This result argued that the fate of axonal branches and the rate at which they are eliminated are related to the identity of the co-innervating axons. But why might the yellow axon be consistently "better" than the blue at all the co-innervated neuromuscular junctions they share? Counts of the total number of neuromuscular junctions each axon innervated (i.e., its motor unit size) provided a hint; the outcome of synapse elimination seemed to depend on the relative sizes of the two axons' motor units. In particular, neurons with larger motor units (such as the cyan axon in Fig. 19.11) were at a disadvantage when confronting neurons with smaller arborizations (such as the yellow axon in Fig. 19.11). One interpretation of this result is that axons with few branches in a muscle could dedicate more resources to a multiply innervated neuromuscular junction than neurons with a larger number of branches that are in some sense overextended. If this idea is correct, then the consequence of losing branches for an axon (such as the cyan one in Fig. 19.11) is that it can now dedicate more resources to its remaining multiply innervated junctions shared with other axons.

These results raise the obvious question of what resources might be in limited supply in an axon that could affect synapse maintenance. One popular idea is that the synaptic activity of an axon terminal is a key determinant in its ultimate fate. Is it possible that large motor units have fewer synaptic resources (e.g., synaptic vesicles per synapse) than small motor units? This idea was tested by generating mice in which a subset of axons had diminished choline acetyltransferase (ChAT, the enzyme that
